ABSTRACT:
The latest developments in steel shear walls (SSW) are a clear indication about the effectiveness and practical applicability of systems consisting of steel frames and thin infill plates. One of the main factors defining the behaviour of such systems is the type of connection between the frame and the infill plate. The estimation of this factor is getting more complicated in case of recently developed hybrid and FRP infill plates. This paper assesses ways of improving energy dissipation properties of steel to hybrid (steel/GFRP) and steel to plain GFRP connections. Different combinations of connections between steel hybrid and FRP plates were developed and tested with the aim to achieve higher energy dissipation. The size of all the plates was 125mmX70mm, with the connection to the steel plates via two M8 bolts. Variations included the application of additional layers of GFRP at the zone of the bolted area, use of adhesive film and additional epoxy around the bolted area. Both ultimate load capacity and energy dissipation of the tested specimens were estimated and analysed. Conclusions leading to the use of the most effective types of connections are offered.

KEYWORDS
Shear walls, GFRP, connections, load capacity, energy dissipation

INTRODUCTION:
This paper is part of a bigger project focused on assessing and improving the energy dissipation of hybrid steel/FRP shear walls. Connections between the infill panel and the outer frame are one of the main factors influencing energy dissipation. Due to the complexity and relatively new application of the hybrid infill plates, detailed assessment must be undertaken to find out the most efficient connecting system in aspect of increasing energy dissipation of the hybrid shear walls.

There has been some research assessing the modes of failure and ultimate capacity of FRP connections. However, there is very limited research on improving energy dissipative properties of FRP and Hybrid steel/FRP connections. Such type of research is crucial in the long term development and application of the innovative FRP and hybrid steel shear wall (SSW) structural systems.

BACKGROUND
The energy dissipation in hybrid shear walls is developed in three different areas; the steel frame, the hybrid infill plate and the connection between them.

Some of the main factors that contribute to the energy dissipation of steel and hybrid steel/FRP shear walls are; plate aspect ratio (span/height), thickness of infill plate, type of column to beam connection, the connection between the infill plate and the outer frame elements as well as the application of different types and orientation of FRP’s. Cut outs in infill shear panels is another factor that influences energy dissipation and ultimate load capacity, as assessed by Maleki (2010). He concluded that the stiffness, energy dissipation and load carrying capacity decrease for specimens with cut-outs. Maleki added that this issue could be resolved via the application of additional stiffeners.
The connection of the infill plate to the exterior frame is one of the main contributors to energy dissipation. Choi and Park (2008), tested the effect of application of various details of SSW infill plate connection to the boundary frame elements. Two of them were M20 bolted connections at spacing of 100mm with a 6mm fish plate and two sided fillet welded connections to the same thickness fish plate. They determined that the effects of bolted connections and welded connections with respect to energy dissipation were approximate the same, up to a drift of 3.6% and that bolted connections exhibited similar initial stiffness and slightly higher load carrying capacity. However, the ratio of cumulative energy dissipation capacity of the bolted connections to the welded connections from their research was 0.52.

FRP structural connections have various failure modes in plane of loading some of the most common are; net section tension failure, shear out failure, bearing, cleavage, slip failure and possibly a combination of the mentioned modes (Zhou and Zhao, 2013). Turvey, G (2000) also confirmed in his overview that for pultruded FRP structural connections with single bolt fastening and an axial load at an angle of 0°, 45° and 90° to the pultruson, there are four basic modes of failure and they are: bearing, tension, shear out, and cleavage. Turvey added that, when the ratios of the end distance to the diameter of the bolt and the end distance to width of specimens are high the failure mode is bearing. Rosner and Rizkalla (1995) developed a design procedure based on their research assessing the behaviour of bolted fibre reinforced polymer connections, taking into account the materials orthotropic properties and pseudo yielding behaviour. They obtained failure envelopes for fibre orientation of 0°, 45° & 90°, depending on the ratios of the hole diameter to width (d/w) and edge distance to hole diameter (e/d). It was concluded that for the connections with a ratio of d/w & e/d falling on the part of the envelope that is curved the failure mode is net tension and for the straight part of the envelope the failure will be bearing or cleavage.

Manalo et al. (2008) analysed the behaviour of hybrid GFRP/CFRP bolted connections both with adhesive and without. It was evaluated that the connections without adhesive failed via bearing of bolts and crushing of fibres, while for the connections with adhesive resulted initially in bearing and delamination between the CFRP and GFRP and eventually net tension of the connection at failure load. Manalo also assessed the effect of bolt torque, revealing that there is a slight increase in capacity with increase of torque.

Research by Petkune et al. (2014) investigated the effects of variation in the type of hybrid and FRP plates on the capacity of plate-to-steel element connections. Hybrid plates with CFRP prepreg unidirectional fabric attached to steel plate and CFRP only laminated plates were investigated as well as application of additional adhesive around the bolted area. It was determined that there is a significant increase in capacity when utilising adhesive around the bolted area. The presented research is focusing mainly on the improvement of energy dissipation in the connections between the frame and infill late.

**METHODOLOGY:**

**Specimens:**

Numerous specimens with a width of 70mm and a length of 125mm were tested. Three samples were tested for each set of specimens and the average results analysed. Varying factors were: the application of additional 2 layers of E722-02 UGE400-02 32%rw (GFRP) at a {−45/+45} orientation on either side of bolted area, application of DP110 Scotch-Weld adhesive and the use of EF72 adhesive film from TENCATE. The adhesive film was applied between the steel layer and the GFRP, as a solution to delamination issues for hybrid specimens. Figure 1 & Table 1 give information about of the geometry, type and number of samples.

The orientation of the specimens with 8 layers of GFRP pre-preg plies were applied at a {−45/+45−45/+45/+45−45/+45−45} orientation. For the hybrid specimens incorporating steel plates the orientation is {−45/+45/S/+45−45}. The test specimens were tested using a displacement control load at an applied rate of 2mm/min. The applied displacement was continued after reaching maximum load capacity to fully assess the mode of destruction and energy dissipation of the specimens.

**Preparation:**

Application of adhesive film EF72 was used between the GFRP and the steel plate to increase the bond between the two layers. Before the film was applied the steel plate was abraded using sand paper and cleaned using acetone. Further to the application of the GFRP, the specimens were placed in a sealed vacuum bag between two plates attached to a 1 bar vacuum pump and placed in an oven for 1hour at 120 °C according to curing specifications of the manufacturer. Images of these steps are illustrated in Figure2.

**RESULTS & ANALYSIS:**

The main factors investigated were the load capacity and the energy dissipation. The energy dissipation was presented by the enclosed area under the load displacement graphs.
For better comparison between the samples they were divided into three groups. The first group included all the specimens consisting of 8 layers of GFRP (2G8, 2G8D, 2G8F and 2G8FD), the second group comprised of the hybrid steel/GFRP samples with 4 layers of GFRP and a 0.8mm steel plate in between them (2SG4, 2SG4F and 2SG4FD) and the third group consisted of hybrid specimens that employed EF72 adhesive film between the steel plate and the first GFRP ply (2SG4FE and 2SG4FED). The behaviour of the samples from each of the three groups is displayed in graphs in Figures 3-5.

Figure 3 illustrates all the specimens that incorporate eight layers of GFRP. The varying factors in the group consisted of the application of Dp110 epoxy around the bolted area (2G8D), the use of additional GFRP strips around the bolted area (2G8F) and the application of both epoxy and additional GFRP (2G8FD). The application of either the adhesive or the additional layer of GFRP shows that the ultimate load capacity for both 2G8D & 2G8F specimens was increased significantly by 103% and 90% respectively when compared to 2G8. However 2G8D exhibited complete failure at approximately 16mm displacement resulting in an increase of 106% in the energy dissipation, while 2G8F displayed gradual destruction allowing it to obtain slightly higher energy dissipation of 121% when compared to 2G8. When applying both additional layers of GFRP and epoxy, the specimen showed an increase in capacity from 8.73KN for 2G8 to 21.35KN.

The second group contained of hybrid steel/GFRP specimens with 0.8mm steel plate and 4 layers of GFRP presented in Figure 4. The variations were of the application of additional GFRP strips around the bolted area (2SG4F) and the application of both adhesive and additional GFRP strips around the same area (2SG4FD). For this group increase in load capacity and energy dissipation was not as drastic as for the pure GFRP specimens in the first group. For the reference hybrid specimen (2SG4) the maximum load and energy dissipation achieved was 12.98KN and 146.08KN.mm. When comparing 2SG4F to 2SG4 the ultimate load capacity was increased by 41% and energy dissipation increase by and 29% for 2SG4F. Applying both additional layers of GFRP and epoxy (2SG4FD) resulted in an increase in maximum load capacity to 24KN and increasing the energy dissipation to 276.5KN.mm.

The graph in Figure 5 compares the hybrid steel/GFRP plates that have additional adhesive film between the steel plate and the GFRP layer as well as additional GFRP around the bolted area (2SG4FE) with the plate that has adhesive film between the steel plate and the initial GFRP layer and both additional adhesive and GFRP around the bolted area (2SG4FED). 2SG4FED shows a clear increase of approximately 37% in the load capacity of the specimen and a 52% rise in energy dissipation when comparing it to 2SG4FE.
Figure 4 Load Vs Displacement of Hybrid connections without EF72 adhesive film

Figure 5 Load Vs Displacement for specimens with adhesive film between the steel plate and the initial GFRP layer

Figure 6 Energy Dissipation & Maximum Achieved Load

Figure 6 is allowing comparison of the maximum load capacity and the energy dissipation of all specimens. The application of epoxy around the bolted area significantly increases the load capacity due to the reduction in slippage between the specimen and the clamping steel plates. Applying additional FRP layers around the bolted area increases the bearing capacity of the specimen due to increased thickness of FRP around the bolts. The application
of adhesive film in hybrid specimens has a minimal effect on both load capacity and energy dissipation, visible when comparing 2SG4F with 2SG4FE and 2SG4FD with 2SG4FED. This minimal effect of additional adhesive film is applicable only for the connections and the effect is not valid for other areas of the infill plate. It was indicated by Petkune et al. (2014) that the application of adhesive film between the steel and CFRP prepreg laminates over the whole infill plate can significantly improve the shear wall behaviour.

While assessing the failure modes it was revealed the most common modes of failure for connection with two bolts were shear-out, cleavage failure and a combination of both. Where adhesive was used to prevent slippage at initial stages of loading, in some specimens failure occurred in mid-section of the specimen resulting in higher load capacity. Some of the specimen’s failure modes can be seen in Figure 7.

![Figure 7 Modes of failure starting from the left; (I) sample before testing, (II) shear out, (III) cleavage, (IV) combination of both shear out and cleavage and (V) failure at mid-section of plate.](image)

**CONCLUSION**

From testing and analysing different variations of hybrid steel/GFRP connections the following conclusions can be made:

1- For GFRP only plates application of either additional layer of GFRP or adhesive around the bolted area will increase both the ultimate capacity and the energy dissipation (Figure 3)

2- Simultaneous application of additional GFRP strips and adhesive around the bolted area will result in even higher ultimate load capacity and similar increase of the level of energy dissipation (Figure 3)

3- For hybrid plates the result of applying additional layer of GFRP and adhesive is similar to the results for plain FRP plates when both materials are applied simultaneously, with significant improvement of the ultimate load capacity and energy dissipation (Figure 4)

4- Additional epoxy layer between the steel plate and the adjacent GFRP layers at the zone of bolting is not so beneficial in increasing the capacity and energy dissipation as the application in internal zones of the infill plate.

5- Comparison of the obtained results with steel only connection indicates that in most of the cases the capacity and energy dissipation for the developed connections are significantly higher up to 2.9 and 2.8 times respectively.

ABSTRACT

Excellent properties of FRP materials are making them attractive component for developing new structural elements and systems. Initial investigations indicated positive effect of using hybrid (steel/FRP) infill plates on the ultimate capacity and energy dissipation capacity of steel framed shear walls. However, the usage of pure FRP plates has not been sufficiently investigated till the moment. The proposed research is investigating the behaviour of steel framed shear walls with GFRP and CFRP infill plates via experimental testing of medium scale samples. The testing of specimens has been conducted via application of displacement controlled quasi-static loading following ATC-24 protocol. Obtained results are analysed and compared with the results for steel framed shear walls with steel infill plates. Corresponding conclusions and considerations for possible future applications are offered.

KEYWORDS
FRP, shear wall, composite plate, quasi-static loading.

INTRODUCTION

The behaviour of steel shear walls was investigated for several decades (Roberts, 1995; Astaneh, 2001). They were used in the number of high rise buildings as primary lateral loading system. Steel shear walls have significant advantages in terms of light weight, high stiffness and energy absorption in comparison to other structural systems. Hybrid structural elements are becoming popular in thin walled structures, sandwich panels and shear walls. Hybrid shear walls (HSW) are innovative structural lateral load resisting system, HSW are defined to be consisted of steel framed elements and steel infill plates laminated with fibre reinforced polymers (FRP) material. By reducing out-of-plane deformations of the infill plate and increasing energy absorption capacity, such systems have the potential to provide highly effective structural solution (Rahai et al., 2011; Maleki et al. 2012; Petkune et al., 2014). Based on the previous studies it was found that the most effective angle of fibers inclination is in the direction of diagonal tension field action.

This study investigates the use of the innovative pure FRP infill plates within the steel boundary elements and compares behaviour and results to the steel shear wall with steel infill plate only. Glass FRP (GFRP) and carbon FRP (CFRP) were used to produce composite infill plates. Fibers were placed at 45° inclination angle, which corresponded to the angle of diagonal tension field action.

EXPERIMENTAL SET-UP

Specimen Description

Single-storey medium scale specimens were tested in the project. Shear wall scaled models, consisting of steel frame and infill plate, were designed at Kingston University London. The steel frames tested in this study were 1/3 scaled model of a shear wall with a height of 1025 mm and width of 1090 mm. The steel frame members consisted of two columns and beam made from Universal Beam Section 127 x 76 x 13 mm (S355 grade) shown in Figure 1a. They were fabricated, assembled and welded by Cannon Steels Ltd. Primary fish plates were welded continuously to the internal part of the steel frame. Three different types of infill plates were used: steel, carbon FRP (CFRP) and glass FRP (GFRP). Steel shear wall specimen (SSW) was designed with steel infill plate 0.8 mm thick (S275 grade). For comparability shear walls with CFRP (CSW) and GFRP (GSW) had the same design configuration, they were made with eight layers of prepreg FRP material and fibres were placed at 45° inclination. Shear walls with CFRP and GFRP plates were referred as composite later in the text. Specification of the specimens is shown in Table 1.

The composite plates were prepared with oven/vacuum method. Prepreg FRP layers were placed by layering them between two steel plates used as moulds. First layer of the FRP material was rolled on the cover steel plate mould, then the rest were laid in accordance to design specifications with fibre orientations at ±45° angle of fibres, eight layers in total. A vacuum breather cloth was wrapped around the specimen, then the specimen was sealed, vacuum bagged and cured inside an oven under vacuum. The curing temperature increased at a rate of 3°C per minute until 120°C and an even pressure up to 980 mbar was applied by using a vacuum pump. Then the temperature was kept constant at 120°C for 1 hour and finally the temperature decreased to 60°C during the cooling down cycle and the sample was then left to cool to room temperature outside the oven.

**Connection Specification**

Two types of the connections were used during testing: bolted connection and bolted connection with adhesive. For steel shear wall specimen a traditional bolted connection was used. M8 bolts are placed sat 70 mm spacing centre-to-centre. They had a minimum breaking torque of 32 N-m for A4-70 stainless steel class, where “A” means cold worked austenitic stainless steel and “70” represents a minimum tensile strength of 700 N/mm².

For composite specimens bolted with adhesive connections were used, which proved to be effective as a result of the previous studies (Petkune et al., 2014b). It was concluded that the use of the adhesive improves the capacity
of the connections by 20%. Devcon epoxy plus adhesive (manufactured by ITW Polymers Adhesive) with shear strength of 20 MPa was used. The adhesive was applied evenly on edges of infill plate and primary fish plates, the composite surfaces were connected and were bolted together with M8 bolts to the specified torque. Any excessive adhesive coming out from the edges was removed. To achieve good bond at the connection, specimen was cured at room temperature for at least 24 hours before testing. In order to provide a stiff connection to the composite infill plate, an additional steel strip 30 mm wide and 1.5 mm thick was attached to both sides around the edges of the infill plate using the same adhesive. Holes were drilled after the strips were attached.

**TESTING METHOD**

Figure 1b shows testing rig used for testing specimens in accordance to ATC-24 protocol (1992). Specimen was fixed to the reaction frame and lateral supports prevented out-of-plane movement of the steel frame. Controlled displacement to the specimen was applied via a screw jack and measured with load cell. Displacement was measured with LVDTs. Figure 2 shows a cyclic sinusoidal loading and applied to all specimens for a range of different amplitudes varying from 0.4 mm to 35 mm displacement. The application of the same displacement in both directions completes one cycle of loading. Initially, three cycles at each amplitude were applied, and then above 15 mm displacement the number of cycles was decreased to two cycles per amplitude according to the ATC-24 protocol. The loading is designed for steel shear wall samples and is kept the same for FRP samples with the aim to achieve comparability.

![Loading Protocol](Figure 2 Cycling loading in accordance to ATC-24 protocol)

**RESULTS AND DISCUSSIONS**

**Behaviour of the specimens during the testing**

The steel shear wall specimen SSW was loaded up to 35 mm displacement. Until displacement of 3.5 mm, diagonal tension action was with elastic deformations and the initial shape of the plate was recovering in the end of the cycles. However, when the infill plate had undergone plastic deformations for displacements above 3.5 mm, out-of-plane deformations were more visible and initial shape was not recovering at the end of the cycle. At
displacements higher than 10 mm, enlargement of holes around bolts in the connections between fish plates and infill plates started. It led to the yielding of the steel infill plate and its tearing around bolt holes, corresponding noise occurred when tearing started. Sliding of the infill plate progressed with the increase of the displacements. After the 15 mm displacement cycle, up to 4 mm sliding from the original position of the border of the infill plate at the top part of the wall was noticed. The initial pinching of the infill plate along diagonal tension field started at a displacement of 15 mm, which further progressed to development of small holes at displacements higher than 30 mm. Development of the plastic hinges at the bottom of the columns of the steel frame was noticed at displacements above 15 mm, and appeared at the top of the columns above 30 mm displacement. At 35 mm displacement, sliding of the plate reached 15 mm at the top border between fish plate and infill plate, and the extension of the bolt holes were visible at fish plate section. Due to the concentrations of stresses in corners of the infill plate, steel snapped forming diagonal cracks at top corners. The final damage of the steel shear wall specimen (Figure 3a) occurred through further development of the plastic hinges around the bottom and top areas of the column and tearing of the steel plate around bolt holes. Test was terminated when significant level of the damage in the infill plate and the frame occurred and the design range of deformations for testing equipment was achieved.

Figure 3 a) SSW specimen after 35 mm displacement b) CSW specimen tested to 25 mm displacement: opening of the crack, ruptures in the specimen, delamination of thin strips of CFRP

CSW specimen was tested until exceeding the ultimate load value which occurred at 20 mm displacement. For the CSW specimen diagonal tension field action through the development of out-of-plane deformations was visible at 2.5 mm displacement. The diagonal waves recovered at the end of loading cycle up to the displacement of 5 mm. Above 5 mm residual deformations were recorded. Tearing and appearance of the first diagonal cracks of the CFRP layers in the corners were developed when specimen was tested to the displacement higher than 10 mm. These cracks in FRP fabric increased longitudinally in diagonal direction at higher displacements. When displacements increased to 15 mm and higher, thin strips of the CFRP perpendicular to the cracks started to delaminate in top corners of the infill plate. At 20 mm displacement, a crack through the whole thickness of the CFRP plate developed. The layer of the adhesive at the connection between fish plates and infill plate cracked when the specimen was tested to 20 mm displacement, however no visible movement of the plate at the connections was recorded. Development of the plastic hinges was noticed at 20 mm displacement in the steel boundary elements. Maximum load of 266 kN was achieved at 20 mm displacement. In contrast to SSW specimen which experienced plastic deformations of the plate and connections, carbon specimen failed at early stages of loading due to the lack of yielding process with significant cracks developing in the direction of diagonal tension field (Figure 3b).

GSW specimen was tested until 35 mm displacement. For GSW specimen after 2.5 mm displacement, out-of-plane buckling of the plate was not fully recovered at the end of the cycle. At 15 mm displacement, crack in the layer of adhesive at the connections was observed near top section of the plate. At 20 mm displacement delamination and tearing of the FRP in corners of the infill plate started and development of the plastic hinges occurred at the bottom of the shear wall columns. The glass FRP infill plate was torn in one of the corners with about 40 mm long crack in FRP layers. At 25 mm displacement, maximum load of 359 kN was achieved. At 30 mm displacement, further delamination of the GFRP developed in both corners of the infill plate. For GSW specimen cracks did not go through all layers of the GFRP fabric, as they were developed for the CSW specimen. At 30 mm displacement, the infill plate slid and a significant gap developed between infill plate and fish plate in adhesive layer in the corners of the infill plate. Due to the diagonal tension field action, fish plates buckled. With the increase of the displacement to 35 mm (Figure 4), in the GSW specimen, areas of the delamination were widened in the corners. Further sliding of the plate occurred and elongated bolt holes were visible, which happened at a later stage in comparison to other specimens. At 35 mm displacement signs of local buckling in the columns of the frame at the zones of plastic hinges was detected.
Hysteresis Curves and Load vs Displacement and Energy Absorption graphs

Based on the hysteresis curves shown in Figure 5, load vs displacement (Figure 6) was made. Loads were calculated by taking the average from the extreme values of the cycles at the same displacement amplitude.

The initial load values for the same levels of displacement for composite specimens were lower than the control specimen SSW. Above 6.5 mm displacement for GSW specimen and above 9 mm displacement for CSW specimen, both specimens showed better load values than the control specimen. Up to 11 mm displacement, GSW and CSW behave similarly, but above this level the difference between the two specimens starts to increase significantly. The load capacity of GSW specimen is higher than capacity of CSW specimen. The difference between two specimens is 20% at 20 mm displacement and increasing up to 33% at 25 mm displacement.

For the CSW specimen the main mode of the failure was a sudden and fast development of delamination and intensive cracking within the CFRP fabric resulting in a relatively brittle failure of the infill plate. In comparison with CSW specimen, GSW had more gradual failure of the infill plate. The connections between the infill plate and the fish plates behaved reasonably well up to the termination of the test. The GSW ultimate load capacity of 359 kN was 35% higher than the CSW ultimate capacity of 266 kN.
The sample with the GFRP infill plate (GSW) has better behaviour and higher values of energy absorption (Figure 7) than the specimen constructed with pure CFRP infill plate (CSW). The energy absorption of the CSW specimen was lower in comparison to other specimen at all levels of loading. Energy absorption of both pure FRP specimens were similar up 15 mm displacement, then the difference between the two specimens increased to 3.0 kJ at 25 mm. The values of energy absorption for the GSW specimen were close to the values of SSW control specimen up to 25 mm displacement.

CONCLUSIONS

The following conclusions can be made:
- The best behaviour in terms of the load capacity and energy absorption is the behaviour of GSW.
- Based on the hysteresis curves, results demonstrated that SSW and GSW specimen have approximately the same energy dissipation capacity up to 25 mm, energy dissipation of the CSW is the lowest.
- CSW is having more brittle failure at early stages of the loading in comparison with GSW.
- The obtained results indicate that GSW specimen could be the successful replacement of SSW.
- Special consideration in design of connections for composite specimens is needed.

Performance under Seismic and Severe Loadings
COMPOSITE MATERIALS AS PART OF AN OPTIMAL STRATEGY FOR SEISMIC RETROFITTING OF RC FRAMES

ABSTRACT
This paper proposes a rational strategy for retrofitting Reinforced Concrete (RC) frame structures, based on combing member- and structure-level techniques, in order to achieve optimal design objectives within the framework of a potentially Multi-Criteria Performance-Based approach. Composite materials, with emphasis on Fiber-Reinforced Polymers (FRP), can be employed in local strengthening interventions, such as confinement of columns, hence representing a viable member-level technique. Therefore, this paper presents the key features of a novel numerical procedure that implements a genetic algorithm capable of selecting the “fittest” solution among the technically feasible ones consisting of alternative configurations of steel bracing systems (as structure-level technique) and FRP-based member-level interventions. The paper reports the main assumptions about the representations of “individuals” as part of this genetic algorithm procedure, along with some details on the algorithm operations (i.e. selection, crossover and mutation). Finally, a preliminary application is proposed.

KEYWORDS
RC frames, seismic retrofitting, soft-computing.

INTRODUCTION
Existing Reinforced Concrete (RC) frame structures were often designed for gravitational loads only, without taking into account the Capacity Design rules introduced by modern seismic design codes (CEN 2005). Therefore, seismic retrofitting of these RC structures is emerging as a technical challenge (fib 2003) and a relevant societal priority, as a result of the significant damage caused by recent earthquakes.

As a matter of principle, retrofitting solutions can generally be grouped into two broad classes that collect, on one hand, the so-called “member-level” (local) techniques and, on the other hand, the structure-level (global) techniques (fib 2003). Techniques belonging to the former, such as confinement of single beams or columns (Rodriguez and Park 1991), aim at improving the capacity of single structural members, in order to contribute to the capacity of the entire structure. The use of composite materials is more and more common in member-level techniques (fib 2006). Conversely, structure-level techniques consist of linking the existing structure with new substructures, such as RC shear walls or steel bracing systems, intended at working in parallel with them. They aim at increasing strength and stiffness of the coupled structural system and, hence, reducing the displacement demand on the existing RC structure and its members (Martinelli et al. 2015).

The aforementioned techniques, considered on their own, represent two somehow “extreme” solutions of the retrofitting problem. However, they may be duly combined with the aim to obtain a synergistic action in both increasing seismic capacity of under-designed members and reducing demand on the existing structure. In fact, each one of the potentially infinite combinations of member- and structure-level interventions leads to different direct costs, life-cycle costs, reliability levels and other quantitative/qualitative parameters that describe the earthquake response of RC structures. In this light, choosing the “optimal” combination of these interventions is clearly an optimization problem, which can be based on the assumption of a properly defined objective functions related to the cost and performance parameters. Although minimising direct costs is often assumed the key objective in retrofitting, a more comprehensive choice of performance parameters (i.e. minimum floor acceleration in presence of sensitive acceleration devices, maximum reliability and so on) may be considered within the framework of a Multi-Criteria optimization problem (Chankong and Haimes 2008).
However, neither in the current practice, nor in most of the available scientific contributions (Thermou and Elnashai 2006), seismic retrofitting of RC frames is approached as an optimisation problem. In fact, it is rather addressed as a merely technical issue; any considerations about optimisation (often restricted to the “economic” standpoint) are left to the engineering judgement and, hence, they are not part of a systematic analysis. This is because this optimisation problem could not be approached by means of analytical techniques commonly employed in structural engineering, but it needs meta-heuristic techniques capable of handling objective functions with no closed-form analytical expressions and possibly multi-criteria performance objectives.

Therefore, this paper outlines a general procedure based on a genetic algorithm inspired to the well-known Darwin’s “evolution of species” concept, based on the “survival of the fittest” rule (Darwin, 1859). Although some pioneering applications of these techniques are already available in the field of structural engineering, they are mainly restricted to the design of new structures (Papadrakakis and Lagaros 2002). The following sections summarise the main aspects of the proposed genetic algorithm and its application in the rational design of retrofitting interventions of existing RC frames.

OVERVIEW OF THE PROPOSED GENETIC ALGORITHM

Problem statement and formulation

As is well-known, the objective of seismic retrofitting can be conceptually described by the following Limit State (LS) function $g_{LS}$:

$$g_{LS,i} = C_{LS,i} - D_{LS,i} \geq 0$$

(1)

where $C_{LS,i}$ is the capacity of the strengthened structure at the $i$-th relevant LS and $D_{LS,i}$ the corresponding demand. Capacity and demand mentioned in Eq. (1) are generally intended in terms of either displacements (for ductile mechanisms) or forces (for brittle mechanisms). Moreover, this relationship should be checked at all the relevant LSs. As a matter of principle, Eq. (1) is not verified in seismically vulnerable.

Therefore, a combination of retrofitting techniques belonging to the so-called member- and structure-level techniques are considered for acting on the two terms of Eq. (1) (Martinelli et al. 2015). Specifically, if $x$ is the vector of design variables defining the generic combination of these techniques intended as retrofitting intervention, the optimal solution $\bar{x}$ may be determined by solving the constrained optimisation problem conceptually defined as follows:

$$\bar{x} = \arg \min_{x} \left[ f(x) \right]$$

$$g_{LS,i}(x) \geq 0 \quad \forall i = 1...n_{LS}$$

(2)

where $f(x)$ is the selected objective function and $L_{S,i}$ is the $i$-th LS out of the $n_{LS}$ of relevance.

As already mentioned, assuming the total direct cost of intervention is the simplest choice for the objective function. This is defined by considering the cost of both member- and structure-level techniques as conceptually denoted below:

$$f(x) = \left[ C_{loc}(x) + C_{glob}(x) \right] \cdot \Phi \left( \max_{i} \left| g_{LS,i}(x) \right| \right)$$

(3)

where $\Phi(\bullet)$ is a penalty function that modifies the nominal cost function of local and global interventions described by the vector $x$ (referred to as $C_{loc}(x)$ and $C_{glob}(x)$, respectively) if the inequality in Eq. (2) in not verified. It is worth highlighting that cost functions should take into account both demolition and reconstruction operations requested by both member- and structure-level techniques. Furthermore, the cost of structure-level intervention should include the possible strengthening of the original foundations, which often require the realisation of micropiles.

Representation of “individuals”

Figure 1 proposes a conceptual map of the numerical procedure proposed to solve the constrained optimisation problem described by Eq. (2). It starts with generating randomly an initial population of $N_{ini}$ individuals: a simple chromosome-like array of bits represents the single “individual” $x$ of that population.
Binary coding is adopted in the current implementation of the algorithm (Biondini, 1999). Since \( x \) includes the description of both member- and structure-level techniques, it is built by concatenating single variables that describe both types of interventions. On the one hand, the first part of the binary code representing the generic individual \( x \) includes the number of FRP layers confining each column of the existing frame. On the other hand, the second part of the \( x \) code represents the profiles adopted for realizing the first level of the concentric steel bracings adopted as a structure-level technique: the sections of the upper level profiles are linked to the former by means of a consistent design criterion chosen among those available in the literature. This leads to have each bracing described by only one steel profile, which is quite convenient in order to keep the cardinality of \( x \) as small as possible.

Based on these assumptions, the binary coding of an individual \( x \) for a simple three-storey frame with rectangular plan takes the form expressed in Figure 2.

Figure 2 Example of binary genotype for coding a retrofitting solution

It is worthwhile to mention here that two bits are adopted for each column: since each bit can take a value either 0 to 1, only \( 2^2 = 4 \) alternative confinement solutions can be taken into account: “00” would represent the absence of confinement, whereas “01”, “10” and “11” would correspond to one, two and three FRP layers, respectively. Moreover, since the maximum number of member-level interventions is equal to the number of columns, a total number of \( 2 \times N_{\text{col}} \) bits are allocated for describing them (Figure 2). The modified Kent and Park model available in OpenSEES (Mazzoni et al. 2006) is taken into account for simulating the effect of FRP confinement on concrete sections (Figure 3): it includes both strength and ductility enhancement due to the confinement.

Figure 3 Model by Kent and Park (1972) for confined concrete sections.

Furthermore, since steel bracings are supposed to be only realised between each couple of columns connected by a beam, the maximum number of bracing systems is equal to the number of beams \( N_{\text{beams}} \) in the first floor. Three bits are employed for codifying structure-level techniques (Figure 2). Consequently, there are only \( 2^3 = 8 \) possible phenotype solutions, which identify the section of steel bracings at the first level. They can range from “000” would mean absence of bracing system whereas “111” would point to the 7th profile in a list of industrial steel members potentially available for designing retrofitting interventions.
Seismic Analysis of “individuals” and evolution criteria

Static NonLinear Analyses (PushOver) are employed to quantify the values of $g_{LS,i}$ through Eq. (1) for a given “individual” $x$ of the population of technically feasible interventions (Figure 4). More specifically, capacity models adopted by current seismic codes (CEN 2005) are considered for determining $C_{LS,i}$, whereas $D_{LS,i}$ is determined by means of the well-known N2-Method (Fajfar 1999): Figure 5 depicts the main operations needed for determining the value of $D_{LS,i}$ requested for quantifying $g_{LS,i}$.

The genetic algorithm evolves through three operators until the counter of population reaches a maximum fixed number. These operators aim at creating new solutions of the retrofitting problem by selection, combination or mutation of the current population.

![Figure 4 Pushover analysis and capacity curve of a sample structure](image)

![Figure 5 Construction of Capacity Spectrum of equivalent SDOF and determination of “performance point”](image)

The first genetic operator is used to select “parents” among a mating pool according to their fitness. The fitness function $F$ of each individual $x_k$ can be defined as follows:

$$F(x_k) = \min_{h=1,N_{ind}} \frac{f(x_k)}{f(x_h)} ,$$

where $N_{ind}$ is the (invariant) number of individual forming each generation (fixed to 50). The function $F(x_k)$ “measures” the performance of individuals solution in the problem domain: it tends to zero for extremely “unfit” individuals, whereas it is equal to one for the fittest individual of each generation. Each individual “compete” with the other ones within the same generation and its probability to “survive” and, hence “reproduce” its features in the successive generation is defined as a function of its fitness:

$$p(x_k) = \frac{F(x_k)}{\sum_{h=1}^{N_{ind}} F(x_h)} .$$

Therefore, the selection procedure is implemented through the so-called “modified roulette-wheel” rule (Lipowski et al 2012), whose circular sections are proportional to the probability of each individual (Figure 6).
Hence, the individual $x$ characterised by higher fitness value has a larger range in the cumulative probability values and, consequently, has a higher probability of being selected for the mating pool. With the aim of selecting $n$ strings, $n$ random numbers are generated in the $[0, 1]$ interval and, for each one of them, the individual whose segment includes the random number is actually selected.

The second operator combines segments of selected strings, delimited with red dashed lines in Figure 7, into new “offspring” solutions by exchanging their genetic information between successive crossover points (“multi-point” crossover): the influence of the number of crossover points on the resulting efficiency is a key aspect, whose discussion is outside the scope of this paper. For further details, Readers may refer to De Jong and Spears (1992).

Finally, the third operation is mutation, which “mutates” the bit from 0 to 1 or vice versa if a fixed probability test is passed. This probability, called mutation rate $p_m$, is usually fairly small and, in the present proposal, is set to 0.02. In detail, a “coin toss” mechanism is employed: the bit is mutated if a random number between zero and one is less than the aforementioned mutation rate (Table 1).

SAMPLE APPLICATION

A regular three-storey frame is considered as a case-study with the aim to show a preliminary example of the potential of the proposed algorithm: three bays are present in the longitudinal direction (represented in Figure 8), whereas there is only one bay in the transverse direction. Therefore, it is worth highlighting that since there are 8 columns and 10 beams, the total length on the binary genotype of each individual is $8 \times 2 + 10 \times 3 = 46$ bits.

![Figure 8 Sample existing structure (a) and optimal retrofitting solution found by procedure (b)](image)

The frame is assumed to have rigid connections and fixed supports. The modulus of elasticity of steel is equal to 210 GPa and the yield stress is $F_y = 350$ MPa. The uniaxial Kent-Scott-Park model with degraded linear
unloading/reloading stiffness and no tensile strength is assumed for modelling the behaviour of concrete and the effect of confinement (Mazzoni et al 2006). The permanent load is taken as $G=5.00 \text{kN/m}^2$ and the live load is taken as $Q=2.00 \text{kN/m}^2$. The gravity loads are contributed from an effective area of $75 \text{m}^2$. Nonlinear beam-column elements with spread plasticity is employed for the FE model employed to perform pushover analysis. Fiber approach is used to account for material inelasticity. Each structural element is discretized into 5 sections located at the Gauss quadrature integration points. Each section is divided into a number of fibers, which comply to beam kinematics and each follows its own constitutive model.

Figure 9 depicts the evolution of the solution search throughout generations: the objective (cost) function starts from a cost of 94127 € and decreases progressively. As expected, the curve shows a very steep slow over the first generations and a slower and slower convergence, often characterised by a staircase shape, towards the final convergence, which is supposed to have been achieved as after 150 generations, as no further improvement is observed in $f(x)$ over the last 18 iterations. In the example under consideration, the optimal solution came up to consist of a simple concentric steel bracing and no local FRP interventions were actually required (Figure 8b) in the case under consideration. Figure 10 shows the optimal genotype in the 150th population and whose phenotype has a cost of 14282 €, the lowest of all previously processed solutions.

![Figure 9 Convergence history: objective function vs generations](image)

![Figure 10 Genotype of fittest individual in the last population](image)

CONCLUSIONS

This paper has proposed a general procedure intended at optimising seismic retrofitting of existing structures by combining member- and structure-level techniques. Despite the limitations of the current implementation (which, for instance, does not consider relevant aspects, such as the cost of the possible foundation strengthening, and assumes the actual cost as a simple objective function), the proposed procedure is a promising tool for approaching a subject of current relevance whose solution is generally left to the engineering judgement. The proposed application confirms the potential of the proposed procedure, as it demonstrates that the implemented genetic algorithm is capable of finding a solution characterised by a cost significantly lower than the initial trial solution. However, the complete implementation of this procedure is still under development: the work ahead should not only be intended at including the aforementioned aspects that are not currently accounted for, but also at enhancing the computational efficiency of the programming code.

ABSTRACT

Concrete columns reinforced by steel-fiber reinforced polymer (FRP) composite bars (SFCB) may have a stable post-yield stiffness and good anti-corrosion performance. The hysteric behavior of three reinforced concrete (RC) columns under quasi-static loading was examined with an axial compression ratio of 0.11, and the longitudinal reinforcement types included ordinary steel bar and steel-basalt FRP (BFRP) composite bar (SBFCB) with different post-yield stiffnesses. The test results showed that the post-yield stiffness of the ordinary RC column was negative, whereas those of the other two SFCB columns were positive. After the columns yielded, the plastic strain of the ordinary RC column was concentrated at the column base while that of the SFCB columns were spread over a longer region, which may result in a smaller residual strain. The ductility of the SFCB columns was even larger than that of the RC column, which demonstrated that the elongation rate of BFRP could satisfy the lateral drift demand of a concrete column under an earthquake excitation.

Concrete column, steel-FRP composite bar, hysteric behavior, strain development.

INTRODUCTION

The Economic Development Research Group (2011) demonstrated that the deterioration of steel in reinforced concrete (RC) bridges and in other facilities of the American transport infrastructure cost approximately $139 billion in 2010. Fiber reinforced polymer (FRP) is a type of composite with a better anti-corrosion performance in concrete structures (Bakis et al., 2002). Mufti et al. (2007) reported that specimens reinforced by glass FRP (GFRP) bars in Canadian concrete bridges or in marine structures maintained an acceptable performance for 5~8 years. Because the bonding between the GFRP and the concrete was nearly perfect, their results prompted the Canadian Highway Bridge Design Code (CAN/CSA-S6-00 (R2005)) to use GFRP bars as one of the primary means of reinforcement in concrete structures.

Due to the elasticity and brittleness of an FRP bar, the stress level when using a GFRP bar as the prestressing tendon is limited to 25% of its ultimate strength (CAN/CSA-S6-00 (R2005)). Because of the low elastic modulus of GFRP or the high price of carbon FRP (CFRP), the application of FRP bars to concrete structures is still not widely accepted by engineers. By combing steel and FRP, a better performance and a more acceptable cost can be achieved. Aiello et al. (2002) used an FRP bar to replace a corner steel bar in concrete beams with an equal area, and the results showed that the steel bar could reduce the crack space and decrease the crack width. Lau and Pan (2010) conducted a test of 12 concrete beams, in which the reinforcement was from a steel bar, a GRP bar, or a steel/GFRP bar. It was found that the minimum reinforcement ratio for a beam reinforced by FRP could be reduced by 25% according to ACI 440.1R-06 (ACI 2006). Pang et al. (2015) focused on the calculation method for determining the load-displacement relationship of the hybrid reinforced concrete beam, and a new ductility coefficient was proposed for the evaluation of the deformation capacity. Kara et al. (2015) analyzed the test results of 46 beam specimens, which included beams reinforced by hybrid steel-FRP bars and concrete beams strengthened by near-surface mounted FRP bars. The failure modes of the concrete beams were investigated based on the ratio of the FRP reinforcement to the total reinforcement.
Concrete structures reinforced by hybrid steel-FRP bars still have a great risk of deterioration failure, a better anti-corrosion performance can be obtained by steel-FRP hybrid bars, which are a new type of rebar with an inner steel bar and an outer FRP. Sixteen hybrid reinforced concrete beams were tested by Nanni et al. (1994), and their results showed that the load-displacement curves of the hybrid reinforced beams can be calculated using the traditional RC theory, and the hybrid beams developed fewer cracks and had a larger crack width. Saikia et al. (2005) tested concrete beams with longitudinal steel-GFRP composite bars and GFRP stirrups, and a slip between the inner steel bar and the outer GFRP happened due to underdeveloped manufacturing technology. By modifying a pultrusion machine for FRP bars, a new type of steel-FRP composite bar (SFCB) can be obtained with good quality (Wu et al., 2010), and the ratio of FRP to steel can be specified by the customer (Sun et al., 2012). An experimental study on a concrete column reinforced with steel-FRP composite bars under quasi-static loading was conducted, and the hysteric behavior and the strain development of an ordinary RC column and SFCB columns are analyzed in this paper.

EXPERIMENTAL PROGRAM

Specimen Design and Test Setup

The longitudinal reinforcement ratio $\rho$ of an RC column is defined by the total area of the rebar over the gross section area. For a concrete column reinforced by a hybrid composite bar, an equivalent longitudinal reinforcement ratio ($\rho_{sf}$) is proposed with regards to a steel reinforced concrete column (Equation (1)), and the post-yield stiffness ratio of a SFCB ($r_{sf}$) can be defined by Equation (2) (Sun et al., 2014),

$$\rho_{sf} = \frac{E_f A_f + E_s A_s}{E_f A_{fg}}$$

(1)

$$r_{sf} = \frac{E_f A_f}{(E_f A_f + E_s A_s)}$$

(2)

where $E_f$ and $A_f$ are the elastic modulus and the total cross-section area of SFCB’s outer FRP, respectively; $E_s$ and $A_s$ are the elastic modulus and the cross-section area of the inner steel bar, respectively; and $A_g$ is the gross cross-section area of the concrete column. As a result, columns with the same $\rho_{sf}$ will have the same initial stiffness.

Three concrete columns were designed, and the corresponding specimen numbers and the mechanical properties of the reinforcements are presented in Table 1. The notation ‘C-S12’ denotes that the longitudinal reinforcement of the column is a steel bar with a 12 mm diameter. The notation ‘C-S10B49’ denotes that the concrete column is reinforced by a type of SFCB made from a 10-mm diameter inner steel bar longitudinally compounded with 49 bundles of 2400 tex basalt fibers; ‘tex’ is the weight (g) of one fiber bundle per kilometer. The notation is similar for C-S10B85, which has 85 bundles instead of 49.

Table 1 Specimen numbers and mechanical properties of the longitudinal reinforcements

![Figure 1 Test set up and geometry of concrete column](image-url)
The detailed dimensions of the columns and the loading patterns are shown in Figure 1. The shear span ratio was five, and an electrohydraulic servo test system applied a controlled vertical load of 200 kN for this test. To minimize the horizontal friction forces caused by the uniaxial compression at the column cap, tetrafluoroethylene plates and a pulley were positioned between the vertical loading actuator and the reaction frame. The friction coefficient between the tetrafluoroethylene plates and the reaction frame was approximately 0.03, and the friction coefficient between the pulley and the tetrafluoroethylene plates was less than 0.03. The compressive strength of the 150×150×150 mm concrete cubes over 28 days was 36.64 MPa, and the corresponding cylinder compressive strength was 29.31 MPa. Therefore, the axial compression ratio was 0.11.

**Loading Procedure and Measurements**

The horizontal cyclic loading on the column cap was controlled by a lateral force prior to column yielding, with a loading gradient of 10 kN for each step. After yielding, the loading was controlled by displacement (7 mm in this experiment), with each displacement cycled three times. The test measurements included the column cap force versus lateral displacement curves and the longitudinal reinforcement’s strain distribution, which was measured by seven strain gauges along the longitudinal bar.

**HYSTERETIC BEHAVIORS**

The load-lateral displacement curves and the failure modes of the columns are shown in Figure 2. Flexural failure occurred in all specimens. During loading, the concrete cover near the column base initially cracked, followed by the yielding of the longitudinal steel bars and the inner steel bars of the SFCBs. Spalling of the concrete cover in the column base subsequently occurred with a rupture or a partial rupture of the FRP. The characteristic values of the concrete columns are listed in Table 2, where \( V_C, V_y, \) and \( V_p \) are the crack load, yield load, and ultimate load, respectively; \( \delta_u, \delta_y, \) and \( \delta_p \) are the corresponding lateral displacements; and \( \mu \) is the displacement ductility coefficient \((\delta_u/\delta_y)\). The yield loads and displacements were determined by the first yielding of the longitudinal reinforcement. The ultimate load displacement was the point at which the load capacity decreased to 85% of the peak load. The post-yield stiffness ratios of the columns \((RC_u)\) are presented in Table 2 and are defined by Equation (3):

\[
RC_u = \frac{K_2}{K_1}
\]

where \( K_1 = V_y/\delta_y \) and \( K_2 = (V_u - V_y)/\delta_u - \delta_y \) are the initial and post-yield stiffnesses of the concrete column. To compare the \( RC_u \) of different columns at similar drift ratios, the \( RC_u \) of the hybrid reinforced columns is calculated at the same ductility level \((\mu = 6.28)\).

</table>

The first flexural crack of C-S12 was observed at approximately 150 mm from the column foundation when the horizontal load was approximately 30 kN; the corresponding crack width was approximately 0.06 mm. The load of the turning point in the hysteretic curve (Figure 2(a)) caused by the cracks was approximately 50 kN. Six corresponding cracks were observed near the column base, with a maximum crack width of 0.08 mm. The average lateral load from pushing and pulling was 72.5 kN when the lateral displacement at the column cap reached 14 mm; the subsequent lateral load began to decrease with an increase to the lateral displacement. When the displacement reached 42 mm, the load capacity decreased to 85% of the peak load, i.e., the failure point. When the lateral displacement at the cap increased to 49 mm, a partial spalling of the concrete at the column base was observed in the second loading loop. As the loading continued, the buckling of three longitudinal reinforcements at the A-side and one at the B-side occurred when the lateral displacement was 56 mm (Figure 2(b)).

The first flexural crack of C-S10B49 occurred at approximately 250 mm from the column foundation when the lateral load was approximately 40 kN; the crack width was approximately 0.02 mm. The load at the turning point in the hysteretic curve (Figure 2(c)) caused by cracking was approximately 54 kN. Fifteen cracks appeared on the two sides of C-S10B49, of which the maximum crack was observed at 150 mm from the column foundation with a width of 1 mm. The outer FRP of the SFCB at the corner of the A-side began to rupture gradually after the lateral displacement reached 33 mm (Figure 2(d)), with the maintained lateral load decreasing with an increasing lateral displacement.

737
As for C-S10B85, the turning point of the hysteretic curve caused by cracking was approximately 56 kN (Figure 2(e)), and three cracks were observed on the column base after this loading step. The maximum crack was located at a 50-mm height from the column foundation with a 0.15-mm crack width. When the lateral displacement of C-S10B85 reached 21 mm, a slight spalling of the concrete cover at the column base occurred. The concrete cover in the four corners of the column base completely crumbled when the lateral displacement reached 42 mm. After the column yielded, the load-displacement of C-S10B85 remained stable until the lateral displacement reached 69 mm (Figure 2(f)). This indicates a good ductility and deformation ability.

STRAIN DEVELOPMENT OF THE LONGITUDINAL REINFORCEMENT

Strain gauge location

Figure 3 shows the strain distribution and strain gauge locations for the longitudinal reinforcement of an ordinary RC column and for an SFCB reinforced column. Strain gauges Nos. 1–3 were in the anchorage region, and Nos. 3–7 were all above the interface of the column foundation and the column base. The curvature of the column section can be obtained from the tensile and compressive strains, and the corresponding column lateral
displacement can be integrated by the curvature along the column height. The lateral drift of a concrete column includes flexural deformation, shear deformation, and slip. For the columns in this paper, the flexural deformation is the dominant component of the column cap displacement.

(e) Strain-lateral displacement (B7)  
(f) Strain-lateral force (B7)

Figure 4 Strain development of steel bar in C-S12
Strain development

The strain-lateral displacement curves and the strain-lateral force curves of C-S12 at strain gauges B2/B4/B7 are shown in Figure 4. The strain of B2 is kept ‘constant’ (approximately 2550 $\mu$e) after the lateral displacement reached 10 mm, the peak compressive strain decreased with an increase in the lateral displacement, and the compressive strain of B2 was smaller than 1300 $\mu$e during the reversed loading (Figure 4(a)). Before the column cracked, the strain-lateral force curve of B2 was almost linear before the load reached 50 kN (Figure 4(b)), the corresponding lateral displacement was 2.42 mm and the strain of B2 was 345 $\mu$e. After cracking, the strain of B2 increased dramatically with an increase in the lateral load. When the steel bar reached 2000 $\mu$e, the lateral displacement was approximately 6.7 mm. The strain of B4 was approximately 3200 $\mu$e when C-S12 yielded at the member level (Figure 4(c)), and a similar turning point can be found in the hysteric curve of C-S12. The general strain-lateral force relationship of B4 (Figure 4(d)) was similar to that of B2, and the peak strain of B4 was kept constant (approximately 3200 $\mu$e) while the lateral displacement was increasing. Because strain gauge B7 was in the elastic region, the strain kept increasing with an increase in lateral displacement (Figure 4(e)), which indicated that the section moment was increasing. However, Figure 4(f) illustrated that the lateral force was decreasing with an increase in the section moment, and as a result, the incremental moment was partially caused by the P-Δ effect.

Because the strain-lateral displacement/load curves of C-S10B49 and C-S10B85 were similar, Figure 5 only presents the strain development trend of C-S10B49. The B3 strain for C-S10B49 had an almost linear relationship to the lateral displacement (Figure 5(a)), even after the yielding of C-S10B49, whereas the B4 strain for C-S12 presented a ‘yield plateau’ after column yielding. Both strain-lateral force curves of B2 and B3 of C-S10B85 are illustrated in Figure 5(b), the tensile strain of B3 was much larger than that of B2, whereas the compressive strain curves of B2 and B3 were similar to each other. Figure 5(c) and Figure 5(d) present the development trend of the B7 strain for C-S10B49 and C-S12. Because B7 was in the column’s elastic region, the strain was proportional to the section force.

![Figure 5 Strain development of steel bar in C-S10B49](image)

Form the strain-lateral displacement curves of C-S12 (B4) and C-S10B49 (B3), as shown in Figure 5(a), the residual displacement of C-S12 increased with the loading process, whereas the residual strain (B3) and the residual displacement of C-10B49 was close to zero, even when the peak strain of C-S10B49 (B3) reached 7000 $\mu$e.
CONCLUSIONS

Three concrete columns under cyclic loading were tested in this paper. The main parameter was the post-yield stiffness of the longitudinal reinforcement, and the axial compression ratio was 0.11. Conclusions are as follows: (1) the post-yield stiffness of the ordinary RC column was negative, whereas that of the SFCB columns were positive, and the post-yield stiffness can be designed to optimize the FRP/steel ratio in SFCB; (2) the ductility of the SFCB columns was greater than that of the RC column because the load carrying capacity of C-S12 decreased faster for the RC column than the SFCB columns; and (3) the plastic strain of C-S12 was concentrated at the column base, whereas that of the SFCB columns could spread the plastic strain over a longer region and decrease the residual strain after loading, and the corresponding seismic resilience of the structures can be enhanced.

ABSTRACT

Glass FRP (GFRP) panels have been used for structural applications due to their advantages of lightweight, corrosion resistance and construction-easiness. This paper evaluates their seismic performances as wall panels, based on combined shaking table tests and finite element (FE) modeling. A scaled GFRP wall panel was tested on a shaking table subjected to harmonic base motions with frequencies ranging from 10 to 15 Hz. A mass that was twice of the panel’s self-weight was attached to the top of the panel to simulate its supported seismic weight. The panel remained undamaged under a peak base acceleration of 3.5g. Numerical simulation was conducted in Abaqus using Rayleigh damping for comparison with the test results. Good correlations in natural frequency and other dynamic responses were achieved. This research shows good potential of using GFRP panels as seismic-resistant structural members.

FRP, wall panel, seismic behaviour, shaking table test, finite element modeling.

INTRODUCTION

Fiber reinforced polymer (FRP) materials have been widely used in civil engineering field. While they are more commonly used to strengthen existing structures, all FRP structures have been increasingly used in recent years since they are easy to retrofit, can achieve time and labor savings and reduce the self-weight, which allows more design flexibility. While early research work mainly focused on static behavior of GFRP structures (e.g. Clarke, 1996; Davalos et al. 1996), their dynamic behavior has been studied recently mainly through experimental investigations (Boscato and Russo, 2009, 2011, 2012, 2014, 2016), including large-scale space frames (Boscato et al. 2015; Xiao et al. 2016), bridge deck panels (Burgueño et al. 2001; Wight et al. 2006; Alampalli, 2006; Reising et al. 2001), beams (Bank, 1989), etc. However, there is still no study available on the seismic behavior of GFRP panels as load-bearing walls, which is the objective of this study.

In this paper, a GFRP wall panel was tested under harmonic ground motions using a shaking table. The displacements and dynamic characteristics of walls were then correlated with the results from Finite Element (FE) analysis. Both results show that GFRP panels have a potential to be used as seismic-resistant structural members.

Figure 1 Geometry profile of GFRP panel wall
PANEL GEOMETRY AND MATERIAL PROPERTIES

The panel used in this study was a Composolite® building panel provided by Strongwell®. It was 61 cm wide and 122 cm long and made of glass fiber using a pultrusion process. The geometry of the panel is shown in Figure 1. As provided by the manufacturer, the out-of-plane and in-plane moment of inertia were $6.62 \times 10^4$ cm$^4$ and $176 \times 10^4$ cm$^4$, respectively. The thickness of the GFRP panel was 0.297 cm for the outer wall, and 0.218 cm for the separation between the cells.

MATERIAL PROPERTIES

A bending test was conducted to determine the stiffness of the panel. Strain gauges were installed at the mid-span of the simply-supported panel (Figure 2). When subjected to a concentrated load of 454 N at the mid-span, the maximum strain at the tension side of the panel was 83 με. This result correlates well with FE result, where the maximum strain is 87 με. The out-of-plane stiffness calculated from the test result is $1.17 \times 10^9$ N cm$^2$. Based on the deflection reported by the manufacturer for a beam with a 183 cm span, the stiffness $EI$ can be calculated to be $1.23 \times 10^9$ N cm$^2$. Therefore, the material properties provided by the manufacturer can be used in the following analysis, where the elastic modulus and Poisson’s ratio are 18.6 GPa and 0.27, respectively.

A free vibration test was also done to obtain the natural frequencies and damping ratio of the GFRP panel. The bottom of the wall panel was fixed to the ground, and a plastic hammer was used to excite the panel at the top, as shown in Figure 3. An accelerometer and an LVDT were installed at the top of the panel to record its acceleration.
and displacement, as shown in Figure 4a. Using Fast Fourier Transform (FFT) to analyze the displacement data, the first three natural frequencies can be calculated as 12.7 Hz, 31.2 Hz and 39.1 Hz, respectively, as shown in Figure 4b. The damping ratio of the structure can also be determined by computing the percentage of amplitude reduction after a certain number of cycles, which is 0.16. It is relatively large compared to typical damping ratios for reinforced concrete (0.05) and steel structures (0.02).

SHAKING TABLE TEST

The shaking table test setup is shown in Figure 5. The GFRP panel was connected to the shaking table using bolts and angles, which can be treated as a rigid connection. A steel block of 24.5 kg was connected to steel angles, which was firmly bolted to the edges at the top of the panel. The attached mass was to simulate the seismic weight of a flat roof in a typical low-rise building, which includes the total dead load and 20% of snow load. Both tests with and without attached mass were conducted to evaluate the dynamic responses of the wall panel.

The GFRP panel was subjected to harmonic ground motions of 10.1 Hz and 15.1 Hz. Key parameters of the harmonic ground motions in the experiment are described in Table 1. Three accelerometers and LVDTs were installed at the bottom, middle and top of the panel, respectively, in order to measure the panel’s displacements and accelerations in the vibration direction. Since the shaking table is displacement-controlled, the maximum displacements of ground motions under different frequencies were about the same, while the maximum accelerations measured during the tests differed. As a result, although the ground motion displacement and displacement at different locations of the panel was harmonic, as shown in Figure 7, the ground acceleration was not harmonic, as shown in Figure 6. Instead, the maximum acceleration is greater than the average value of peak accelerations for all cycles, as can be seen from Figure 6.

Figure 5 Shaking table test setup

Figure 6 Acceleration of 15.1 Hz ground motion

a) 10.1 Hz ground motion b) 15.1 Hz ground motion.
TEST RESULT AND ANALYSIS

Figure 7 shows the displacements at the top of the wall panel when subjected to different ground motions provided by the shaking table. Since the shaking table movements are nearly the same under all frequencies as explained above, the deformation of the wall panel can be represented by the displacement at the top of the wall. Since the hollow sectioned GFRP panel is light, the deformation of the wall panel can be represented by the displacement at the top of the wall.

Since the hollow sectioned GFRP panel is light, the displacement at the top of the wall panel is close to that from the ground motion when only the wall panel was tested. In contrast, attaching seismic weight to the wall panel can significantly increase the top displacement, which is about twice of the displacement of the wall panel without the added mass, as shown in Figure 7(b). The increase of the displacement under 15.1 Hz ground motion is much greater than that under 10.1 Hz ground motion, because 15.1 Hz ground motion provides considerably larger acceleration and is closer to the natural frequency of the wall panel.

The acceleration in the 15.1 Hz ground motion test reached 3.5g. The recorded displacements of the GFRP panel remained unchanged during the whole process, indicating that no damage occurred despite the large shear force induced by the attached seismic weight. The maximum story drift of the GFRP panel was 0.33%, which is smaller than that of steel or concrete structures under the same load, mainly because of the high stiffness provided by the panel’s internal structure and the GFRP material’s ability to remain linear under high strain.

FINITE ELEMENT ANALYSIS

FE models are constructed using Abaqus (v6.14). Shell element S4R is used to simulate the GFRP panel (Figure 8). Boscato and Russo (2009) concluded that, in vibration analysis, GFRP pultruded structural members can be treated as isotropic materials using currently available theories and computational methods. According to the bending test results, the GFRP material is linear elastic with an elastic modulus and Poisson’s ratio of 18.6 GPa and 0.27, respectively. In the FE model, the bottom of the GFRP panel is fixed except the in-plane direction, where in-plane movements are exactly the same as the ground motions used in tests. From the free vibration test, it was found that the damping ratio of the GFRP panel is about 16%, and the first and second natural frequencies are 12.7 Hz and 31.2 Hz, respectively. Linear frequency analysis in the FE model agrees well with the free vibration test, as shown in Table 2.

Rayleigh damping is included in the material properties. The damping ratio for the nth mode can be expressed as:

\[
\zeta_n = \frac{\alpha}{2\omega_n} + \frac{\beta}{2\omega_n}
\]  

Figure 7 Displacement at the top of the wall panel under different frequencies

Figure 8 Mesh of finite element model (with and without mass)
where $\xi_n$ and $\omega_n$ are the damping ratio and natural frequency for the $n^{th}$ mode, $\alpha$ and $\beta$ are Rayleigh damping parameters, respectively. If both the first and second modes are assumed to have the same damping ratio, the coefficients can be calculated from Eq. 2, with the results shown in Table 3.

$$\alpha = \zeta \frac{\omega_1 \omega_2}{\omega_1 + \omega_2}, \quad \beta = \zeta \frac{2}{\omega_1 + \omega_2}$$ (2)

| Natural frequencies and Rayleigh damping parameters used in FE model |
|--------------------------|-----------------|-----------------|
| damping ratio            | $\alpha$       | $\beta$        |
| 0.16                    | 9.09           | 0.00116         |

The shaking table tests are also modeled using FE method. The errors between test and FE results are within 13% and 12% for the cases with and without attached mass (Figure 9). The error is probably because the out-of-plane displacements could occur in the shaking table tests, which is not considered in the FE model. The FE result also validates that the GFRP panel was intact during the testing.

![Figure 9. Dry wall 10.1 Hz FE simulation results](image)

**CONCLUSIONS**

Based on this study, the following conclusions can be drawn:

1. The GFRP panel in the shaking table tests exhibited good resistance to seismic load due to its high strength and stiffness despite the high intensity of input ground motion, indicating that GFRP panels have a potential to be used as seismic-resistant structural walls in low-rise buildings.

2. FE model can successfully predict natural frequencies and displacements of the GFRP panel in the tests using Rayleigh damping and assuming that GFRP material is linear elastic.

Based on the promising results from this study, further research will be done to study the performance of GFRP wall panels when they are connected to other structural members in frame structures.

ABSTRACT

To investigate the seismic performance of rectangular reinforced concrete (RC) columns strengthened with carbon fiber reinforced polymer (CFRP), four full-scale rectangular RC columns were tested under combined constant axial load and unidirectional lateral horizontal cyclic load. The constant axial compression ratio for all the columns was 0.4, while the lateral cyclic displacement was applied in strong axis (i.e. 0 degree) and weak axis (i.e. 90 degree) of specimens, respectively. All the specimens have the identical section of 300 mm × 450 mm and cantilever height of 1400 mm. The failure modes, lateral load-displacement responses, ductility were compared and investigated. The test results indicated that the seismic performance of rectangular RC columns could be significantly improved after being strengthened with CFRP, especially in the strong axis direction. The failure mode of control specimen in strong axis was a more brittle shear model, while the strengthened columns exhibited a more ductile flexural mode. The ductility factor of rectangular RC columns was significantly improved in both strong and weak axis directions after being strengthened with CFRP.

KEYWORDS

FRP, rectangular RC columns, strengthening, seismic performance, full-scale test.

INTRODUCTION

The reinforced concrete (RC) rectangular columns are commonly existed in the RC frame structures. As a critical member, the severe damage of the columns under earthquake may lead to the collapse of the whole structure. Also with the modifying of the seismic design code of buildings, the seismic performance of existing RC columns is no longer satisfied the requirements of the current seismic design code. Consequently, there is an urgent needed to improve or enhance the seismic performance of these existing “substandard” RC columns. Externally bonding fiber reinforced polymer (FRP) has been widely used in the seismic strengthening or retrofitting of RC structures in the past two decades. As a result, many studies have been conducted on the seismic performance of FRP strengthened RC columns (e.g. Seible et al. 1997; Iacobucci et al. 2003; Memon and Sheikh 2005; Wu et al. 2008; Ozcan et al. 2008; Realfonzo and Napoli 2009; Gu et al. 2010; Dai et al. 2012; Ma and Li 2014; Cai et al. 2016). However, most of these studies are focus on FRP strengthened small-scale circular or square RC columns. Relatively limited experimental investigations have been conducted on the seismic performance of FRP strengthened rectangular RC columns (e.g. Ilki et al. 2009; Ozcan et al. 2010; Realfonzo and Napoli 2012; Li et al. 2013). All of these limited studies were focus on the principal strong loading direction. The influence of loading direction was not investigated. However, real structures may subject earthquake excitation in any direction. In addition, the limited studies on the RC columns under biaxial or multi-direction lateral loading indicated the loading path has significant on the seismic performance of RC columns, especially for rectangular columns (e.g. Pham and Li 2013; Rodrigues et al. 2013). To the best of the authors’ knowledge, only two experimental studies on FRP strengthened rectangular RC columns have been conducted considering the influence of lateral loading direction (e.g. Dong et al. 2013; Rodrigues et al. 2015). Against this background, this paper presents the experimental study on seismic performance of 4 full-scale rectangular RC columns with and without strengthening by CFRP. The specimens were tested under combined constant axial load and reversed cyclic lateral load in strong and weak direction, respectively. The seismic performance of columns before and after being strengthened was investigated and evaluated by comparing the failure modes, lateral load-displacement hysteretic response and ductility capacity in the strong and weak direction, respectively.
EXPERIMENTAL PROGRAM

Test specimens and materials

A total of 4 full-scale rectangular RC cantilever columns were fabricated and tested under constant axial load and reversed lateral cyclic load. The columns were designed according to the old national seismic design code of China (GBJ11-89), representing the existing substandard RC frame columns. All specimens have the same cantilever height of 1400 mm (from the top surface of footing to central of lateral loading point) and the rectangular cross section of 300 × 450 mm. Eight 20 mm diameter hot-rolled deformed steel bars were adopted for the longitudinal reinforcement which resulted in the longitudinal reinforcement ratio of 1.86%. The plain steel bars with 8 mm diameter were used as hoop steel reinforcement. According to the old seismic design code (GBJ11-89), the potential plastic hinge zones of columns should be strengthened with dense hoops reinforcement. In this study, the hoops dense area was the bottom 500 mm height of the columns. The centre to centre spacing of hoops at the dense and normal area was 100 mm and 200 mm, which resulted in the volumetric hoop reinforcement ratio of 0.6% and 0.3%, respectively. The concrete cover thickness, measured to the outside of the hoops, was 30 mm. The columns were casted in in strong concrete stub footing with the dimension of 1500 × 650× 600 mm to simulate the fixed-end boundary. The dimension and reinforcement details of the specimens are shown in Fig. 1.

![Figure 1 Specimen dimension and reinforcement details](image1)

![Figure 2 Test setup and instrumentation](image2)

All specimens were casted in one batch of ready mixed concrete. The average compressive strength of standard cylinders at the age of 28-day and testing time was 29.1 MPa and 38.2 MPa, respectively. After 28-day standard curing time, two specimens were strengthened with three layers of unidirectional carbon FRP (CFRP) sheet at the potential plastic hinge region. The height of strengthened region was 500 mm which was the same as that of hoop dense area. The corner radius was formed by securing iron sheets at the mode with the constant value of 0.1h (i.e. 45 mm) for two strengthened columns. The measured average tensile strength and elastic modulus of steel reinforcement and CFRP material is shown in Table. 1.

Table 1 Tested mechanical properties of steel reinforcement and CFRP

Test setup and instrumentation

A purpose designed and built loading apparatus was utilized in this test, in which the axial load can be ensured constant and moving with the upper lateral displacement of the specimens. The schematic diagram of test setup is shown in Fig. 2. The second-order effect (i.e. P-Δ effect) could be incorporated and simulated by using this test system. At the beginning of the test, the axial load of 2063 kN corresponding to axial compression ratio of 0.4 was first applied on top of each columns. Then the reversed lateral load was applied by an electro-hydraulic actuator under displacement control mode. Two specimens, with and without strengthened, were tested with the lateral load in the strong axis direction (i.e. 0°), while the remaining two were tested in the weak direction (i.e. 90°). The specimen identification convention utilized in this study was initiated with the letter L, which refers to lateral load.
The following number of 0 or 90 refers to the lateral load direction. The last letter C or R represents the without strengthened control specimens or strengthened (retrofitted) specimens, respectively. Considering the displacement capacity difference between control and strengthened specimens, two different displacement control lateral loading schemes were adopted. For control specimens, the displacement levels were incremented by 4 mm with two cycles per level, except the first level was repeated once only. For the strengthened specimens, the first and second displacement levels were also incremented by 4 mm with and repeated once, while the following levels were increased with the imposed increment of 8 mm and two cycles at each level. The tests were finally stopped when the lateral resistance of the columns reduced to 70% of the tested peak load capacity. The lateral displacement was measured by three linear variable displacement transducers (LVDTs). In addition, two LVDTs (i.e. LVDT 4 and 5) were installed vertically to monitor the potential rotational displacement of the footing, as shown in Fig. 2. The lateral force was measured by the load cell embedded within the actuator.

EXPERIMENTAL RESULTS AND DISCUSSIONS

Test Observations and Failure Modes

The comparison of the typical failure modes of control and strengthened specimens are shown in Fig. 3. For specimens tested in the strong direction, the unstrengthened control column of L0-C exhibited a brittle shear failure mode. The flexural cracks initially formed at the plastic region under the displacement level of 8 mm. With the increase of lateral displacement, the existing flexural cracks kept developing with increasing width and length and extending diagonally and more new cracks appeared. Spalling of concrete cover in the bottom corner area of column at the displacement level of 16 mm was noticed. The column brittle failed at the displacement level of 28 mm. A main diagonal shear crack extending the whole height of the column was finally formed. Severe concrete spalling occurred at the plastic hinge region of column, leading to the total exposure of steel reinforcement in one side. The internal hoops bent outward and longitudinal bars buckled, as shown in Fig. 3 (a).

![Figure 3. Failure modes](image)

After being strengthened with CFRP, the failure of the column (i.e. L0-R) changed to ductile mode. Micro cracks were occurred in the upper unstrengthened area at the displacement level of 8 mm, and kept developing and extending diagonally with the increase of displacement level. With the displacement increased to 24 mm, horizontal cracks on CFRP wraps were first noticed at the height of 150 mm above the footing surface. The width of such cracks increased up to 2 mm with the displacement level increased to 72 mm and the wrapped CFRP locally bent outward. Finally, the CFRP was ruptured at this region with the displacement level increased to 88
mm, as shown in Fig. 3 (b1) and (b2). In this case however, the lateral resistance of the column was not rapid reduced and still remained about 70% of the tested peak load capacity. To further observe the damage of the strengthened area, the wrapped CFRP was removed after test. It was found that the damage level of concrete was significantly confined compared with the control specimen, as shown in Fig. 3 (b3) and (b4). The longitudinal steel bar buckling at the CFRP rupture region was observed (see Fig. 3 (b4)).

The shear span ratio was about 4.67 for specimens tested in the weak direction. Therefore, the control specimen of L90-C finally exhibited flexural failure mode. The concrete surface of column mainly cracked horizontally due to flexural. The concrete spalling and crushing area was concentrated in the bottom 200 mm height of column at the ultimate displacement level of 36 mm, as shown in Fig. 3 (c). The concrete damage area was smaller compared with that of specimen L0-C, and the ductility was increased. The damage process and failure mode of strengthened specimen L90-R was similar with specimen L0-R (see Fig. 3 (d1) and (d2)), but the ductility was reduced. The lateral resistance reduced to about 60% of the peak load at the displacement level of 72 mm. However, no rupture of CFRP wraps was observed and the concrete of the strengthened area was found only slightly damaged after removing the CFRP wraps, as shown in Fig. 3 (d3) and (d4).

**Lateral Load-Displacement Hysteretic Curves**

The comparison of experimental lateral load-displacement hysteretic curves of control and strengthened specimens is shown in Fig. 4. It can be seen that the control specimens tested in strong and weak direction both exhibited poor hysteretic behaviour as observed by narrow hysteretic loops and rapid decrease in lateral load after peak load at small drift ratio. The lateral resistance capacity in strong direction was much larger than that of in weak direction, but the ductility capacity was reduced. After being strengthened with CFRP, the lateral resistance capacity has hardly improved but the ductility and energy dissipation was significantly improved, especially in strong direction (see Fig. 4(a)). The strengthened specimens exhibited much wider hysteretic loops and more gradual post-peak strength degradation response compared with control specimens in both directions. The strengthening technical significantly improved the seismic performance of the rectangular RC columns in strong direction.

![Experimental lateral load-displacement curves](image)

**Figure 4.** Experimental lateral load-displacement curves

**Envelop Curves and Performance Indexes**

The envelop curves of all the specimens obtained from the experimental lateral load-displacement hysteretic curves are shown in Fig. 5. In addition, the performance indexes, such as the strength and corresponding displacement of yield (i.e. \( P_y \) and \( \Delta_y \)), peak (i.e. \( P_p \) and \( \Delta_p \)) and ultimate (i.e. \( P_u \) and \( \Delta_u \)) point are presented in Table 2. The yield point was obtained based on the energy method (e.g. Cai et al. 2016). The ultimate point corresponding to the lateral resistance reduced to 85% of the tested peak load. It can be seen from Fig. 5 and Table 2 that the wrapping CFRP has slight influence on the lateral resistance capacity, but significant effect on the deformation capacity and the strength degradation. The control and strengthened specimens exhibited similar yield strength and displacement. This due to the externally bonded CFRP wraps has almost no effect on the initial stiffness of the strengthened columns. However, the yield displacement in strong direction was smaller than that in weak direction, while the yield strength was larger. The peak strength and displacement were both slightly increased in both directions after being strengthened with CFRP. For example, the peak displacement increased about 11.8% and 4.0% in strong and weak direction, while the increment in peak strength was only about 3.9% and 2.1%, respectively.
The specimens were tested in strong and weak axis direction, respectively. The test results indicated that the seismic performance of rectangular RC columns could be significantly improved after being strengthened with CFRP, especially in the strong direction. The control specimen exhibited brittle shear failure mode and flexure failure mode in strongly and weak direction, respectively, while the strengthened columns exhibited a more ductile failure mode in both directions. The lateral resistance capacity of the columns was slightly improved after being strengthened with CFRP, while the ductility capacity was significantly enhanced, especially in strong axis direction.

**CONCLUSIONS**

This paper has presented an experimental study on the seismic performance of full-scale rectangular RC columns with and without strengthening with CFRP wraps. The specimens were tested in strong and weak axis direction, respectively. The test results indicated that the seismic performance of rectangular RC columns could be significantly improved after being strengthened with CFRP, especially in the strong direction. The control specimen exhibited brittle shear failure mode and flexure failure mode in strongly and weak direction, respectively, while the strengthened columns exhibited a more ductile failure mode in both directions. The lateral resistance capacity of the columns was slightly improved after being strengthened with CFRP, while the ductility capacity was significantly enhanced, especially in strong axis direction.

</tbody>
</table>

It was easily noted that the most significant improvement index after being strengthened was the ultimate displacement, especially in strong direction. For example, after being strengthened with CFRP the ultimate displacement increased about 160% in strong direction, while the incensement was about 20% in weak direction. The ultimate drift ratio ($\delta_u$) of control specimen in the two directions was both around 2%, which just met exactly the limit of the ultimate inter-storey drift ratio (i.e. 2%) of RC frame structures specified by the national seismic design code of China (GB50119-2010). While the ultimate drift ratio of strengthened frame was about 2.54 and 1.27 times of the specified ultimate limited value in strong and weak direction, respectively.

The other important performance index is displacement ductility factor ($\mu$), which reflects directly the plastic deformation capacity of structures or members. It can be seen that the ductility factor in strong direction was larger than that of in weak direction for both control and strengthened specimens. After being strengthened with CFRP, the ductility factor was significantly increased in both directions, especially in strong direction. The above discussion again demonstrated that the externally bonded CFRP could effectively improve the seismic performance of rectangular RC columns, especially in strong direction.

ABSTRACT

The rapid construction nature and outstanding self-centring ability make the post-tensioned precast segmental (PTPS) bridge pier a promising alternative to traditional cast-in-place piers. In this paper, PTPS piers reinforced with both steel and fibre reinforced polymer (FRP) bars were numerically analyzed. This type of pier is referred to as a hybrid bars reinforced PTPS bridge pier in this paper. The steel bars which continuously cross the segment joints (referred to as ED bars) were expected to improve the energy dissipation ability of the PTPS piers, while the FRP bars were expected to increase the post-yield stiffness and to decrease the residual displacement. Monotonic and cyclic analyses on hybrid bars reinforced PTPS piers were subsequently conducted. Three parameters were investigated, namely, the mechanical properties of FRP bars, the FRP bar reinforcement ratio and the proportion of FRP bars to ED bars. According to the analysis results in this study, the FRP bars are effective on improving the self-centring ability of the hybrid bars reinforced PTPS piers.

INTRODUCTION

The post-tensioned precast segmental (PTPS) bridge pier is attractive due to its accelerated construction nature and the self-centring ability. As illustrated in Figure 1(a), this type bridge pier is constructed by assembling precast concrete segments with post-tensioned tendons. Ou et al. (Ou et al. 2007) proposed to reinforce the PTPS piers with longitudinal steel bars which continuously crossed the segment joints (referred to as ED bars). The investigations on such ED bar reinforced PTPS piers indicated that the hysteretic energy dissipation ability of the piers increased significantly with the ED bar reinforcement ratio (Bu et al. 2012; Ou et al. 2007; Wang et al. 2008). Furthermore, their researches also showed that the ED bar ratio should be no larger than 0.5% in order to maintain the proper ductility and to avoid over-deformation. In order to further improve the energy dissipation ability of the PTPS piers, steel and FRP bars were simultaneously used to reinforce the piers in this paper. The energy dissipation ability of the hybrid bars reinforced PTPS piers is in the focus of this paper. In order to evaluate the energy dissipation ability of the hybrid bars reinforced PTPS piers, monotonic and cyclic analyses were conducted.

to maintain negligible residual displacement (Ou et al. 2007). However, such an upper limit is even smaller than the specification on the minimal steel reinforcement ratio for cast in place bridge piers according to the Guidelines for Seismic Design of Highway Bridges of China (MTPRC 2008). In spired by the concept of ED bar reinforced PTPS pier, the hybrid bars reinforced PTPS piers were proposed by the authors of this paper. As shown in Figure 1(b), both the ED bars and the fibre reinforced polymer (FRP) bars are adopted in this new type of pier specimen. The ED bars were expected to improve the energy dissipation ability of the PTPS piers, while the FRP bars were expected to increase the post-yield stiffness and to decrease the residual displacement. These longitudinal bars can be used in the potential plastic hinge region only in order to make this type of pier more cost-effective. In order to validate the concept of the hybrid bars reinforced PTPS pier, both pushover and cyclic analyses were conducted in this study.

SIMULATION OF THE HYBRID BARS REINFORCED PTPS PIERS

Finite Element Model

The proposed hybrid bars reinforced PTPS pier was modelled with OpenSees program, which is an open source, objected-oriented software framework (McKenna 1997). Each pier segment was simulated by one force-based beam-column element with 5 Gauss-Lobatto integration points uniformly distributed along the element (Neuenhofer and Filippou 1997). The zero-length element with a fibre section was adopted to model the behaviour of the segment joint (Zhao and Sritharan 2007). This element can take into consideration the bond slip of ED bars at segment joints by using the Bond_SP01 material of OpenSees. Note that this kind of bond slip is caused by strain penetration, instead of anchorage failure (Sritharan et al. 2000). According to Sun (Sun et al. 2014), the strain penetration effects of a composite bar made with FRP skin over a steel rod can also be approximately modelled with Bond_SP01 material. Therefore, this material was adopted in this study to consider the strain penetration effects of the FRP bars as well. Accurate stress-slip relationship of the FRP bar can be established by pull-out tests; however, such experimental investigation is beyond the scope of this paper and will be conducted in the future. A truss element which can incorporate the geometric nonlinearity was used to model the un-bonded post-tensioned tendons. Concrete02 material (Yassin 1994) and Steel02 (Menegotto and Pinto 1973) material were used to model the concrete and ED bars, respectively. It is worthy to note that the tensile strength of the concrete fibre in the joint section was defined as zero. FRP bars were modelled with uniaxial elastic material which can take into consideration the differences of mechanical properties between tension and compression. For simplicity, the elastic modulus and strength of FRP bars in compression were defined as 50% of those in tension in this study (Mohamed et al. 2014; Tavassoli et al. 2015).

Model Validation

Two sets of quasi-static tests available in the open literature were utilized to validate the finite element model of the hybrid bars reinforced PTPS pier. Three ED bars reinforced PTPS pier specimens, tested by Ou et al. (Ou et al. 2010), together with another three column specimens reinforced with both steel bars and FRP bars, tested by Ibrahim et al. (Ibrahim et al. 2015), were simulated with the aforesaid fibre model. The predicted hysteretic curves were compared with the experimental results. Due to space limitation, only two comparisons were shown in Figure 2. As shown in this figure, the simulated cyclic behaviours compared well with the tested results, implying that the numerical model used in this study was reasonably accurate.

Figure 2 Comparison of predicted hysteretic curves with test results
Parametric analysis was then carried out in order to investigate the seismic performance and the self-centring ability of hybrid bars reinforced PTPS piers. A prototype cantilever PTPS pier was designed. As shown in Figure 3, the height and the diameter of the prototype cantilever pier were 9.0m and 1.5m, respectively, resulting in a shear span ratio of 6. The PTPS pier consisted of 6 segments with the same height of 1.5m. The superstructure gravity load was 0.05$f'_cA_g$, in which $f'_c$ was the cylinder strength of the unconfined concrete and $A_g$ is the cross sectional area of the pier. In addition, the post-tensioning force was 0.05$f'_cA_g$ as well (Bu et al. 2012). The hoop reinforcement volumetric ratio for all the segments was approximately 1.0%. The variation in the mechanical properties of FRP bars, the reinforcement ratio of FRP bars $\rho_{FRP}$ and ED bar ratio $\rho_{ED}$ is shown in Table 1. Therefore, there were $2 \times 4 \times 4 = 32$ specimens in total analysed in this study. Note that the mechanical properties of BFRP bars and CFRP bars in this table were extracted from experimental investigations of Ibrahim et al. (Ibrahim et al. 2015) and Mohamed et al. (Mohamed et al. 2014), respectively.

![Figure 4 Comparison of pushover curves of hybrid bars reinforced PTPS piers and ED bar reinforced ones](image)

**Pushover analysis results**

The aforesaid 32 specimens were firstly analysed under monotonic displacement. Due to limited space, Figure 4 only presents the pushover curves for the eight specimens of which the ED bar ratio $\rho_{ED}$ equalled to 1.0%. BFRP bars and CFRP bars were used in the specimens of Figure 4(a) and (b), respectively. The ultimate point in this study is defined as the drift ratio at which the FRP bars reached the ultimate tensile strain $\varepsilon_u$ and broke, or the drift ratio at which the lateral resistance degraded to 85% of the lateral load capacity. From this figure it is evident that
the FRP bars in the hybrid bars reinforced PTPS piers are very effective on increasing the lateral load capacity and the lateral stiffness after the specimens yield.

The influences of the FRP bars on the post-yield stiffness of the hybrid bars reinforced PTPS piers were further investigated. In this study, the post-yield stiffness ratio $r$ is defined in the following equation:

$$r = \frac{P_{\text{max}} - P_{\text{yield}}}{D_{\text{yield}}} \cdot \frac{D_{\text{yield}} - D_{\text{max}}}{P_{\text{max}} - P_{\text{yield}}} = P_{\text{max}} - P_{\text{yield}}$$

where, $P_{\text{max}}$ and $D_{\text{max}}$ are the lateral resistance and displacement at the peak point of the pushover cure, respectively; while the $P_{\text{yield}}$ and $D_{\text{yield}}$ are the lateral resistance and displacement, respectively, at the yield point defined by the energy method. The post-yield stiffness ratios for all the 32 specimens were shown in Figure 5.

BFRP bars and CFRP bars were adopted in the specimens in Figure 5(a) and (b), respectively. As indicated in this figure, adding additional FRP bars into ED bar reinforced PTPS piers is very effective on increasing the post-yield stiffness ratio. Furthermore, it can be found by comparing Figure 5(a) and (b) that, FRP bars with higher elastic modulus are more effective to improve the post-yield stiffness ratio. In addition, Figure 5 shows that the post-yield stiffness ratio of hybrid bars reinforced PTPS piers increases with the proportion of FRP bars to ED bars.

Cyclic analysis results

Residual drift ratio

Based on the pushover analysis results, the CFRP bars of all the hybrid bars reinforced PTPS pier specimens broke at drift ratios smaller than 4%. Therefore, only BFRP bars were used in the cyclic analysis. A total of 16 specimens were analysed under lateral cyclic displacement excursions up to 4% drift ratio with an increment of 0.5% drift ratio. In order to illustrate the differences in lateral cyclic behaviour between the hybrid bars reinforced PTPS piers and the ED bar reinforced ones, four specimens were chosen as examples and their hysteretic curves were plotted in Figure 6. It is evident from this figure that reasonable amount of FRP bars is very effective on decreasing the residual drift ratios of the PTPS piers. Here, the residual drift ratio is defined as the ratio of the residual displacement to the height of the PTPS pier.

In order to systematically investigate the effect of FRP bars on decreasing the residual drift ratio of hybrid bars reinforced PTPS piers, the residual drift ratio to the loading drift ratio curves for all 16 specimens were plotted in Figure 7. For the four specimens in each of the Figure 7(a) ~ (d), the ED bar ratios were identical while the FRP
bar ratios were variable. It can be drawn from the Figure 7 that if the ED bar ratio of a PTPS pier is no larger than 1.5%, reinforcing with additional FRP bars was very effective on reducing the residual drift ratios.

![Figure 7 Residual drift ratio of hybrid bars reinforced PTPS piers](image1)

**Cumulative hysteretic energy dissipation ability**

Cumulative energy dissipation is an important indicator of seismic performance of a structural member, as insufficient energy dissipation may lead to overlarge displacement demand of structures in earthquake disasters. Therefore, cumulative energy dissipation at the end of cyclic analysis $E_d$ of all specimens was calculated and plotted in Figure 8. The analysed specimens were separated into four group based on the ED bar ratio (ranging from 0.5% to 2.0%) and each group consisted four specimens with variable BFRP bar ratio (ranging from 0% to 0.8%). As shown in this figure, the cumulative energy dissipation $E_d$ for the four specimens in the same group was generally the same. This result indicates that the energy dissipation ability of the hybrid bars reinforced PTPS pier is comparable to its ED bar reinforced counterpart.

![Figure 8 Cumulative energy dissipation of hybrid bars reinforced PTPS piers](image2)

**CONCLUSIONS**

This paper presented a numerical analysis on the hybrid bars reinforced PTPS bridge pier, i.e., the pier reinforced with both FRP bars and steel bars. Based on the analysis results presented herein, the following conclusions can be drawn:

1. The FRP bars in the hybrid bars reinforced PTPS pier were very effective to improve the lateral load capacity and the post-yield stiffness ratio. This improvement would be even more evident if FRP bars with higher elastic modulus were used.
2. Increasing the proportion of FRP bars to ED bars would increase the post-yield stiffness ratio of hybrid bars reinforced PTPS piers.
Comparing to the ED bar reinforced PTPS pier counterparts, the hybrid bars reinforced piers exhibited smaller residual drift ratio and similar cumulative hysteretic energy dissipation.

The focus of the current study was to numerically validating the concept of hybrid bars reinforced PTPS piers. Further experimental validation and systematic analysis are also under way.

ABSTRACT

Loads of explosion, either within or adjacent structures, have rapid transient nature and the potential to cause collateral damage and casualties could be considerable. Dynamic load at high strain rates, such as the explosion, changes in the mechanical properties of materials depends on the strain rate and the probability of failure mode from ductile flexural failure mode under static and quasi-static loading to brittle shear mode under dynamic load. Therefore, taking into account the considerations in the analysis and design of structures and components, providing safe and economic solutions for efficient operation of the structure and its components is important in their lifetime. In recent years, the use of fiber-reinforced polymers (FRP) is a common technique in order to retrofit and rehabilitation of reinforced concrete structures and other structures. In this paper, the behavior of reinforced concrete beams retrofitted with FRP fabrics subjected to blast loading is investigated. In this regard, first with the finite element method and the help of software modeling in LS-DYNA results in order to validate the results of the laboratory studies were compared. Then, with the development of numerical models the effect of parameters such as the type of retrofit, fiber, and explosive intensity, and reduce the use of FRP materials in order to strengthen economic plan, on response of beam in terms of displacement, crack pattern and failure mode, ductility and energy absorption is studied.

INTRODUCTION

Previous studies focused on flexural members of reinforced concrete under blast loading through experimental, analytical and numerical methods. Experimental studies in this field are limited due to high cost and other restraints. Concrete slabs reinforced with FRP composite layers experimentally examined under blast load. The results indicated that FRP-reinforcement can improve performance and expand the load bearing capacity of slabs under blast load (Razaqpur et al. 2007; Silva and Lu 2007; Kim et al. 2009; Tanapornraweekit et al. 2010; Orton et al. 2013). The behavior of concrete beams experimentally and numerically examined under blast loading. Concrete beams designed to fail in flexure may fail in a shear mode when loaded dynamically (Magnusson et al. 2010I, 2010II; Morales Alonso et al. 2013). Also, reinforced concrete beams analytically studied under blast load. The results indicated that using approximated and simplified methods such as a one-degree-of-freedom system can provide smaller amounts of stress than reality (Hamed and Rabinovitch 2005; Carta and Stochino 2013). In this paper, the control samples are constructed according to laboratory research data by Magnusson et al. (2010) and Tanapornraweekit et al. (2010). The numerical models are constructed based on finite element method through LS-DYNA software (2012). After validating the results of the numerical models, the behavior of reinforced concrete beams retrofitted with FRP fabrics subjected to blast loading is investigated.

Validation OF NUMERICAL MODEL

According to our literature review, no research was found on retrofitted RC beams by using FRP against blast loading. On the other hand, experimental research has been carried out on FRP retrofitted RC slabs. So, in this
paper, validation is limited to two parts. First, unstrengthened RC beams under blast load and second, strengthened RC slabs under blast loading. Table 1 shows definition of tested specimens.

Magnusson et al. (2010) experimentally assessed B40 beam under blast load. The beam dimensions and its reinforcement have been illustrated in Figure 1. Figure 2 shows pressure-time history that measured during the test.

![Figure 1 Dimensions and reinforcement of the concrete beam. Dimensions in mm](image)

![Figure 2 Reflected pressure applied in the analysis of the beam (Morales Alonso et al. 2013)](image)

![Figure 3 Dimensions and reinforcement of the concrete slab. Dimensions in mm](image)

Tana Pornraweekit et al. (2010) performed the laboratory research that involved an unreinforced C3 slab and reinforced G-2S-1L slab with a GFRP layer on both sides of the slab. The slab dimensions and its reinforcement have been illustrated in Figure 3. Blast loading applied in modeling is extracted from Conwep (2005) as a pressure-time curve derived from 0.45 Kg of TNT at a distance of 0.5 meters from the center of the slab.

The material model used in the software for simulation of concrete is concrete damage Model (072R3). Plastic-kinematic model is adopted for behavior of reinforcement steel. Moreover, composite layer involved composite material model 54 labeled Enhanced Composite Damage. Contact between the concrete and the composite layer is modeled through AUTOMATIC-SURFACE-TO-SURFACE-TIEBREAK. According to experimental data, the concrete compressive strength in the modeling is considered 43 MPa while the steel yield stress is 604 MPa. The concrete compressive strength in the slab modeling is considered 32 MPa while the steel yield stress is 356 MPa.

Figure 4 compares the crack pattern of B40 beam in the laboratory sample and numerical model. Comparison between the midspan displacement and beam support reaction modeled through laboratory samples have been illustrated in Figure 5. Furthermore, the comparison between the displacement results of laboratory and numerical modeling for unreinforced slab and slab reinforced with a composite layer has been shown in Figure 6. The slight difference in the results is due to such factors as uncertainty of behavior modeling and the damage to concrete and blast loading.

![Figure 4 Predicted and Experimental Crack Patterns for B40 Specimen (Magnusson et al. 2010)](image)
PARAMETRIC STUDY

In this paper, calibrated B40 beam in the previous section is retrofitted in flexural and shear terms in different ways and different types of fibers through FRP layers with a thickness of 0.5 mm. Table 2 describes the retrofitted samples, each examined through unidirectional layers of carbon fiber composite (CFRP), glass fiber (GFRP) and Kevlar fibers (KFRP). In the Stirrup Shaped specimens, the middle stirrup has 300 mm length and the other stirrup has 150 mm length in the free span of the beam. The mechanical properties of each unidirectional layer have been illustrated in Table 3.

Maximum peak pressure, time duration, and impulse are the main characteristics of explosions. In this paper also, the intensity of the explosion is investigated. In this purpose, B40 beam is assessed exposure to five scenarios of blast loading with different peak pressure and time duration. For applying the same energy level on specimens the impulse of the explosion is assumed constant and it is equal to 3500 KPa-msec. Blast loading applied in modeling is extracted from Conwep as a pressure-time curve derived at a distance of 3.5, 5, 10, 15, and 20 meters from the explosion source. Figure 7 shows these curves. Then, for critical specimen according to table 2 effect of retrofitting is investigated.

RESULTS AND DISCUSSIONS

Ductility ratio is the ratio of the maximum displacement of the member to member yield displacement. The area under the force-displacement curve is elastic energy absorption until yielding of rebars, while the area under the force-displacement curve is maximum energy absorption until the maximum load, where If the elastic energy absorption is subtracted, plastic energy absorption will be obtained. The force-displacement curve for reference B40 beam and retrofitted beams have been shown in figures 8. For reference B40 beam the ductility ratio, maximum energy absorption, and plastic energy absorption is 9.82, 3040 J, and 2777 J, respectively. Figure 9 shows reduction of these criteria in retrofitted specimens in percent in comparison with B40 beam.

Several laboratory studies have shown that reinforced concrete members going through ductile flexural failure under quasi-static loading might experience brittle shear failure under dynamic loading (Magnusson et al. 2014). Therefore, cracking pattern is predicted in figure 10. According to figure 9, Percentage of the cracked height of retrofitted specimens have been shown in figures 11.
Assessing the intensity of the explosion on the B40 beam indicates that among different explosive loading conditions having the same energy level, the impulsive loading condition with less duration time and high pick pressure, is the most critical one in terms of beam displacement and crack growth (Figure 12(a) and Figure 13(a) ). In these figures, R is the distance from the explosion source in the meter. The effect of strengthening on the response of the beam in terms of crack pattern and displacement have been shown in figure 12 and 13.

CONCLUSIONS

Results show the maximum reduction of displacement in the case of U-shape retrofit mode with carbon fibers. Also, U-shape mode with carbon fibers leads to the most reductions in the growth of flexural cracks as well as flexural-shear cracks along the free span of the beam. Ductility of the beam is reduced in different states of retrofitting, which the greatest amount of ductility reduction is obtained when reinforcement with carbon fibers. Maximum and plastic energies absorbed by the retrofitted beams are decreased in all of the investigated cases. Retrofitting with carbon fibers shows the greatest reduction in the plastic energy absorption, in different states. The retrofit plan of the beam using stirrup shape made of carbon, kevlar or glass fibers leads to the optimum state of strengthening from the viewpoints of ductility and plastic energy absorption as well as Reduce consumption of FRP materials in comparison with the other plans.

Performance in Severe Environments
ABSTRACT

This study aimed to reveal the strengthening effect of an externally bonded fiber reinforced polymer (FRP) sheet for deteriorated reinforced concrete (RC) members. The salt breeze damages RC structures located in coastal areas. Against this background, the authors prepared RC beams having a corroded main reinforcement bar. The corroded bars were simulated by electrolytic corrosion process. The target ratio of corrosion mass loss was 30%. An FRP sheet was then bonded to the lower side of the RC beam for flexural strengthening. Thereafter, the authors conducted a flexural loading test. The test results show that the maximum load capacity after strengthening using an FRP sheet was almost equal to the control beam’s capacity even if damaged cover concrete was unrecovered using section repair. However, the ductility of the beam could not be restored after strengthening. If the cover concrete was repaired, the performance of the flexural behavior after strengthening was recovered to be the same as the control beam’s performance.

Salt attack, FRP sheet, strengthening, cover concrete, section repair.

INTRODUCTION

Reinforced concrete (RC) structures located in coastal areas suffer from reinforcement corrosion due to the salt breeze. Strengthening techniques for reinforced concrete structures damaged by salt have been proposed by many researchers around the world. Against this background, this study will focus on a strengthening technique using a fiber reinforced polymer (FRP) sheet for an RC member damaged by salt. In order to restore an RC member deteriorated due to reinforcement corrosion, the corroded reinforcement bars can be strengthened using splice reinforcement, or the damaged cover concrete parts can be repaired using section padding. However, the cost and effort spent on strengthening and repair is considerable. Therefore, an administrator of a structure needs to decide on the maintenance priority for the RC structure while considering cost limitations. However, if the administrator can identify a strengthening technique to realize a short-term prolongation of the lifetime of the structure, it can be added as a new choice for maintenance. Thus, the authors will discuss the effect of a repaired or non-repaired section patch for strengthening using an FRP sheet bonded to an RC beam deteriorated by salt.

OUTLINE OF THE EXPERIMENTS

All the specimens used in this study are summarized in Table 1. The parameter of the experiment was repair or non-repair of the cover concrete damaged by reinforcement bar corrosion. The FRP sheet was fabricated from carbon fiber (CFRP sheet).

The mixture proportion of concrete for the RC beam is summarized in Table 2. The water-cement ratio was 45%, and the mixed cement was high early strength cement. The compressive strength after a flexural loading test was 42.1 N/mm².

Electrolytic corrosion test

An electrolytic corrosion test was conducted on the RC beams, except for specimen No.1. A schematic view of the test is shown in Figure 2. According to the specifications of the common test, the specified current density was almost 10A/m² after starting conduction. According to that specification, the current density was determined to be 10A/m². An electric current of 0.65A was also applied during the test. To fulfill the target ratio of the corrosion mass loss, the current integration amount and the energizing time was calculated as follows (Tamori et al. 1988):

\[ W = 0.766 \sum (I \times T) \]  

where \( W \) is the amount of corrosion mass loss [g], \( I \) is the electric current [A], and \( T \) is the energizing time [hours].

In order to reproduce the damage of an RC member such as the deterioration period (JCI, 1998), the target corrosion mass loss ratio was set to 30%. The electrolytic corrosion test was conducted for three RC beams prior to strengthening using a CFRP sheet. The test period was approximately 1067 hours (44.5 days).
After the electrolytic corrosion test, deteriorated RC beams were taken out from the submersion tank. One week later, some deteriorated beams were strengthened using a CFRP sheet. The material properties of the CFRP sheets and the section repair material are shown in Tables 3 and 4, respectively. The fiber direction of the CFRP sheet was one-way. The section repair material was ordinary polymer cement mortar, and was a pre-mixed type. In order to realize flexural strengthening, the CFRP sheet was bonded underneath the RC beam. Specimen No.3 was bonded using a one-layer CFRP sheet. The damaged cover concrete of this specimen was not repaired. Details of strengthening method are as follows: 1. The surface of the beam’s bottom was treated with a grinder to remove laitance and corrosion products. 2. Then, the surface was primed with resin. 3. A CFRP sheet was bonded to the bottom of the beam between both supports. The bonded CFRP sheet was 80mm in width and 1220mm in length. In specimen No.3, corrosion cracks had a maximum width of 2.5mm and an average width of 0.7mm. However, in consideration of the convenience of construction work, the crack injection work was not conducted before

strengthening. The damaged cover concrete was repaired using section repair material, as shown in Table 4. The repair method is shown in Figure 3. First, damaged cover concrete was carefully removed by hand using a small chipping hammer. Then, the beam was set to the formwork that was used during beam casting. After that, the beam surface was wetted after the removal of cover concrete. Then, section repair work was conducted. Finally, a CFRP sheet was bonded to the bottom of the beam, as with specimen No.3.

Figure 4 The distributions of the corroded reinforcement bar diameter.

Loading test

A flexural loading test was conducted for all specimens, as shown in Figure 1. The load, deflection at the mid-span, and strain of the sheet were measured using a data acquisition system. The sheet strains were measured every 70 mm.

Measurement of diameters of corroded reinforcement bars

In specimen Nos.2 to 4, the corroded reinforcement bars were excavated after the loading test. Then, the corrosion product was removed by soaking in an aqueous ammonium citrate solution. After that, in order to check the distribution of the corrosion mass loss, the decreased diameter of the reinforcement bar was measured every 25mm. The bi-directional diameters were measured in orthogonality.

RESULTS AND DISCUSSION

Corrosion behavior of reinforcement bars

The average corrosion mass loss ratio of the main reinforcement bar is shown in Table 1. The ratios for specimens Nos.3 and 4 were greater than the target ratio of 30%. The distributions of the corroded reinforcement bar diameter are shown in Figure 4. The non-corroded diameter is plotted in this figure. The diameter of specimen No.2 was unevenly distributed. The declining ratio of the diameter, which was more than 30%, was a maximum for specimen No.2.

Flexural behavior of loading test

The relationships between the load and deflection at the mid-span obtained from loading tests are shown in Figure 5. In addition, the strain distributions of the CFRP sheet are shown in Figure 6. The flexural behavior of specimen No.3, which did not have a repaired damaged cover concrete, is discussed as follows. The relationships for specimen Nos.1 and 2 are plotted in Figure 5. Specimen No.1 was a control specimen, and specimen No.2 had a corroded main reinforcement bar without repairs. Specimen No.1 exhibited flexural compression failure. On the other hand, specimen No.2 failed due to rupture at the corroded main reinforcement bar. The rupture location is indicated by the arrow shown in Figure 4. The bonded sheet of specimen No.3 de-bonded between the mid-span to the bonded end at the ultimate state. The maximum capacity of specimen No.3 was almost the same as that of specimen No. 1. However, the ductility of specimen No.3 decreased more than that of specimen No.1. This is
concerned about the distribution of the decreased diameter of the corroded main reinforcement bar. The diameter of specimen No.3 was greatly decreased near the location at the maximum flexural moment. As shown in Figure 6, the CFRP sheet strain increased near that location. The results of the above discussion suggest the possibility that the reduced ductility cannot be recovered by the strengthening process when the decreased cross-section of the main reinforcement bar is unevenly distributed.

![Figure 5 The relationships between the load and the deflection at the mid-span.](image)

![Figure 6 The strain distributions of the CFRP sheet.](image)

The load-deflection relationship of specimen No.4, which had repairs to the damaged cover concrete, is shown in Figure 5. Specimen No.4 had a bonded CFRP sheet subjected to flexural strengthening. This specimen failed due to sheet de-bonding at the ultimate state. The maximum capacity of specimen No.4 was greater than that of specimen No.1 because the damaged cover concrete was repaired prior to sheet bonding. In addition, the sheet strain of specimen No.4 is shown in Figure 6. The sheet strain increased at the ultimate state. Therefore, the tensile stress of the main reinforcement bar was redistributed to the FRP sheet.

**CONCLUSIONS**

The conclusions of this study are as follows:
1. Reinforced concrete beam specimens, which had a corroded main reinforcement bar, were fabricated. The ratio of corrosion mass loss was almost 30%.
2. The deteriorated beams were strengthened by bonding using a carbon fiber reinforced polymer (CFRP) sheet without repairing the damaged cover concrete. As a result, the ultimate flexural capacity was almost the same as
that of the control specimen. However, the ductility of the retrofitted specimen was not recovered because the cover concrete was still damaged.

3. On the other hand, another deteriorated beam was strengthened by bonding using a CFRP sheet with patch repair of the damaged cover concrete. The ultimate capacity after retrofitting was increased to be greater than that of the control beam.

The results of the above studies suggest that if damaged concrete is not repaired prior to FRP sheet bonding, the ultimate capacity after retrofitting will be almost the same as the initial capacity. However, if the damaged concrete is repaired, a strengthening effect will be achieved. However, the suggestions are based on small-scale beam test. In future work, the author will conduct the large-scale beam test, and then the detail of strengthening effect will be discussed.

ABSTRACT

This paper presents the effectiveness of carbon fiber reinforced polymer (CFRP) sheets on protecting concrete in an acidic service environment. Concrete members constructed in an industrial zone frequently deteriorate and, accordingly, the need for strengthening arises. Concrete cylinders are prepared with and without CFRP-wrapping and are subjected to a 5% concentration of sulfuric acid (H$_2$SO$_4$) for six weeks. Interests include changes in concrete properties owing to the H$_2$SO$_4$ exposure, and the performance of CFRP-wrapped specimens. Various experimental approaches are employed: microscopic imaging, thermogravimetric analysis, infrared spectroscopy, and mechanical loading to failure. CFRP-wrapping retards the chemical interaction between the core concrete and H$_2$SO$_4$, which is active in the case of unstrengthened concrete. According to microscopic examinations, the plain concrete specimens are damaged by H$_2$SO$_4$ at its surface level; however, the CFRP-wrapped concrete is not degraded. This observation is supported by the thermogravimetric analysis in terms of a marginal mass reduction in the concrete with CFRP-wrapping. The strength of the plain concrete decreases by 57% due to the six-week conditioning, which is significant when compared with the strength drop of 23% observed in its CFRP-wrapped counterparts.

KEYWORDS

Axial, CFRP, damage, durability, environmental distress, strengthening, sulfuric acid (H$_2$SO$_4$).

INTRODUCTION

Industrial structures are frequently constructed with concrete. The presence of biogenic bacteria in such a service condition may degrade the performance of constructed members. Sulfuric acid (H$_2$SO$_4$) is widely observed in wastewater plants and sewer structures (Fattuhui and Hughes 1988; Vincke et al. 1999; Idriss et al. 2001). Equation 1 shows the chemical reaction that occurs when concrete interacts with H$_2$SO$_4$, creating gypsum and ettringite:

$$Ca(OH)_2 + H_2SO_4 \rightarrow CaSO_4 + 2H_2O$$

In the United States, an annual budget of $25 billion is required to operate and maintain wastewater infrastructure (O’Connell et al. 2010). It is also estimated that over $390 billion should be spent to repair deteriorated wastewater systems until 2030 (Gutierrez-Padilla et al. 2010). Because of this practical significance on acid-induced damage, active research has been conducted. Durning and Hicks (1991) examined the behavior of concrete subjected to several detrimental chemicals, namely, acetic acid (CH$_3$COOH), sulfuric acid (H$_2$SO$_4$), formic acid (HCO$_2$H), and phosphoric acid (H$_3$PO$_4$). The calcium silicate hydrate paste of concrete led to an increase in durability under these chemical exposure circumstances. Bassuini and Nehdi (2007) studied the effect of sulfuric acid on the performance of self-consolidating concrete. Differential scanning calorimetry and X-ray power diffraction were used. The integrity of the concrete was enhanced by adding steel and polypropylene fibers. The mass loss of concrete was not directly related to the loss of its load-bearing capacity. Monteny et al. (2003) cast concrete with various admixtures (e.g., superplasticizers, blast furnace cement, polymer, and silica fume), and exposed the concrete specimens to H$_2$SO$_4$. The performance of the concrete mixed with blast furnace cement was the best, whereas that of the concrete with silica fume was the worst.

Despite a wide variety of research endeavors, effective methods are still incomplete to extend the service life of constructed concrete structures in industrial regions. It appears that adding admixtures may have limited efficacy, since calcium hydroxide in concrete chemically reacts with H$_2$SO$_4$. A fundamentally different approach may
resolve current concerns. This paper discusses the potential of CFRP sheets to upgrade the capacity of constructed concrete members suffering sulfate-induced damage and, at the same time, protects the concrete, so that the members’ service life can be improved. An experimental program is conducted to chemically and mechanically examine the behavior of CFRP-wrapped concrete immersed in an H$_2$SO$_4$ solution.

**RESEARCH SIGNIFICANCE**

Sulfate-induced damage is a critical problem in industrial structures (e.g., concrete columns are directly exposed to chemicals in a sewer system). As such, constructed members deteriorate and need rehabilitation. CFRP strengthening is a proven technology with numerous advantages. Existing research encompasses a wide range of scopes from mechanics-oriented investigations to durability observations. To the best knowledge of the authors, no research has been conducted to evaluate the performance of CFRP-confined concrete when exposed to acidic environments. Given that CFRP-strengthening can likely be used for industrial structures, this research gap needs to be filled.

**EXPERIMENTAL PROGRAM**

**Materials**

Twelve concrete cylinders (100 mm in diameter and 200 mm in height) were cast in the laboratory to have a specified compressive strength of 20 MPa: Type III cement (500 g), water (250 g), fine aggregate (811 g), and coarse aggregate (1,700 g) per cylinder. Upon completion of moisture curing, six cylinders were wrapped with CFRP sheets. The CFRP has a nominal tensile strength of 3,800 MPa with a modulus of 227 GPa, based on its equivalent fiber thickness of 0.165 mm. The bonding agent used was a two-part epoxy, consisting of a hardener and a resin to be mixed at a ratio of 1:3 by weight. CFRP and epoxy coupons were prepared to examine the effect of H$_2$SO$_4$ exposure (to be explained). According to the manufacturer’s guidelines, the CFRP-wrapped cylinders were cured for seven days. The top and bottom surfaces of each cylinder were sealed using the epoxy to avoid direct exposure to H$_2$SO$_4$ (Figure 1).

**Chemical conditioning**

A 5% concentration H$_2$SO$_4$ solution was made in the laboratory, which is frequently used in accelerated durability testing (McMurry 2012). Two test categories were planned (i.e., plain concrete and CFRP-wrapped concrete). The cylinders and coupons were immersed in the solution, as shown in Figure 1. A pH meter was used to measure the acidity of the solution for six weeks. After achieving the planned six-week exposure period, the specimens were completely rinsed and dried for mechanical testing.

**Mechanical testing**

Two universal testing machines (90 kN and 900 kN capacities) were employed to load the coupons and cylinders, as shown in Figure 2. (loading rates of 2.5 mm/min and 5 mm/min for the coupons and cylinders, respectively). The deformation of these specimens was measured using a non-contact extensometer [Figure 2(a)].

![Figure 1 Test specimens: (a) CFRP and epoxy coupons; (b) prepared cylinders; (c) plain concrete in H$_2$SO$_4$; (d) CFRP-wrapped concrete in H$_2$SO$_4$.](image-url)
Chemical testing

Fourier transform infrared spectroscopy was used to examine the chemical interaction between H$_2$SO$_4$ and the CFRP and epoxy. Wave numbers ranged from 550 cm$^{-1}$ to 4000 cm$^{-1}$, and the specimens’ absorbance was detected at zero and six weeks of exposure. Thermogravimetric analysis was also conducted at elevated temperature from 20°C to 1,000°C to evaluate the decomposition of constituents in the concrete.

RESULTS AND DISCUSSIONS

Concrete deterioration

As the exposure time increased to six weeks, the pH values of the solution increased up to 64% and 197% for the CFRP-wrapped concrete and the plain concrete, respectively. This fact indicates that the plain concrete interacted with H$_2$SO$_4$, whereas the CFRP retarded the interaction between the core concrete and the acid. The plain cylinders were noticeably deteriorated, as shown in Figures 3(a) and (b). By contrast, the CFRP-wrapped concrete merely revealed a change in color [Figures 3(c) and (d)] without damage of the core. The mass-loss of these two test categories was 1% and 7% for the CFRP-wrapped and plain concrete specimens, respectively.

Chemical analysis

Figure 4 shows the results of the Fourier transform infrared spectroscopy for the epoxy and CFRP materials exposed to H$_2$SO$_4$. Although there was no remarkable change in chemical responses (i.e., functional groups), their absorbance was distinct. The C-H stretch of alkanes in the epoxy and CFRP (wavenumber 2850-3000 cm$^{-1}$) increased by 47% and 26% due to the exposure, respectively. The H-C==O:C-H stretch (wavenumber 2695-2830 cm$^{-1}$) increased by 22% in the epoxy and 13% in the CFRP. The -C=C- stretch of alkenes (wavenumber 1620-1680 cm$^{-1}$) increased by 20% and 13% in the epoxy and CFRP specimens, respectively. Other responses such as -C≡X−H: C-H bend of alkynes (wavenumber 610-700 cm$^{-1}$) were also noticeable.

Figure 3 Deterioration of specimens: (a) plain concrete at zero week; (b) plain concrete at six weeks; (c) CFRP-wrapped concrete at zero week; (d) CFRP-wrapped concrete at six weeks
Shown in Figure 5 are the results of the thermogravimetric analysis. The epoxy component in the CFRP composite disappeared at 420°C [Figure 5(a)]. The mass loss of the plain concrete exposed to H₂SO₄ was significant [Figure 5(b)], which is different from the case of the CFRP-wrapped concrete [Figure 5(c)]. These observations corroborate the fact that CFRP-wrapping protected the core concrete, although some acid penetration has occurred through the CFRP.

**Strength variation**

Figure 6 summarizes the capacity of the epoxy, CFRP, and concrete specimens before and after the H₂SO₄ exposure. The capacity of the epoxy was reduced by 60% [Figure 6(a)], whereas that of the CFRP decreased by 23% [Figure 6(b)]. This means that carbon fibers inside the composite played an important role in preserving its strength. At zero-week exposure, the confined concrete showed a 440% higher strength compared with the plain concrete [Figure 6(c)]. This trend was maintained at six weeks with a 600% increase in strength.

**Failure mode**

The failure modes of the concrete specimens exposed to H₂SO₄ for six weeks are illustrated in Figure 7. The failure of the plain concrete occurred owing to the development of a vertical splitting crack [Figure 7(a)], which is different from conventional concrete failure. This reveals that the cohesion characteristics of the cement binder were deteriorated by the acidic exposure. The strengthened concrete failed by typical CFRP rupture [Figure 7(b)], without showing any damage in the core concrete according to visual examinations.
Figure 6 Strength variation induced by H$_2$SO$_4$ exposure: (a) epoxy; (b) CFRP; (c) concrete

Figure 7 Failure mode: (a) plain concrete at six-week exposure; (b) CFRP-wrapped concrete at six-week exposure

CONCLUSIONS

This paper has dealt with the performance of CFRP-wrapped concrete subjected to H$_2$SO$_4$, with an emphasis on chemical and mechanical responses. Twelve concrete cylinders (six plain and six CFRP-wrapped specimens), and epoxy and CFRP coupons were immersed in a 5% concentration H$_2$SO$_4$ solution for six weeks, and tested. Below are conclusions from this experimental study:

- The degree of acidity was influenced by the interaction between the plain concrete and H$_2$SO$_4$, in conjunction with a mass loss of 7%. The CFRP-wrapped concrete, however, did not show a noticeable change in pH, which indicated that the CFRP protected the core concrete from the chemical interaction with H$_2$SO$_4$.
- The functional groups of the epoxy and CFRP were not influenced by the acid exposure. Nonetheless, their absorbance degree was altered by H$_2$SO$_4$. According to the thermogravimetric analysis, the integrity of the concrete protected by the CFRP was better maintained in comparison with that of the plain concrete.
- The load-bearing capacity of the epoxy and CFRP was reduced by 57% and 23% due to the exposure, respectively. The capacity of the CFRP-wrapped concrete was 600% and 400% higher relative to the plain concrete specimens at six weeks of exposure to H$_2$SO$_4$. The core concrete protected by the CFRP was undamaged, unlike the case of the plain concrete.

ABSTRACT

This paper studies the flexural behavior of Carbon Fiber-Reinforced Polymer (CFRP)-reinforced concrete beams attacked by acid rain. To this end, an artificial acid rain with a pH level of 1.5 was prepared by mixing sulfate and nitric acid solutions. Three reinforced concrete beams with CFRP applications were constructed and conditioned using the artificial acid rain under different corrosion time (0, 45, 90 days). After conditioning, the concrete strength and corrosion depth were measured by combined ultrasonic-rebound methods. Constitutive relationships of concrete under acidic corrosion were determined. Dynamic tests were applied to estimate the integrity of the beams. Four-point bending tests were performed to investigate the load capacities. The cracks on beams were recorded to analyze their effect on the flexural behavior of CFRP-reinforced concrete beams. Finite element (FE) models were built. The frequency, load-displacement curve, strain and the ultimate strength from FE models were correlated with test results. Both the test and FE results indicate that the failure mode of CFRP-reinforced concrete beam changes from balanced-reinforced beam failure to ductile failure as corrosion time increases.

KEYWORDS

Flexural behaviour, carbon fiber-reinforced polymer, reinforced concrete beams, acid rain, experimental investigation, finite element analysis.

INTRODUCTION

The properties of concrete structures degrade under aggressive environment such as acid rain, which typically has a pH value less than 5.7 (Larssen et al. 1999; Fan et al. 2014; Ernest et al. 2013). At least one fourth of the territory of North America is covered by acid rain (Varma et al. 1990). For example, a rain fall with a pH value of 1.5 was recorded in West Virginia (Keller 2012). The damage caused by acid rain is related to sulfate corrosion and expansive corrosion reaction when sulfide ions are combined with hydrogen ions, resulting in losses of billions of dollars per year in North America (Mansfeld et al. 1988). Therefore, it is necessary to study the mechanism of acid rain attack on concrete structures to minimize its impact. Fick’s II Diffusion Law is typically used for modeling concrete corrosion under acid rain (Tsutomu et al. 2001).

Composite materials such Carbon Fiber-Reinforced Polymer (CFRP) have been widely used with concrete structures over the last two decades due to their high tensile strength, light weight, durability, flexibility, corrosion resistance and ease of installation (Liu et al. 2014; Sen et al. 2015; Ali et al. 2012). Similar to other structures, CFRP-reinforced concrete structures are also attacked by acid rain during their service life (Francois et al. 2013). However, in contrast to extensive studies on reinforced concrete structure, studies on the damage mechanism and process, and loading capacities of CFRP-reinforced concrete structures attacked by acid rain are limited (Haber et al. 2012). Therefore, the degradation mechanism of CFRP-reinforced concrete structures under acid rain needs be investigated, which is the motivation of this study.

In this study, an artificial acid solution with a pH level of 1.5 was prepared by mixing sulfate and nitric acid solutions to corrode the reinforced concrete beams with CFRP applications. Bending load was imposed to the top surface of concrete beams to simulate the coupled acid-load action during conditioning. The concrete strength was
measured by ultrasonic-rebound combined method. Four-point bending tests were performed to investigate the load capacities, including cracking, yielding and ultimate loads; yielding and ultimate deflections; ductility; failure mode; and crack patterns. Finite element models were built. The load-displacement curve, strain and ultimate strength of concrete beams from FE model were compared with those from test results.

**EXPERIMENTAL INVESTIGATION**

**Design of specimens**

The dimension of concrete beams was 1800×120×200 mm$^3$ (Figure 1). Commercial concrete (C40) was used, with mix details shown in Table 1. Longitudinal steels were HRB400 (φ16) hot rolled reinforcing steel, with tensile strengths of 330 MPa. Stirrups were HPB335 (φ6). The concrete cover was 35 mm, a tensile strength of 3400 MPa and an elastic modulus of 220 GPa. The monolayer CFRP was attached to the bottom surface of the concrete beams with u-shaped clamp hoops on both sides (ACI 440. 2R-08, 2008), as shown in Figure 2.

Experimental procedures

The artificial acid rain was prepared in the laboratory to represent the chemical components of acid rain found in China, with a pH value of 1.5 (Hou et al. 2012). The molar ratio of sulfuric and nitric acid was 9:1. Since neutralization reaction occurred when Ca(OH)$_2$ inside concrete reacted with acid rain and nitric acid was volatile, the injection of nitric acid every 8 hours was needed to maintain a constant pH level. Based on relevant standards (ACI 343R-95, 1995), 1% of the ultimate capacity ($P_u$) of concrete beams was added to the top surface as an external bending load, which is shown in Figure 3. Table 2 lists details of experimental conditions.

After the artificial corrosion process was completed, comprehensive ultrasonic-rebound tests were conducted to evaluate the compressive strength of the concrete. Subsequently, an acceleration transducer was attached to the top surface of the beams. Based on the principle of wave propagation, a knock response method was adopted to measure the frequency of the beam. Next, four-point bending tests were performed to investigate the flexural behavior of the damaged beams (ACI 437.2-13, 2013). The experimental setup is shown in Figure 4.

Results and analysis

Test results are listed in Table 3. The relationship between load and deflection of CFRP-reinforced concrete beams are shown in Figure 8. Compressive strengths of concrete decrease as corrosion time increases, where the compressive strengths under 45 and 90 days are 34.1% and 25.3 % lower than that of non-corroded concrete. The frequency of U-3 is 22.9% larger than that of U-1, which indicates that the frequency of CFRP-reinforced concrete beam increases as corrosion time increases. It is similar to our previous results (Fan et al. 2014). This phenomenon can be attributed to the Hydrated Calcium Sulphate (H-C-S) which is the production of sulfate and expansive corrosion when sulfate ions penetrate into cementitious materials. The ultimate strengths of U-2 and U-3 are 4.0% and 6.1% lower than that of U-1, which manifests that the ultimate strength of CFRP-reinforced concrete beam decreases with corrosion time increases. The cracks under different loading levels and the failure mode of the CFRP-reinforced concrete beams are shown in Figure 5. The failure mode of U-1 and U-2 is a balanced-reinforced beam failure, which indicates that CFRP sheet in tensile zone is debonded and concrete in compressive zone is crushed almost at the same time. However, the failure mode of U-3 is more ductile, where concrete in the compressive zone is not crushed when CFRP sheet in tensile zone is debonded.

FINITE ELEMENT ANALYSIS

Constitutive relationships

Mechanical properties of concrete, rebar and CFRP are listed in Table 4. Based on the concentration gradient between the interior and exterior of the concrete samples, $\text{SO}_4^{2-}$ spreads inside the concrete under acid rain. The function of concrete strength at different corrosion time can be expressed as:

$$f_e(t) = f_0 - k f_0 \alpha (t - t_0)^{-3} \sum_{n=1}^{\infty} \frac{(-1)^n}{n^3} \frac{n \pi}{R} \sin \left( \frac{e R}{R} \right) \left( \frac{-D n^2 \pi^2 t}{R^2} - e \frac{R^2}{R^2} \right)$$

where $f_e(t)$ is the strength of concrete at $t$ days under acidic corrosion, $f_0$ is the initial strength of concrete, $t_0$ is the day when the strength of concrete is the maximum, $k$ is the strength reduction ratio of concrete, $D$ is the damage parameter, and $R$ is the radius of concrete sample. A concrete damaged plasticity model is adopted to simulate cracking propagation until the failure of concrete beams. The yield function is:

$$F(\bar{\sigma}, \hat{\varepsilon}) = \frac{1}{1-\alpha} (\bar{q} - 3 \alpha \bar{p} + \beta(\hat{\varepsilon}^{pl}) \hat{\sigma}_{ms} - \gamma(-\hat{\sigma}_{ms})) - \sigma_{pl}^{t} \leq 0$$

where $\alpha$, $\beta$ and $\gamma$ are dimensionless material constants; $\hat{\sigma}$, and $\hat{\sigma}$ are effective tensile and compressive cohesion stresses, respectively; $\bar{q}$ is the Mises equivalent effective stress; $\bar{p}$ is the effective hydrostatic pressures; and $\hat{\varepsilon}^{pl}$ is strain function which is defined as:

$$\beta(\hat{\varepsilon}^{pl}) = \frac{\bar{\sigma}}{\hat{\sigma}} \frac{(\hat{\varepsilon}^{pl})}{(1-\alpha) - (1+\alpha)}$$

In this study, we assume that the damage only occurs in concrete. The strength of concrete attacked by the acidic corrosion is from comprehensive ultrasonic-rebound tests above.

FEA models

The geometry of the Finite Element (FE) model is shown in Figure 6. The Model has 14400 CPS4R, 1200 S4R elements and 1200 T3D2 elements to represent concrete beam, CFRP sheets and longitudinal rebar, respectively. A displacement was applied on the top of the model.

![Figure 6 FE model](Image)

Results and comparisons

Based on the FE analysis, the frequency and mode of vibration under different modes are obtained. Comparisons of frequency between test and FE results are shown in Figure 7. The load-deflection curves of test and modeling results under different corrosion times are shown in Figure 8. The cracks and plastic strain of CFRP-reinforced concrete beams from both test and modeling results under different corrosion times are shown in Figure 9.

The frequency of the FE model increases as corrosion time increases, which is similar to the test results. However, the frequency of model corroded by 90 days is only 3.3% larger than that of non-corroded model. The load-deflection curves from test and FE results closely correlated with each other, where the ultimate strength of the FE
model decreases with corrosion time increases. The effective plastic strain of the FE model is shown in Figure 9, which represents cracks of concrete beam under compressive load. The result shows that cracks are generated in tensile zone and concrete in compressive zone is crushed, which indicates that failure mode of non-corroded model is balanced-reinforced beam failure. From Figure 9(b), it can be seen that some cracks along the loading direction are obvious in the tensile zone of the FE model. However, crack is not generated in the compressive zone, which indicates that concrete in compressive zone is not crushed. Similar to U-3, the failure mode of the corroded model (90 days) is more ductile.

CONCLUSIONS

From this study, the following conclusions can be drawn:
(1) The frequency of the beam under 90 days’ corrosion is 22.9% larger than that of non-corroded beam, which indicates that the frequency of CFRP-reinforced concrete beam increases as corrosion time increases. The ultimate strengths of beams under 45 and 90 days’ corrosion are 4.0% and 6.1% lower than that of non-corroded beam, which manifests that the ultimate strength of CFRP-reinforced concrete beam decreases with corrosion time increases.
(2) The failure mode of CFRP-reinforced concrete beam become more ductile (corroded by 90 days) compared to the balanced-reinforced beam failure (corroded by 0 and 45 days), which indicates that long-term acidic corrosion has negative effect on the ultimate bending capacity of CFRP-reinforced concrete beam.
(3) Based on the strength from test, constitutive relationships of different materials are determined. The flexural behavior of FE model is similar to the test results. Similar to the test results, the failure mode of non-corroded model is a balanced-reinforced failure. However, corroded model is more ductile.

ABSTRACT

An experimental study was conducted to investigate the axial compressive performance of CFRP-confined concrete after exposure to a cyclic wet-dry environment with 3.5% salt solution. A total of sixty 150x300mm concrete cylinders unconfined or confined with CFRP were tested. The test parameters included the number of wet-dry cycles (0, 60, 120, 240 and 360) and the number of CFRP layers (0, 1, 2 and 3). The results show that the axial compressive strength and hoop strain of concrete confined with three layers of CFRP were reduced by up to 13% and 19% respectively after 360 wet-dry cycles. The ultimate axial strain increased with the increase of the number of CFRP layers, but the effect of the number of wet-dry cycles was insignificant.

INTRODUCTION

Due to aging of existing infrastructures and an increase of natural disasters such as earthquake, there has been an increasing demand to rehabilitate or strengthen damaged/deteriorated concrete structures (Guo et al. 2016). Because of their high strength-to-weight ratios and superior corrosion resistance, fibre reinforced polymer (FRP) composites have been widely used for this purpose. In particular, the use of FRP wrapping has been a very popular research topic for confining concrete to improve its compressive strength and ductility. However, studies on the long-term behaviour of FRP-confined concrete are relatively scarce, which could significantly hinder the application of FRP in structural reinforcement (e.g. Micelli et al. 2015; Eldridge et al. 2014). Hanna and Jones (1997) tested and studied how the compressive strength of glass FRP (GFRP) confined concrete was affected by environmental factors, including humidity, saline environments and different temperature cycles. The effect of wet-dry cycles on the compressive strength of carbon FRP (CFRP) confined concrete have also been studied by a number of researchers (e.g. Toutanji 1999; Toutanji and Deng 2002; Gharachorloou and Ramezanianpour 2010). In addition, Belarbi et al. (2004) and Belarbi and Bae (2007) investigated the effects of freezing-thaw cycles, high-temperature cycles, high-humidity cycles, ultraviolet (UV) radiation and immersion in saline solution on the compressive strength of GFRP and CFRP confined concrete. These tests showed that these environmental factors reduce the compressive behaviour of FRP confined concrete. However, more research is required because the conclusions were drawn based on limited research so are rather qualitative. In particular, the compressive behaviour of CFRP-wraped concrete exposed to cyclic wet-dry environment is still not clear.

In this study, five series of specimens were tested to investigate the compressive behaviour of CFRP-confined concrete after exposing to a cyclic wet-dry environment.

EXPERIMENTAL PROGRAMME

Test specimens and materials
A total of 60 cylinder specimens of 150 mm diameter and 300 mm height were cast. They were divided into 5 series, subjected to 0, 60, 120, 240 and 360 wet-dry cycles respectively. A saline solution with 3.5% salt was used. Each cycle took 24 hours: 16 hour wet and 8 hour dry. The temperature was set at 40°C throughout the wet-dry process. Each series of specimens consisted of four groups of three specimens wrapped with 0, 1, 2 and 3 layers of CFRP respectively. All specimens subjected to the cyclic wet-dry environment had both top and bottom faces sealed with epoxy. All cyclic tests started when the concrete was 28 day old.
The mix proportion and cylinder compressive strength of concrete are shown in Table 1. The CFRP used in this study was UT70-30 unidirectional carbon fibre sheet with a nominal thickness of 0.167 mm for each layer. The stress-strain curves for both CFRP and epoxy resin were tested with seven flat coupons. The results are shown in Figures 1(a) and 1(b) respectively, where CFRP specimens are designated by CRT-n and epoxy specimens designated b ERT-n, here n is the specimen number. The CFRP had a tensile strength of 4569 MPa and a Young’s modulus of 232.0 GPa. The epoxy resin had a tensile strength of 35.5 MPa and a Young’s modulus of 2.48 GPa.

### Instrumentation and testing

The specimens were tested under uniaxial compression in an electro-hydraulic servo test machine MATEST5000 with a capacity of 5000 kN. They were all tested under displacement control with a cross-head displacement rate of 0.18 mm/min. The longitudinal deformation in the middle third of the specimens was measured using two LVDTs. Four 20 mm foil strain gauges were evenly placed around the specimen at the mid-height to measure the hoop strain, as shown in Figure 2.

![Figure 2](image2.png)
**EXPERIMENTAL RESULTS AND DISCUSSIONS**

**Stress–strain relationship**

Figure 3(a) shows the stress-strain curves of the unconfined cylinder specimens after exposure to different numbers of wet-dry cycles. Each specimen is designated by either RT-n-m or WD-n-m, where RT stands for room temperature indoor environment and DW stands for cyclic wet-dry environment, n is the number of CFRP layers and m is the number of wet-dry cycles. “-A” or “-H” are added at the end of the specimen designations, with the former representing axial strain and the latter horizontal (circumferential or hoop) strain. It shows that comparing to the RT specimens the concrete strength initially increased slightly with an increase of wet-dry cycles. As the strength of the RT specimens were measured at 28 days, this should be interpreted that the increase of the strength of concrete was faster due to the increase of age than the reduction due to the effect of wet-dry cycles. When the number of wet-dry cycles continued to increase, the strength slightly reduced as the increase due to aging became less significant.

Figure 3(b), (c) and (d) show the stress-strain curves of CFRP-confined concrete exposed to different wet-dry cycles. Clearly, all the CFRP strengthened specimens had nearly bi-linear stress-strain curves. For specimens strengthened with one layer of CFRP (Figure 3(b)), the number of wet-dry cycles had almost no effects on the stress versus both axial and circumferential strains when the stress is lower (before the CFRP is activated at about 48 MPa). After that, the slope of stress versus both axial and hoop strain curves of the confined concrete gradually decreased with an increase of the exposure cycles (Figure 3(b)). When the CFRP confinement was increased to 2 or 3 layers, the slope of the hardening (second) branch reduced with an increase of the number of wet-dry cycles (Figure 3(c) and (d)).
After 360 wet-dry cycles, the compressive strength of the unconfined cylinders was increased by 9.4% but the ultimate axial strain was reduced by 9.4% and the ultimate hoop strain was reduced by 9.5%. Due to the degradation of mechanical properties of the CFRP, the ultimate compressive strength of CFRP confined cylinders was reduced by 12.1%, 10.8% and 13.9% for specimens wrapped with 1, 2 and 3 layers of CFRP respectively. The corresponding reductions were respectively 11.4%, 2.2% and 4.1% for the ultimate axial strain and 16.8%, 5.2% and 15.6% for the ultimate hoop strain.

**Comparison of the experimental results with model predictions**

The test results are compared with the predictions from the ACI 440.2R-08 (2008) design guidelines, and the Chinese (50608-2010 GB) and Italian (CNR-DT 200/2004) standards as shown in Figure 4. The tested rupture strain of CFRP after applying an appropriate environmental reduction factor from these documents was adopted as the design hoop strain. Figure 4 shows that all the three design provisions especially CNR-DT 200/2004 underestimated the impact of the salt solution environment on the ultimate compressive strength when the cylinders were confined with 1 layer of CFRP. When the concrete was confined with 2 or 3 layers of CFRP, the calculated values of all three codes were conservative compared with the experimental results, but the Chinese code (50608-2010 GB) predictions were more conservative than the other two.

**CONCLUSIONS**

This paper has presented an experimental study on the effect of cyclic wet-dry exposure in a 3.5% salt solution on the strength of CFRP wrapped concrete cylinders. With the increase of the number of wet-dry cycles, the degradation of mechanical properties of concrete confined with CFRP under axial compression increases. After 360 wet-dry cycles, the ultimate hoop and axial strain of the confined concrete with one layer of CFRP decreased by 16.8% and 11.4%, respectively. The reduction of hoop strain would directly affect the ultimate compressive strength of the confined concrete, and the decrease of axial strain would reduce the ductility of confined concrete.
When concrete confined with one layer of CFRP, the design provisions in the ACI, Chinese and Italian design guidelines or standards appear to underestimate the impacts of the salt solution environments on the ultimate compressive strength.

ABSTRACT

This paper presents an investigation on the tensile properties (including tensile strength and Young’s modulus) of BFRP (basalt-fibre reinforced polymer) bars within SWSSC (seawater and sea sand concrete) solution using the accelerated corrosion tests. Three temperatures (room temperature, 40°C and 55°C) were adopted in the testing program. After exposed in SWSSC solution for 21, 42 and 63 days, respectively, each specimen was tested to failure. The test results showed that the tensile strength degradation rates of BFRP bars within SWSSC solution are slightly higher than those under alkaline solution generated from normal concrete at room temperature and 40°C condition, while at 55°C SWSSC solution appears much more aggressive than alkaline solution. The Young’s modulus of all BFRP bar specimens basically keeps unchanged after exposure to SWSSC solution for 63 days. Finally, the prediction of long-term performance of BFRP bars under SWSSC environment at five Australian capital cities is proposed, and the expected time corresponding to the tensile strength retention 50% was conservatively estimated.

KEYWORDS

BFRP bars, tensile properties, sea water and sea sand concrete (SWSSC), long-term performance.

INTRODUCTION

The degradation of reinforced concrete (RC) structures is mainly caused by the corrosion of steel bars inside structures. To overcome this problem, fibre reinforced polymer (FRP) bars are proposed to replace the traditional steel in civil construction due to their excellent corrosion resistance and high strength-to-weight ratio. Recently, basalt fibre reinforced polymer (BFRP) has been developed because basalt fibre possesses higher mechanical behaviour and better chemical resistance than E-glass fibre and remarkably lower production cost than carbon fibre (Lu et al. 2015). Besides, basalt fibre is an environmentally friendly and non-hazardous material as it is directly produced from volcanic rocks without additives.

The increasing use of BFRP bars in construction field necessitates a comprehensive investigation on the durability of BFRP bars under various civil engineering environments. However, only limited works (Wu et al. 2014; Benmokrane et al. 2015) were reported on the long-term durability of BFRP bars. Wu et al. (2014) systematically investigated the durability of BFRP bars pre-exposed to four different simulated corrosion environments (i.e. concrete pore solution, seawater/deicing salt, acid rain and damp environments). The test results showed that the tensile strength retention of BFRP bars after 42-day pre-exposure to alkaline concrete pore solution at 40°C is 88.9%, which is obviously lower than those of BFRP after exposure for the same duration to deionized water, salt and acid environments at 40°C. It was also proved that the sustained loading can effectively accelerate the degradation of BFRP bars in alkaline solution because compared with the case without any pre-loading the tensile load makes the microcracks in the resin matrix easier to initiate.

Compared with the conventional normal concrete, the seawater and sea sand concrete (SWSSC) has a distinct advantage including saving fresh water and river sand (Li et al. 2016). Conventional steel bars can be replaced by BFRP bars to provide internal reinforcement to SWSSC. Very limited work has been done on the durability of BFRP bars under the SWSSC environment (Dong et al. 2016a). To fill this knowledge gap, the tensile properties
of BFRP bars within SWSSC environment were studied, using the accelerated corrosion tests in the present study. In addition, the long-term behaviour of BFRP bars under simulated SWSSC solution was predicted with the Arrhenius relationship model.

EXPERIMENTAL PROGRAM

Materials

The unidirectional BFRP bars with a normal diameter of 6mm used in this research program were identical to those in Wu et al. (2014). BFRP bars were made of continuous basalt fibres (approximately 65% fibres by volume) impregnated in a Bisphenol A epoxy resin using the pultrusion process. The basalt fibres were manufactured by ZheJiang GBF Basalt Fiber Co. Ltd. (Hengdian, China). The fibre had a tensile strength of 3800-4840 MPa, an elastic modulus of 93.1-110 GPa. The epoxy resin was procured from Bluestar New Chemical Materials Co. Ltd (Wuxi China). The reported tensile strength, elastic modulus and elongation of unconditioned BFRP bars were 1398 ± 30 MPa, 46 ± 0.4 GPa and 3.0 ± 0.07% (Wu et al. 2014), respectively.

Simulated Seawater and Sea Sand Concrete Solution

In practice, the BFRP bars embedded in seawater and sea sand concrete (SWSSC) structures can be exposed to moisture, chloride and alkali conditions. The simulated SWSSC pore solution was prepared by mixing: sodium hydroxide (2.4 g/l, NaOH), potassium hydroxide (19.6g/l, KOH), calcium hydroxide (2 g/l, Ca(OH)_2), sodium chloride (35 g/l, NaCl) and distilled water (to make the volume of solution of one litre). The mass concentrations of NaOH, KOH and Ca(OH)_2 were chosen according to Chen et al. (2007) to simulate the normal concrete pore solution. The measured pH of SWSSC solution is 13.5-13.7.

Test Plan

To evaluate the durability of BFRP bars, the tensile tests of reference specimens and exposed specimens were conducted in accordance with ACI-440.3R B.2. The length of the tensile specimen was 760 mm. Each end was coated with silica sands and then placed into 250 mm-long steel tubes grouted with an epoxy resin mortar matrix. Aluminium caps were used to close both ends of the steel tubes and to keep the bar in the centre of the pipe during anchor installation. The reference specimen thus prepared is shown in Figure 1(a). The length of the test section was 260 mm. The test was carried out by gripping the steel tube into the wedges of a Baldwin machine with a capacity of 500 kN. A loading rate of 2 mm/min was adopted and string potentiometers were used to measure the deformation of BFRP bars.

As shown in Figure 1(b), a solution circulating system was designed for the exposure experiment. The middle part of the tensile specimen was inserted inside a 30 mm-diameter and 240 mm-long PVC pipe worked as the container for exposure to the SWSSC solution. Both ends of the PVC pipe were sealed with epoxy adhesive to ensure a perfect closure during conditioning. The SWSSC solution was contained in a beaker with 5 L capacity that was placed in the thermostatic water bath to maintain the temperature. A submerged pump was used to circulate/transport the SWSSC solution through the whole circulating system.

Figure 1 Images of BFRP tensile specimens
Three exposure temperatures (room temperature, 40 and 55 °C) were adopted for the simulated environment. After exposure in SWSSC solution for 21, 42 and 63 days at each temperature, BFRP specimens were removed from the aging system and tested under tension to compare their tensile strength with that of the reference specimen. A summary of the test matrix is presented in Table 1. All the pre-exposure experiments were conducted in the indoor environment. The room temperature of SWSSC solution at room temperature condition during the whole exposure period is monitored as 32.2 ± 1.2°C. Therefore, the “room temperature” in this study refers to 32°C.

### RESULTS AND DISCUSSIONS

#### Tensile Test Results

**Tensile strength retention**

The tested tensile strength of reference BFRP specimens was 1351 ± 74 MPa, which was close to the reported data (1398 ± 30 MPa) in Wu et al. (2014). Corrosion damages were caused by SWSSC and alkaline solution (the later represents normal concrete pore solution) to the BFRP bar. The tensile retention results of BFRP specimens pre-exposed to the two different solutions at different temperatures were compared (Figure 2). The solid lines represent the data for the SWSSC solution, which is compared with the data for the alkaline solution that were extracted from Wu et al. (2014). This shows that the tensile strength of BFRP bars decreases with an increase in exposure period for both solutions at all temperatures, and the degradation was more severe at higher temperatures.

After 63 days of exposure to SWSSC solution at 32 and 40 and 55°C, the tensile strength retention was 92.7%, 81.7% and 26.0%, respectively. After 63 days of exposure to alkaline solution at 25, 40 and 55°C, the tensile strength retention is 94.0% and 84.8% and 68.5%. These data suggest that SWSSC solution has caused more damage to BFRP than alkaline solution, especially at the higher test temperature, 55°C. This phenomenon is mainly due to that SWSSC solution has obviously higher concentration of alkali-ions than alkaline solution that is used in Wu et al. (2014). It was reported (Coricciati et al. 2009) that the crystallographic structure of basalt is made by olivine (single tetrahedron), pyroxenes (linear chain) and plagioclase (tetrahedral space structure). The great reduction in strength is attributed to the breaking of some bonds of the linear tetrahedral chain of pyroxenes during exposure to the aggressive alkaline environment (Coricciati et al. 2009).

![Figure 2 Comparison of tensile strength retention of BFRP in SWSSC and alkaline environments at different temperatures](image)

**Young’s Modulus**

As shown in Figure 3, all the stress-strain relationship curves under different exposure conditions show a lineally elastic behaviour until tensile failure. Failures were typically of brittle nature for FRP bars with unidirectional fibres. In addition, the linear regions of all curves are very close to each other, suggesting a negligible change in their Young’s modulus. This result also indicates that the Young’s modulus of BFRP bars is not affected by
exposure to SWSSC solution. Similar test results for BFRP bars and GFRP bars under various environment conditions were also reported in reference (Robert and Benmokrane 2013; Wu et al. 2014). This is possibly explained by the fact that the modulus of unidirectional FRP bars mainly depends on the modulus of basalt fibre, while the degradation of modulus of basalt fibre under SWSSC solution may not be significant.

Figure 3 Change of stress-strain relationship curves of BFRP exposed to SWSSC solution at different temperatures for various durations

Surface appearance

Figure 4 shows the surface appearance of BFRP specimens that were pre-exposed to SWSSC solution for 63 days at different temperatures. As shown in Figure 4, the surface colour of all exposure specimens changed obviously compared with the reference specimen. Moreover, the severe surface fuzz and porousness occurred clearly for the specimen at 55°C condition. It is believed that the degradation of matrix and fibre-resin interphase were both significant, which was mainly caused by the SWSSC solution attack at high temperature. The surface appearance is also consistent with the tensile strength results.

Figure 4 Surface appearance of BFRP specimens after 63 days exposition to SWSSC solution at different temperatures: (a) reference; (b) 32°C; (c) 40°C and (d) 55°C

PREDICTION OF LONG-TERM BEHAVIOUR

Arrhenius Relationship

The degrade rate can be expressed in the Arrhenius relationship by the following equation (Wu et al. 2014):

\[
k = A \exp\left(-\frac{E_a}{RT}\right)
\]

where \(k\) = degradation rate (1/time); \(A\) = constant of the material and degradation process; \(E_a\) = activation energy; \(R\) = universal gas constant; and \(T\) = Kelvin temperature. The basic assumption of this model is that the single dominant degradation mechanism of the material does not change with time and temperature during the exposure, whereas the rate of degradation is accelerated with the increase in temperature. Eq. (1) can be transformed into:

\[
\frac{1}{k} = \frac{1}{A} \exp\left(\frac{E_a}{RT}\right)
\]

\[
\ln\left(\frac{1}{k}\right) = \frac{E_a}{RT} - \ln A
\]

Eq. (2) shows the degradation rate \(k\) can be expressed as the inverse of the time needed for a material property to reach a given value. Eq. (3) shows the logarithm of time needed for a material property to reach a given value is a linear function of \(1/T\) with the slope of \(E_a/R\) value.
Prediction Procedure

Firstly, the following degradation model was used to define the relationship between tensile strength retention of BFRP bars and exposure time for the accelerated test:

\[ Y = 100 \exp (-t/\tau) \]  

where \( Y \) = tensile strength retention (%); \( t \) = exposure time; and \( \tau \) = fitted parameter.

On the basis of Eq. (4), the fitted curves are shown in Figure 5 and corresponding \( \tau \) values and correlation coefficients (\( R^2 \)) are listed in Table 2. The \( R^2 \) of all the curves are above 0.88.

\[ \text{Figure 5 Fitted curves for tensile strength retention versus time} \]

Table 2 Coefficients of the regression equations in Eq. (4)

<table>
<thead>
<tr>
<th>Temperature (°C)</th>
<th>BFRP bars in SWSSC solution</th>
<th>( \tau )</th>

<td></td>
<td>0.99</td>
</tr>
<tr>
<td>55</td>
<td>46.5</td>
<td></td>
<td>0.99</td>
</tr>
</tbody>
</table>

Secondly, with the regression coefficient \( \tau \) listed in Table 2 the time (\( t \)) needed for the tensile strength retention to reach 60, 70, 80, and 90% at 32, 40, and 55° C were calculated from Eq. (4). Next, Eq. (3) was fitted to those values (\( \ln(1/k) = \ln t \) and \( 1/T \)), and the straight lines were exactly parallel. The slopes of the straight lines \( (E_a/R) \) were 12082 and the correlation coefficients (\( R^2 \)) are all over 0.98. Due to the limited space, the details of fitted curves are not given in this manuscript. Thirdly, based on Eq. (1), the time-shift factor (TSF) for the tensile strength to reach the same value (represented by \( c \)) at temperatures \( T_1 \) and \( T_0 \) can be obtained from the previous Arrhenius plots. The TSF can be expressed as:

\[ \text{TSF} = \frac{t_0}{t_1} = \frac{c/k_0}{c/k_1} = \frac{k_1}{k_0} = \frac{\exp(-E_a/RT_1)}{\exp(-E_a/RT_0)} = \exp \left[ \frac{E_a}{R} \left( \frac{1}{T_0} - \frac{1}{T_1} \right) \right] \]  

In this study, five capital cities located in Australia were chosen to predict the long-term behavior of BFRP. The annual mean temperature of each city is listed in Table 3. According to Eq. (5), the TSF with reference temperatures \( T_0 \) equal to annual mean temperature of each chosen city are calculated and listed in Table 3.

Note: a: annual mean temperature, the average of Annual Mean Maximum Temperature and Annual Mean Maximum Temperature from Australian Government Boricua Meteorology online database. (http://www.bom.gov.au/climate/averages/tables/ca_site_file_names.shtml)

Once the TSF values for 55, 40 and 32 °C were obtained, Figure 5 was transformed into Figure 6 by multiplying exposure times at 55, 40 and 32 °C with corresponding TSF values. Finally, master curves for tensile strength retention versus exposure time at five different cities were obtained by fitting Eq. (4) in Figure 6. From the master curves, the tensile strength retention of BFRP bars in SWSSC solution drops to 50 % after 2.6 years, 6.0 years, 10.0 years, 14.8 years, and 21.0 years at Darwin (27.6°C), Brisbane (21.4°C), Sydney (17.8°C), Melbourne
(15.1°C), and Hobart (12.7°C), respectively. It should be pointed out that this estimation may be conservative. On the one hand, the humidity of the concrete in service condition is obviously lower than that of simulated solution (Dong et al. 2016b). On the other hand, the temperature inside the concrete may be much less than the environmental temperature. More research is needed to clarify this issue.

Figure 6 Master curves of BFRP bars exposed to different annual temperatures in five Australia capital cities

CONCLUSIONS

(1) At room temperature and 40°C, SWSSC solution caused slightly more damage to BFRP bars when compared with the damage caused by alkaline solution generated from normal concrete (Wu et al. 2014). When the aging temperature reaches to 55°C, SWSSC solution was found more severe than concrete-pore alkaline solution.

(2) Nearly no change was found in Young’s Modulus of BFRP bars after exposure in SWSSC solution for 63 days. This is mainly because the modulus of BFRP bars depends on the Young’s Modulus of basalt fibre, while the degradation of modulus of basalt fibre under SWSSC solution may not be significant.

(3) Arrhenius relationship theory was adopted to predict the long-term performance of BFRP bars under SWSSC solution at five capital cities in Australia.

ACKNOWLEDGMENTS

The authors wish to acknowledge the financial support provided by the Australian Research Council (ARC) through an ARC Discovery Grant (DP160100739). The tests were conducted in the Civil Engineering Laboratory at Monash University with help provided by Mr. Long Goh, Mr. Saravanan Mani and Mr. Philip Warnes. We thank Mr. Dong ZhiQiang of Southeast University for his assistance to obtain BFRP bars.

ABSTRACT

In civil engineering, when pultruded carbon fiber reinforced polymer (P-CFRP) laminate-reinforced structures are subjected to fire, the P-CFRP material is simultaneously affected by high temperatures (potentially up to 1200°C) and mechanical loadings. This paper presents an experimental comparison between the thermo-mechanical behaviour and the residual one of P-CFRP material subjected to the temperature levels ranging from 20°C to 600°C. The evolution of the ultimate tensile stress and of the elastic modulus of the pultruded CFRP material as a function of the temperature level has been experimentally identified. The results show a gradual decrease in ultimate stress and in elastic modulus of P-CFRP material as the temperature level rises and the rate of this reduction increases with the rise of this level. The P-CFRP material ultimate stresses obtained from the thermo-mechanical tests are always lower than those obtained from the residual tests for the same temperature level (in particular for temperature levels above 400°C). Additionally, the P-CFRP material failure modes as a function of the loading paths at different temperature levels are also analysed and discussed.

KEYWORDS

Carbon fibre reinforced polymer (CFRP), high temperature, thermo-mechanical behaviour, residual behaviour.

INTRODUCTION

Pultruded carbon fibre reinforced polymer (P-CFRP), a polymer-matrix composite reinforced by carbon fibre, is commonly used in industries such as aerospace, automotive, civil engineering for its high strength-weight ratio, good properties in corrosion resistance and fatigue. In construction industry, CFRP is applied to repair structures or to increase the strength and ductility of concrete structures such as columns beam and slab. When the CFRP reinforcing structures is subjected to fire, the CFRP material is exposed to very high temperature up to 1200°C while undertaking mechanical loading (service load). In the literature, there are few experimental researches which study the residual behaviour of fibre reinforced polymer (FRP) subjected to fire (Adelzadeh et al, 2014 ; Feih et al, 2012; Correia et al, 2010; Foster et al, 2005). There are also much fewer experimental studies regarding the thermo-mechanical behaviour of CFRP at high temperature (Y. C. Wang et al, 2007; K. Wang et al, 2011). Base on discrete testing results from different type of material, there is a proposal evolution for the properties of CFRP at high temperature (Saafi, 2002). As far as the knowledge of author, there is not available comparative study concerning the thermo-mechanical and residual behaviour of CFRP material subjected to high temperature condition. This research is aimed to clarify the difference between two working cases of pultruded CFRP material as well as to develop material property data concerning the variation of strength and stiffness of CFRP at different levels of temperature.

EXPERIMENTAL METHODS

Experimental device

In this research, the used device, called TM20kN-1200C, is a system including three major parts: mechanical part, furnace and laser sensor (Figure 1). The mechanical part (Figure 1a) is a direct tensile machine which can provide axial tensile force up to 20 KN. The furnace (Figure 1b, Figures2) is an oven which can generate high temperature up to 1200°C with the maximum heating rate of 30°C/minute. The third part, the laser sensor (c), includes two laser diodes and two cameras, allows measuring the displacement of the concerned points. When the tested material
is homogeneous as pultruded CFRP, the measurement of the laser sensor can provide the axial strain of the part of the specimen placed in the furnace during the test. During this, via laser sensor, the strain of the material will be observed and recorded. The laser sensor of this machine, placed outside the furnace, is regularly calibrated to ensure their reliability. The development and validation of the laser sensor measurement have been discussed in previous works (T.H. Nguyen et al, 2016). The previous studies show that the laser sensor measurement of the used machine is reliable. This research uses the testing system to study the behaviour of pultruded CFRP material under the effects of thermal and mechanical load. This is very important because when a fire happens, structures like beams, columns, slabs and all the reinforced materials are subjected to the heat and supposed mechanical loads at the same time. The testing system is programmed to control the furnace and the mechanic part at the same time so that the mechanical loading and the heating will act on the sample. All the data including force, temperature and strain will then be collected and analysed to study the actual behaviour of material/structure under different loading paths.

**Experimental specimens**

In this research, the studied CFRP (Sika® CarboDur® S512) is pultruded–carbon-fibre plate and contains 68% of carbon fiber. As in the product’s specification, its tensile strength is 2800 MPa, its tensile modulus is 165GPa. Glass transition temperature, Tg is above 100°C. The CFRP product is provided in the standard rolls of laminate with the dimension of 1.2mm in thickness, 50mm in width and 25m in length. Due to the dimension, capacity of testing system, the CFRP is cut in to dimension: 800mm in length and 25mm in width. In order to effectively transmit the tensile force from the mechanic parts to the CFRP material, two aluminium plates is attached in each end by epoxy (two components with commercial name of Etancol 492). As the product specifications of Etancol 492, its shear resistance, tensile resistance and compression resistance are 15 MPa, 29.5MPa and 83 MPa respectively. However, the smooth surface of CFRP laminate leads to low bond strength of the adhesives. This results in an unexpected mode of failure that is occurred at the anchorage position. There are many types of anchorage systems that have been tried by a large number of studies. There are two reliable methods that are appropriated to be applied on the CFRP specimen. They are expansive cement confined by a circular steel tube that is suitable with CFRP tendon (Y. C. Wang et al, 2007), and the aluminium plates embraced with bolts that is suitable to for specimen in thin plate form. The later form is effectively applied to thin plate textile reinforced concrete (R. Contamine et al, 2011). Therefore, the aluminium plates are required to be embraced to the CFRP to ensure that the failure will occur in the test specimen, not in the anchorage region. In this research, based on the testing capacity of the system, the properties of the adhesive and CFRP material, there are two methods to embrace the aluminium plates, with bolts (Figure 3a) and with clamp (Figure 3b). The first is intentionally applied to samples that are tested at low temperature condition while the latter is expected to work at high temperature testing condition. As the instruction from the producer of Etancol 492, the adhesives will reach 83% of its tensile strength after 3 days that is applied onto the joint. In this research, the minimum duration for this waiting time is 7 days (Figure 4a,b). The samples then are trimmed down as the initial configuration (Figure 4c). The specimen’s width in this research varies from 6mm to 8mm due to the constraints from the testing capacity of the machine and tensile resistance of CFRP laminate.

**Experimental procedure**

In this study, there are used two loading paths: thermomechanical test (TM) and residual resistance one (RR). In the thermomechanical tests, Regime 1 (Figure 5), the temperature rises to desire one ($T_{target}$). Once the furnace temperature reaches the target value, it is then kept constant for one desired exposure duration ($T_w$). The force, applied to the specimen, increases monotonically until the maximum one that the specimen can be resisted ($F_r$).
In this study, direct tensile tests, at different target temperature levels (20°C, 200°C, 400°C, 500°C, 600°C, 700°C) and with a thermal exposure duration of one hour (T_w=1 hour), have been carried on CFRP specimens. There are two or three exploitable tests for temperature levels (20°C, 200°C, 400°C, 600°C) and one exploitable test for temperature levels (500°C, 700°C) (see Tables 3 and 4). The thermal exposure duration (T_w=1 hour) is chosen so that the temperature within the tested material is uniform and the measurement of the axial strain by the laser sensor can be performed (T.H. Nguyen et al, 2016). Indeed, during the raise in temperature of 20°C to the desired temperature level T and the beginning of the temperature exposure duration, there are fumes emitted from pultruded CFRP, that disturb the measurement of material axial strain. The laser sensor is so activated after that the studied material specimen is exposed to a desired temperature during 1 hour and the beginning of the raise of the mechanical loading (see Figure 5). In the residual resistance tests, Regime 2 (Figure 6), CFRP specimens are preheated to the same target temperature levels (T_target) and with the same exposure duration (T_w=1 hour) (the same as the thermomechanical tests). They are then naturally cooled in the furnace until reach the state at ambient temperature. The quasi-static and monotonous mechanical load is then applied to these "cooled" specimens to failure (F_r). With testing regime 1, during the duration that the specimen is exposed to high temperature, the middle part (observing region, Figures 3a,b) of sample is heated while two ends are not. During this time, the condition of observing region and two end-regions are working in different states. During the heating phase and the exposure duration, a small initial tensile force (100 N) is applied on specimen and controlled stable until the end of the exposure duration phase. Thanks to this technical solution, both extremities of the specimens are clamped (restrained) during the heating phase and the exposure duration.

In order to investigate the thermo-mechanical behaviour of CFRP material, it is necessary to measure the strain development of CFRP specimen only in the observing region. However, during high temperature testing condition (700°C, in this research), it is difficult to measure the strain in this position for the insufficient of testing device. In this research, the heating room is closed and isolated. A small rectangular glass window is designed on the side of the heating room, enough for the laser rays to pass through and measure the strain of the CFRP in the observing region (Figure 3a). This allows maintaining the stable and homogeneous temperature inside the heating room even at very high temperature testing condition (up to 1200°C). This system objectively measures the deformation of CFRP in the observing region without directly interact with the sample, which reduces the possibility of distortion.
to the deformation data. For each test, the temperature inside the heating room is continuously measured via three thermocouples at top, middle and bottom positions of the observing region (Figure 3b, Figure 2). The testing program bases on these three temperature data to control the level and the homogeneity of the temperature inside the heating room. During the time the mechanical load is applied, the temperature surrounding the sample is maintained stable and homogenous, same as the level of testing temperature with the regime 1, and at the normal-room temperature with the regime 2.

RESULTS

Figures 7 and 8 present the stress-strain curves obtained with the tests performed on the pultruded CFRP according to the thermomechanical regime (Figures 7) and the residual resistance regime (Figure 8). In these figures, there is one representative “stress/strain” curve for each temperature level. Each representative “stress/strain” curve is chosen among the curves obtained with the tests carried out in the same condition and on different specimens of the pultruded CFRP. The test is terminated when the specimen is loaded to failure. In all test, as intended, the fracture happens in the observing region in the specimen, not in the anchorage with the aluminium plates (Table 1, Table 2, Table 3). The type of failure is various depending on the level of temperature that the specimen is exposed to (Table 2, Table 3). This is because that the polymer matrix is softened between 300°C-400°C, and partly burns at 600°C. At 700°C, the matrix is burnt out after 17 minutes exposing to this temperature. In regime 1, the laser performs reliably in measuring the strain of the specimen even in very high temperature condition (up to 600°C). However, at higher temperature, 700°C, when all the polymer matrix all burns out, there is no flat surface left. This leads the laser device fail to capture the data of deformation.

DISCUSSION

For both regimes, it is clear that the ultimate strength of CFRP material is reduced as long as the temperature level is increased. For results obtained from regime 2 (Figure 9), firstly, it is shown that when the temperature level increases from 20°C to 200°C, the ultimate strength decreases significantly. Between 200°C and 400°C, the
ultimate strength reduces more gradually. From 400°C until 600°C, the ultimate strength decreases steadily. For the thermo-mechanical test, the result of ultimate strength shows the similar reduction trend. These results confirm the general reduction trend that is similar to experimental results obtained in the literature (Y.C.Wang et al, 2007; K.Wang et al, 2011); it is significantly different from the prediction model which shows a linear reduction when the temperature increases from 100°C to 400°C (Saafi, 2002) (Figure 10). Secondly, the results from two regimes also show a reduction in elastic tensile modulus of CFRP when the temperature increases (Figure 11). From 20°C to 200°C, the elastic modulus increases less than 1%. When the temperature increases up to 400°C, this modulus decreases about 10% to that at 20°C. However, at the temperature level from 400°C to 600°C, the elastic modulus decreases significantly from 15% to 70% with regime 2 and 85% with regime 1. There is a small different between these result and experimental results in the literature review (Y.C.Wang et al, 2007), but the difference is significant to prediction model proposed by (Saafi, 2002) (Figure 12). The results from regime 1 show that the mode of failure is depended on the temperature range that CFRP is exposed (Table 2). At 20°C, the CFRP is broken at randomly position in the middle of specimen (failure mode A). With the temperature between 200°C and 400°C, the specimen failure happens in the middle of specimen, however, the plate of CFRP is still able to keep its normal shape (failure mode B). From 500°C to 600°C, the specimen failure happens in the middle of specimens, but the CFRP plate is unable to maintain its normal shape (failure mode C). At temperature that above 700°C, the CFRP is broken due to the burning of all material (failure mode D). These results confirm what have been observed by (K. Wang et al, 2011).
In this study, the tests with regime 2 only show similar in evolution trend of failure mode, however, at 400°C, CFRP has the tendency to failure following mode C (Table 3). In this research, the results show that the value of ultimate strength is always lower than that obtained from residual test at each temperature level (Figure 9). At the temperature from 20°C to 200°C, the ratio of ultimate strength obtained from regime 2 to that of regime 1 is small. However, when the temperature increases to 400°C, the ratio becomes greater and this value is more significant at 600°C (Figure 13). Specifically, when the temperature level increases between 20°C-400°C, the ratio of residual to thermo-mechanical performance is low, it increases from 1 to 1.27. When temperature level increases from 400°C to 600°C, this ratio steadily increases from 1.27 to 4.98. In addition, the elastic modulus obtained from regime 1 is also lower than that of regime 2 (Figure 11). The ratio of elastic modulus obtained from regime 2 to that of regime 1 is small at the temperature below 500°C but becomes greater at higher temperature level than that (Figure 14). Particularly, the ratio of elastic modulus obtained from regime 2 to that from regime 1 is about 1 at the temperature from 20°C to 500°C, but from 500°C to 600°C, it increases from 1.04 to 2.92.

CONCLUSIONS

The aim of this work is to experimentally compare the thermomechanical behaviour and the residual resistance of a pultruded carbon fiber reinforced polymer (CFRP) laminate. The evolution of the ultimate tensile stress and of the elastic modulus of the pultruded CFRP material as a function of the temperature level has been experimentally identified. For the results obtained from the tests, it is clear that the performance of the pultruded CFRP material reduces when the temperature, to which it is exposed, increases. This confirms what have been observed before (Wang et al, 2007; Saafi, 2002). The performance of the pultruded CFRP material during exposing to an elevated temperature levels (in particular for temperature levels above 400°C) is lower than that after cooling to normal temperature. In addition, the failure mode of CFRP material varies depending on temperature level that the material is exposed and the regime that the test is taken. When the temperature level increases, the polymer matrix is burnt with the increase in the ratio of burning part. Therefore, the original carbon fibre loses its skeleton and the failure changes from brittle fibre material to more soften one. In the design of structures incorporating pultruded CFRP strips, the residual properties of CFRP are used as a referent value to estimate the performance of structures in fire. However, the results of this research show that using the thermo-mechanical properties in evaluating performance of the pultruded CFRP material subjected to elevated temperatures will improve the reliability and safety of structures incorporating this material.

ACKNOWLEDGEMENTS

This research has been performed with the financial support of the LMC2 (thanks to its industrial projects) for the experimental works. This research has also been realized with the financial support of a doctoral scholarship from the Ministry of Education and Training of Vietnam. We would like to thank the team of technicians of the Civil Engineering Department of the IUT Lyon 1, University Lyon 1 for their technical support.

ABSTRACT
This paper presents an approach for assessing the remaining strength after fire of bridge decks reinforced with fibre reinforced polymer (FRP) bars. In fire incidents not resulting in bridge collapse, the challenge is to evaluate the remaining strength of the bridge to decide on further use. The approach involves estimation of the temperatures in bridge decks under two potential fire scenarios for bridges. The first scenario considers a hydrocarbon fire as a worse-case scenario underneath the bridge while the other examines a fuel spill burning on the top of the bridge deck. The study considers typical slab-on-girder bridges with either steel or concrete girders supporting an FRP reinforced concrete slab. The thermal model is verified against fire tests that have been performed by the authors on FRP reinforced concrete slabs. Material tests on GFRP bars were performed earlier by the authors and provide a data source that can be used with the numerical thermal analysis shown in this paper to assess the remaining strength of FRP reinforced concrete bridge decks.

KEYWORDS
Fire resistance, FRP bars, bridge decks, finite element analysis, thermal analysis.

INTRODUCTION
Concerns about the durability of coated steel reinforcement and the high cost of stainless steel have increased applications of glass fibre reinforced polymer (GFRP) bars in construction. During the service life of a bridge, fire is one the most severe hazards. For example, between 1980 and 2012, 30 highway bridges collapsed due to fire in the United States (Lee et al. 2013). In the same time period, 20 bridges failed due to earthquakes (Lee et al. 2013). In recent years, rapid development of ground transportation and increasing transport of hazardous materials have raised concerns about significant losses in a fire incident. Fire has become a real concern for bridges where they are a significant component of urban infrastructure (Garlock et al. 2012). Fire may be a more critical incident to consider for bridge components reinforced with GFRP bars since such bars are susceptible to high temperatures.

MATERIAL TESTS
In a recent study, the tensile strength at high temperature of two different GFRP reinforcing bars was investigated (Hajiloo et al. 2015). In addition, the bond degradation of GFRP reinforcing bars at high temperature was studied using standard pullout tests (Hajiloo and Green 2015). While the GFRP reinforcing bars lost a considerable amount of bond strength at elevated temperatures, results of pullout tests on specimens heated and then cooled down to room temperature before loading showed that the bond strength was to some extent recoverable. Figure 1(a) shows the results of residual bond strength tests on a widely used GFRP reinforcing bar in Canada. The rate of increasing temperature was set at 5 °C/min based upon the expected rate of heat increase of FRP bars embedded in concrete. To ensure uniformity in heating, samples were held at the target temperature for 15 minutes. Then, the furnace was turned off and the samples were left to cool down to room temperature before they were loaded to failure. To include the effect of sustained loads during heat exposure, some samples were loaded to the expected service load during the heat exposure. The specimens shown with triangle symbols in Figure 1(a) were subjected to a sustained load of 10 kN during the exposure to the elevated temperatures. The specimens shown with diamond symbols in Figure 1(a) were not loaded during the heat exposure. For the specimens without sustained load, the temperatures were in the range of 115-274 °C at the interface between the FRP bar and concrete. Since these bars were not loaded during the heat exposure, no mechanical damage was observed after heating and the specimens were tested.
after 24 hours to determine the recoverable bond strength. For the specimens with a sustained load of 10 kN, the temperature was limited to 140 °C because the specimens failed when the temperature reached 140 °C during heating exposure. For exposures up to 140 °C, the residual bond strength was at least 60% of the original bond strength.

To assess the remaining tensile strength of the FRP reinforcing bars after exposure to fire, the same type of GFRP bar, which was used in the pullout tests, was tested in tension using a similar heating and sustained loading procedure to that used for the pullout specimens. For the tensile tests, each reinforcing bar was loaded to 25% of its room temperature strength, and then exposed to the specific level of temperature. The recovered strengths of the reinforcing bars for the examined temperatures were all above 50% of their strength at room temperature as shown in Figure 1(b). The remaining tensile strength should be sufficient to resist service loads since most design provisions limit the stress in GFRP bars at service conditions to approximately 25% of their ultimate strength.

Figure 1 Remaining (a) bond strength and (b) tensile strength after exposure to elevated temperature

**NUMERICAL MODELLING**

The fire resistance of reinforced concrete members has generally been assessed with standard fire tests. In this study, a numerical method is employed as an alternative to standard fire tests for evaluating the post-fire remaining resistance of structural members. However, fire test results provide a basis for verification of the numerical modelling (Hajiloo et al. 2016). Numerical modelling of heat transfer facilitates prediction of the performance of FRP bars at different locations in the member in either fire exposed or cool zones. Thermal properties of the concrete are significant factors in the model because they determine the heat propagation along the length and through the depth of the concrete. The numerical analyses were conducted using the finite element computer program ABAQUS (Hibbitt et al. 2014), which is capable of running coupled and uncoupled thermo-mechanical problems. The thermal properties of concrete are defined in several sources such as Lie (1972) and the Eurocode (2004). These two sources define thermal conductivity and specific heat in a fairly similar way except that the specific heat defined by Lie spikes between 400 to 600 °C due to the assumed presence of quartz. Moisture content and aggregate type affect the specific heat of concrete, but the effects of moisture become insignificant when temperatures are greater than 200 °C. The Eurocode has defined a peak value for the specific heat that occurs between 100 and 200 °C depending on the moisture content. For the modelling in this paper, the thermal properties of the concrete were assumed to follow the recommendations of Lie (1972).

Figure 2(a) shows contours of the heat distribution in a FRP reinforced concrete slab (Hajiloo et al. 2016) that was tested under full service load while exposed to the standard ASTM E119 (2015) fire curve. The results show lower temperatures at the supports than in the centre of the slab. In the modelling, the support regions, 200 mm long at both ends of the slabs, were not exposed to heat. Figure 2(b) shows the reliability of the model by comparing the numerical results with experimental measurements (Hajiloo et al. 2016) at several locations throughout the depth of the slab at midspan.
OVERHANGING CANTILEVER PORTIONS OF DECKS

One of the critical locations during a bridge fire is the overhanging cantilever portion of decks reinforced with negative moment GFRP reinforcing bars that are particularly vulnerable to a fire on the surface of the bridge.

Post-Fire Performance for a Fire on Top of the Deck (Pool Fire)

For a case of fire on top of the deck, the overhanging length and half of the interior bay (in total 2.6 m) was considered to be exposed to a pool fire from spilled diesel fuel that would burn for three hours while the vehicle was on the deck. Hayasaka (1997) measured the liquid and pool temperatures for an uncontrolled fuel depth. It was shown that, after ignition, the liquid fuel and the pool heated up, and boiling in the liquid fuel was observed. As a result, the liquid pool temperature remained constant until it suddenly dropped as the fuel burnt out. It was shown that, throughout the boiling phase, the temperature of kerosene remained below 300 °C. In this study, the maximum temperature on the surface of the bridge deck was assumed 400 °C since the fuel would be diesel rather than kerosene.

The temperatures along the top reinforcing bars, which are placed 50 mm deep from the top slab, are shown in Figure 3. Temperatures dropped dramatically at locations away from the spill area. The temperature along the reinforcing bar in the fire exposed zone reached approximately 160 °C after three hours. According to the steady-state bond strength tests, there is a little bond left at temperatures above 150 °C (Hajiloo and Green 2015). However, as long as the FRP bars have continuity into the cool zone, failure due to bond loss would not occur (Nigro et al. 2011; Hajiloo et al. 2016). In the fire-exposed zone, temperatures of 160 °C would reduce the residual tensile strength of the bars by less than 10 % as shown in Figure 1(b). In the cooler anchor zone, the temperatures were predicted to be below 50 °C (Figure 3) and thus no significant loss of residual bond strength would occur as shown in Figure 1(a). Assuming that the bridge deck survives the fire, based on the study of the pool fire on the deck and indications from the material testing (Figure 1), the remaining post-fire strength of the FRP reinforced concrete deck slab should not be affected significantly by this type of fire as long as the FRP bars have continuity into the cool zone. More detailed structural analyses will be needed to confirm this preliminary assessment.

To conduct such structural analyses, the thermal field developed in the bridge deck can be predicted from the numerical analysis presented in this paper considering different fire scenarios. Then, the amount of damage to the reinforcing bars can be assessed based on the available experimental information on the remaining post-fire strength of FRP bars, and thus the overall remaining strength of the bridge component can be estimated. Structural modelling is currently being conducted by the authors to implement this methodology in more detail. In this approach, different configurations of reinforcing bars (e.g., length of reinforcing bars in the fire-exposed area, the development length of the reinforcing bars, and possible splices in the fire areas) are being considered. The continuity of the reinforcing bars into cool zones over the girders is very significant since fire tests (Nigro et al. 2011; Weber 2008; Hajiloo et al. 2016) revealed that bond deterioration and the length of the anchor zone into cooler parts of the concrete control the fire resistance of FRP reinforced concrete flexural members.
Post-Fire Performance for a Fire from Underneath

For a fire from underneath the bridge, the overhanging length to the centreline of the exterior girder is subjected to heat exposure. In this case, a hydrocarbon (tunnel) fire is considered as a worse-case scenario. Most bridges are in open areas and thus the temperatures would not build up to the same degree as they would in a tunnel. Numerical thermal analyses were performed on the overhanging (cantilever) portion of the bridge deck with a 200 mm thickness and a 1500 mm overhanging length from the centre of the steel girder. The hydrocarbon temperature-time curve (European committee for standardization 2002) used in this study is shown in Figure 4(a). For the overhanging portion of the bridge deck, Figure 4(b) shows that a hydrocarbon fire from underneath of the bridge would not increase the temperature in the top layer (150 mm from the bottom of the slab) of the reinforcing bars to more than 50°C and thus the post-fire strength of the bars would not be reduced.

INTERIOR BAY

Thermal analysis for fire in the interior bay showed that both the type of girders (steel or concrete) and the size of girders play a significant role in providing cool zones. For bridges with steel girders, the steel will be severely damaged when the fire temperature exceeds 600°C, and the bridge will fail because of girder failure prior to any strength deterioration of FRP bars.

Figure 5 shows temperatures in reinforcing bars in an FRP reinforced concrete deck on concrete girders 400 mm wide with exposure to a hydrocarbon fire from underneath. The temperature profiles demonstrate that the concrete girder can play a protective role for the FRP reinforcing bars since the temperatures along the bottom bars drop significantly over the girder area thus creating a cool zone to protect the bond strength of the FRP reinforcing bars.
If the FRP bars are continuously extended into the regions over the girders (i.e., all splices over the girders rather than in the spans), then the FRP reinforcement should maintain at least 50% of its original strength after a fire. As previously mentioned, such strength retention should be sufficient for most designs that are governed by serviceability requirements. However, the exposure to fire may change the properties of the polymer matrix in the FRP and thus the long-term properties of the FRP may be affected. More research is needed to investigate such effects.

![Image of FRP bars in bridge deck](image)

**Figure 5 Temperatures along the top and bottom bars due to hydrocarbon fire (Three-hour exposure)**

For the bridge deck with concrete girders, the parts of the deck located over the girders would need to have a sufficiently long cool zone to provide the required embedment length to transfer the forces in the reinforcing bars to the concrete. More research is required to determine the minimum length of this cool zone to provide sufficient embedment.

For a pool fire on top of the deck, temperatures will rise around the FRP bars while the deck carries the dead load and live load due to a burning vehicle. For the interior spans, the temperature increases in the top FRP reinforcing bars are not critical because the bottom layer carries the forces due to positive moment in the span. For the negative moment area, the forces in the top reinforcing bars due to dead and live loads have to be calculated, and strength of the FRP reinforced concrete deck can be investigated using the information on residual material properties after exposure to elevated temperatures.

**CONCLUDING REMARKS**

Nonlinear finite element analyses were conducted to provide a preliminary assessment of the post-fire remaining strength of FRP reinforced concrete decks. The modelling showed that the maximum temperatures of the negative FRP reinforcing bars remained around 160 °C due to an assumed pool fire extending into the cantilever portion of the bridge deck. Thus most of the original strength of the deck would likely be recoverable based on the results of residual bond and tensile strength material tests. However, this conclusion was drawn assuming that the pool fire does not spread over the entire deck, and that there is sufficient unaffected length of the FRP reinforcing bars to prevent bond failure. For a fire incident under a bridge, the negative moment reinforcement, which is critical for the overhanging portion of the deck, should not be affected because the modelling showed that the temperatures in these bars remained below 50 °C. Additionally, the results indicated that concrete girders could provide some protection to prevent bond failure of the bottom reinforcement in FRP reinforced concrete decks since the temperatures over the girders were reduced to approximately 50 °C. Finally, these preliminary assessments should be regarded as indications of potential performance of bridge decks after fire scenarios. Additional investigations with more thorough structural analyses and potentially additional fire tests are needed to provide more rigorous conclusions.

ABSTRACT

This paper reports a set of tensile tests of glass fiber reinforced polymer (GFRP) bars after exposure to high temperatures. The effects of both temperature and duration of exposure were investigated. The test results show that the stress-strain relationship of the GFRP bars remained close to linear elastic within the range of the tested temperatures (up to 270°C) but both the tensile strength and the ultimate fracture strain of the GFRP bars reduced gradually as temperature rose whilst the tensile modulus of elasticity was less affected. At 270°C, the vast majority of thermal decomposition was completed within half an hour. The bars had little mechanical strength and stiffness left when the exposure temperature was 350°C. A tensile strength reduction factor for the GFRP bars was proposed for high temperatures up to within 270°C.

Glass fibre reinforced polymer (GFRP) bars, high temperatures, tensile properties, strength reduction factor.

INTRODUCTION

One of the main causes for deterioration of reinforced concrete structures is the corrosion of steel reinforcement bars. FRP bars have many advantages, such as high tensile strength, light weight, excellent corrosion resistance and durability, electromagnetic resistance etc. (Guo 2006). FRP bars may be used in concrete structures either replacing steel bars or as supplementary reinforcements and have been used in many practical applications. There are a wide range of commercial FRP bars available, including GFRP, CFRP and BFRP bars. Among them, GFRP bars are the most commonly used in concrete structures because of its low cost.

The matrix in FRP bars is usually a polymer material, its bond performance usually degenerates quickly when exposed to high temperatures. As the temperature resistance of FRP bars is poorer than that of steel bars, FRP bars are mainly used in concrete structures where no fire resistance is required. This may significantly limit the scope of application of FRP bars (Gao et al. 2008a). The performance of FRP bars in concrete structures is thus of great interest when they are exposed to fire.

Wang et al. (2007) studied the mechanical properties of CFRP and GFRP bars at elevated temperatures. The experimental results show that the stress-strain relationships of FRP bars remained almost linear at elevated temperatures until failure. However, there was a gradual reduction in the failure strength of FRP bars at elevated temperatures. This reduction is almost linear with temperature and the strength reaches zero at about 500°C. Their elastic modulus remained almost unchanged until 300~400°C. As temperature further increases, there was a sharp drop in the elastic modulus. A temperature of about 350°C appears to be critical for the two FRP bars. Correia et al. (2013) performed an extensive study about the tensile, shear and compressive responses of pultruded GFRP plate and I sections at temperatures varying from 20°C to 250°C. The test results showed that the mechanical performance of the pultruded GFRP was severely deteriorated at 250°C, particularly when loaded in shear and compression, owing to the low glass transition temperature of the resin. Yu and Kodur (2014) studied the effect of temperature on tensile strength and elastic modulus of CFRP strips and CFRP rods as near-surface mounted (NSM) reinforcement (but tested bare), within a temperature range of 20 to 600°C. The results showed that both the CFRP strips and rods retained most of their initial tensile strength and elastic modulus up to 200°C. However, these properties degraded significantly beyond 300°C due to the decomposition of the resins. The test data were used to
propose empirical relationships between strength and modulus of NSM CFRP reinforcements with temperature. Lu et al. (2015) investigated the effects of elevated temperature on the mechanical properties of basalt fibre roving and BFRP plates. For comparison, E-glass fiber roving and GFRP plates were also tested under the same conditions. It was observed that as the temperature increased from room temperature to 200 °C, the tensile strength and the modulus of elasticity were reduced by 37.5% and 31% for the BFRP plates, and by 8.3% and 9.7% for the basalt fibre roving, respectively, due to the deterioration of bond between basalt fibres and the epoxy resin matrix at elevated temperatures. After exposure to 120 °C and 200 °C for 4 hours, negligible degradation on the mechanical properties occurred in the BFRP plates, while a reduction in the Weibull shape parameter (m) was found for the basalt fibre roving. Compared to the glass fiber rovings and GFRP plates, the basalt fibre roving and BFRP plates showed much better tensile properties and temperature resistance.

Although there have been valuable investigations on the mechanical properties of FRP bars after high temperature exposure, relevant test data are still scarce for design and for safety assessment of FRP bar reinforced concrete structures exposed to fire. This paper reports the longitudinal tensile performance of GFRP bars after exposure to high temperatures. Test parameters included the peak temperature and duration of exposure.

**DESIGN OF EXPERIMENTS**

**Materials and parameters**

A total of 50 GFRP bars with a diameter of 8mm were tested in this study. The GFRP bars were produced in Shenzhen. The bar specimens were divided into 10 groups, each with five bars providing sufficient data for measuring the scatter. The specimens were tested in two series: one with varying temperature (laboratory room temperature RT, 70 °C, 120 °C, 170 °C, 220 °C, 270 °C and 350 °C) but a constant exposure time of 6 hours, the other tested at a constant temperature of 270 °C but with exposure time equal to 0.5, 1, 3 and 6 hours.

**Specimen design and test procedure**

The tensile FRP bar specimens were designed and prepared according to the Guide Test Methods for Fiber-Reinforced Polymers (FRPs) for Reinforcing or Strengthening Concrete Structures (ACI440.3R-04). Figure 1 shows the geometry of the specimens. The specimens were exposed to higher temperatures in a GWL series high temperature furnace at a heating rate of 5 °C/min. The temperature was kept constant once it rose to the set value. The temperature fluctuation within the furnace was within ±5 °C. The specimens were allowed to cool down to room temperature once the designed exposure time was reached. They were tested at room temperature following ACI440.3R-04 using a 1000kN hydraulic servo controlled universal testing machine. An extensometer with 100mm gauge length was attached to the test specimen to measure the tensile deformation.

![Figure 1 Geometry of tensile FRP bar specimens](image)

**TEST RESULTS AND ANALYSES**

**Failure modes**

The GFRP bars were originally shining black. As the temperature increased, the shininess was gradually lost. The integrity GFRP bars looked intact with bare eyes when the exposure temperature was below 270 °C, but the resin was carbonised and fell off to expose some red-brown basalt fibres with the GFRP bars distorted when the temperature reached 350 °C.

For specimens without temperature exposure, sounds due to fibre rupture were emitted when the tensile load was increased to about 15% of the tensile capacity. The sound intensity increased with the increase of loading. A specimen usually failed accompanied by a loud noise and very rapid drop of loading. The data logger was set to stop collecting data when the load was dropped to 45% of the peak load. As the exposure temperature increased, the emission of sounds was delayed and the intensity was reduced.
All test specimens failed within the test zone. The failure modes of the GFRP bars under tensile test may be classified into: a) “pitting” failure where outer fibres fractured resulting in a pit (Figure 2a); b) fracture failure of fibres (Figure 2b) and c) fibre splitting failure (Figure 2c). All the specimens with low exposure temperature (including those without temperature exposure and those with exposure temperature up to 220°C) failed due to either pitting or fracture. The fracture surface was white for those without temperature exposure or with very low (70°C and 120°C) temperature exposure, it became toast tan when the exposure temperature was 170°C and 220°C. All specimens exposed to 270°C failed due to fibre splitting during tensile tests with floc like loose mahogany fibres exposed (Figure 2c).

Test results

The test results for tensile strength, elastic modulus and ultimate strain of the GFRP bars are tabulated in Table 1. Each group of specimens was designed by G8 representing the 8mm diameter bars, followed by the exposure temperature with RT standing for room temperature, followed by the number of high temperature exposure time.

In Table 1, P, E, f_u and ε_u represent the ultimate load, tensile modulus, tensile strength and ultimate strain respectively.

Analysis of test results

Effect of exposure temperature

Table 2 shows the reduction of tensile strength of the GFRP bar specimens after exposure to different high temperatures. When the temperature increased from room temperature to about 200°C exposure temperature, the tensile strength of the GFRP specimens reduced gradually at a low rate, with the GFRP bar specimens retained about 90% of its original strength at 120°C. When the exposure temperature increased further, the GFRP bar specimens experienced much faster strength degradation. At 350 °C, the tensile strength was reduced sharply by about 77%. Note that strength reduction = (tensile strength at room temperature - tensile strength after high temperature exposure) / tensile strength after high temperature exposure) × 100%. Similar calculation applies to the reduction of modulus of elasticity and rupture strain.

The main reason for this phenomenon may be as follows. When the temperature is lower than the glass transition temperature of the resin which is usually in the range of 50°C to 120°C (Zhang et al. 2010; Firmo et al. 2015), the resin is in a glassy state and its performance is more or less the same with that at room temperature, so the tensile strength of the GFRP bars change little.

When the temperature is higher than the glass transition temperature but lower than the thermal decomposition temperature of the resin, the resin gradually vitrifies as the temperature increases. However, when the temperature decreases to the room temperature again, the vitrified resin will regain its ability to bond fibers, and the glass fibers can still work together to a certain degree, as such the tensile strength of GFRP bars shows only a slight reduction compared to that of room temperature.

When the temperature is higher than the thermal decomposition temperature of the resin, the resin at the surface of GFRP bars gradually oxidizes and decomposes. Even after the temperature decreases to room temperature again, the properties of the resin cannot be restored, resulting in degradation of the bond between resin and fibres. In addition, the tensile strength of the fibers also gradually decreases as the temperature rises (Bisby and Kodur 2005; Wu 2011), leading to a significant reduction of the tensile strength. When the temperature continues to rise, the resin may ignite and those in the GFRP bars will be in a hypoxic state leading to carbonation and decomposition, resulting in complete softened GFRP bars with sharply reduced tensile strength.

Table 3 shows the change of the elastic modulus of the GFRP bar specimens after exposure to different high temperatures, here the negative numbers indicate an increase of the elastic modulus. It is clear that the change of the elastic modulus is very small after exposure to high temperature within the test temperature range. This is mainly due to the fact that the major factor determining the elastic modulus of FRP bars is the fibers not the resin. Within the test range, the elastic modulus of glass fibers change very little after the high temperature exposure because the test temperatures did not reach the softening temperature of the fibers which is usually within the range of 800°C to 1000°C (Gao et al. 2008b).

Correia et al. thought that if a GFRP composite material is heated up to a temperature above the glass transition temperature (Tg) but below the decomposition temperature (Td) and then cooled down, the decrease in the elastic modulus measured during the heating process can nearly recover to the initial value after cooling. This is because the glass transition is a reversible process and the broken secondary bonds within the polymer molecular structure form again after cooling (Correia, et al. 2015; Bai and Keller 2007)

Table 4 shows the reduction of the ultimate strain after exposure to different high temperatures is show. It can be seen that the ultimate strain of FRP bars was gradually reduced with an increase in the exposure temperature. Note that the ultimate strain is the ratio of the tensile strength to the elastic modulus. As the temperature rises, the tensil
strength decreases but the elastic modulus changes very little, so the ratio of them (being the ultimate strain) decreases with the strength.

The effect of duration of high temperature exposure

Figures 4-6 shows that at an exposure temperature of 270°C, the tensile strength and the ultimate strain of the GFRP bars show a downward trend with an increase of the duration of exposure. The strength reduction is especially rapid when the exposure time is 0.5 hours (Figure 4). The elastic modulus after high temperature exposure is overall slightly higher than that at room temperature (Figure 5). This suggests that most of vitrification and thermal decomposition of the GFRP bars occur within the first half hour.

CONCLUSIONS

This paper has presented an experimental study on the effects of high temperature exposures on the tensile properties of GFRP bars. The test results have shown that the tensile strength and the ultimate strain of the FRP bars decrease gradually as the temperature increases. When the temperature is lower than 270 °C, the tensile strength reduction is less than 36%. When the temperature reaches to 350°C, the tensile strength of GFRP bars reduced drastically with only 23% of tensile strength at room temperature retained. The effect of high exposure temperature on the elastic modulus of the FRP bars is very small within the test temperature range.

At an exposure temperature of 270°C, most of vitrification and thermal decomposition reaction of GFRP bars is completed within half an hour.

TEMPERATURE EFFECT ON THE MECHANICAL PROPERTIES OF FRP-WOOD COMPOSITE

Ao Zhou and Denvid Lau
Department of Architecture and Civil Engineering,
City University of Hong Kong, Hong Kong. Email: denvid.lau@cityu.edu.hk

ABSTRACT

With increasing environmental concern, wood has drawn a global interest as a sustainable structural material. In particular, applying fiber reinforced polymer (FRP) to the tension face of wood beam has been proven as an effective method to achieve strengthening or rehabilitation of wood structures. Although FRP can provide good mechanical enhancement to wood structures, the long-term performance of FRP-wood composite is still a big concern as the deterioration of wood structures is much faster than that of concrete and steel. A comprehensive understanding of the temperature effect on FRP-wood composite is of great importance for a reliable application of FRP strengthening technique. In this paper, the temperature effect on the entire FRP-wood composite has been investigated experimentally. The temperature of environmental chamber for conditioning FRP-wood composites ranges from -5 °C to 50 °C. Three identical FRP-wood specimens have been conditioned and tested for each temperature scenario. It is found that the mechanical properties of FRP-wood composite changes significantly at different temperature levels. The knowledge from this work can act as a foundation for a more reliable design and maintenance strategy for FRP strengthened wood structures.

FRP-wood composite, mechanical properties, temperature.

INTRODUCTION

Due to its great environmental benefits, low cost and good mechanical properties, wood is widely used for manufacturing structural component in building industry. However, a relatively low load capacity of wood restricts its application when it is compared to steel and concrete (Bergman et al. 2010). Moreover, wood undergoes biological deterioration with time and it is more vulnerable to detrimental environmental conditions (Calkins 2008). In order to improve the strength and durability of wood structures, strengthening and retrofitting wood structural members should be essentially considered.

Fiber reinforced polymer (FRP), which is made of high strength fibers and a polymer matrix, is widely used in building industry due to its high strength, ease of handling and high resistance to environmental deterioration factors (Lau and Büyükoztürk 2010). Externally bonding FRP to wood is proven as an efficient method to enhance the load capacity of wood structural members (Zhou et al. 2015; Yu et al. 2016). The bonding of FRP to wood is usually achieved by different adhesives, for example: polyurethane, polyester and epoxy (Tam and Lau 2015a). Epoxy has been demonstrated to provide satisfactory bonding performance, and hence it is most common used in FRP externally bonding technique (Tam and Lau 2014).

A number of studies have been conducted to investigated the flexural properties of wood beams strengthened by FRP, including different FRP materials, bond performance between FRP and wood and failure modes, etc (de Jesus et al. 2012; Raftery and Harte 2011; de la Rosa García et al. 2013). Based on these studies, it can be concluded that externally bonding FRP technique is an effective and efficient way to enhance strength and stiffness of flexural wood members. However, the long-term performance of FRP-wood composite is still a big concern as the deterioration of wood structures under environmental conditions are much faster than that of concrete and steel structures (Gunes et al. 2013). In real life applications, wood structures go through four seasons every year and they suffers from significant temperature and humidity changes. Previous study has shown that the mechanical properties and fracture behavior of FRP-wood composite change significantly under different levels of humidity exposure. Water molecules decrease the adhesion energy between epoxy and wood notably (Zhou et al. 2015; Tam and Lau 2015b). Through experimental and molecular dynamic simulation approaches, the interfacial
properties between FRP and substrate material has been demonstrated as the most critical part that governing the mechanical properties of entire composite system and integrity of multi-layer material system under prolonged humid condition (Lau 2012; Tam and Lau 2015c; Lau et al. 2014). However, the temperature effect on FRP-wood composite is still unclear and of great importance for a reliable application of FRP strengthening technique to wood structures.

The objective of this paper is to investigate the effect of temperature on the mechanical behavior of FRP-bonded wood composite experimentally. The temperature conditioning for FRP-wood composites ranges from -5 °C to 50 °C and the duration lasts ten weeks. In each temperature scenario, four identical FRP-wood specimens have been prepared and conditioned. After temperature conditioning, the specimens are tested and the mechanical behavior of FRP-wood composite is obtained.

EXPERIMENTAL PROGRAM

Materials and Samples

The species of wood used in this experiment is the Canadian pine. All wood samples were from one tree to minimize the variability. The wood samples were put into environmental chamber at 20 °C and 10% relative humidity for conditioning (Raftery et al. 2009). After the condition period, an equilibrium moisture content was measured as 13% and the mean density was determined as 510 kg/m³. The tensile and compressive properties of wood along the parallel to grain direction were measured following the Standard ASTM D143. The reinforcement used in this study is unidirectional carbon FRP. The average thickness of FRP is 0.167 mm. The coupon test of FRP sheet was conducted to evaluate the tensile properties in longitudinal direction. The epoxy is used to bond FRP to the tension face of wood beams. The epoxy used here possesses high tensile strength (55 MPa) and high tensile modulus (1.72 GPa) according to the manufacturer, and it can transfer the stress from wood to FRP effectively.

Before bonding FRP to wood, the wood surface should be knife planned to remove impurities to achieve high quality bonding. Meanwhile, the surface of FRP should be cleaned with methylated spirit. After the surface preparation, epoxy is brushed on the wood surface and FRP is placed on the wood beam. The air gaps and excessive epoxy between FRP and wood should be removed though roller. A uniform pressure should be applied on FRP for 24 hours to make sure FRP and wood are well bonded. The FRP bonded wood samples are put in the laboratory condition seven days for curing.

A total of 12 FRP bonded wood beams were prepared. The dimension of wood beam is 420 × 70 × 70 mm. The temperature conditioning in this study contains three levels, i.e. -5 °C, 20 °C and 50 °C. For each temperature scenario, four identical samples were prepared, conditioned and tested. After ten weeks of temperature conditioning, all samples were taken out for four-point bending test. Five strain gauges were bonded to FRP surface of each sample to measure the strain variation during test.

Test Setup

The FRP bonded wood beams were under four-point bending test setup to measure the flexural load carrying capacity. The schematic diagram and photo of four-point bending test setup is shown in Figure 1. The load was applied through a 100 kN load actuator and test was under displacement control at rate of 2.5 mm/min. Linear variable displacement transducers (LVDT) were used to measure the mid-span deflection of FRP bonded wood sample. The strain variation on FRP can be measured by strain gauges bonded to FRP surfaces. During test, the load, mid-span deflection and strain variations were recorded simultaneously by TDS-530 Data Logger.

![Figure 1 (a) Schematic diagram and (b) photo of four-point bending test setup for FRP-bonded wood sample.](image-url)
RESULTS AND DISCUSSIONS

Mechanical Properties of Wood

The tensile and compressive properties of wood are measured as 34.3 MPa (standard deviation: 6.3 MPa) and 38.3 MPa (standard deviation: 4.3 MPa). The tensile elastic modulus and compressive elastic modulus of wood are 9.0 GPa and 7.3 GPa, respectively. The tensile strength of FRP is measured as 3689 MPa with a standard deviation of 330 MPa. The ultimate strain of this FRP is 1.58 % with a deviation of 0.06 %. The elastic modulus of FRP is 234 GPa, which is much higher than that of wood. Based on these data, it can be found that FRP can improve the serviceability limit of wood members significantly. Meanwhile, the tensile strength of wood is smaller than that of epoxy, which implies that epoxy would not fail before wood failure.

Load-deflection Behavior of FRP Bonded Wood Composite

The temperature has a complex effect on FRP bonded wood composite as the thermal expansion coefficient of each component (FRP, epoxy and wood) is quite different. The diversity of thermal expansion coefficient may result in stress concentration along the interface when the entire system is under changing temperature environment, further leading to the failure of interface. The load-deflection relation of FRP bonded wood samples under different temperature conditioning is shown in Figure 2. One representative load-deflection curve is shown for each temperature scenario. The FRP bonded wood sample under 20 °C condition shows the highest load carrying capacity and relatively ductile behavior when it is compared with samples under -5 °C and 50 °C conditioning. When the conditioning temperature increases to 50 °C, a 25.3 % decrease of load carrying capacity can be observed and failure deflection (deflection at ultimate load) also decreases in corresponding load-deflection relation. When the conditioning temperature decreases to -5 °C, the deterioration of load carrying capacity is even severer, up to 38.9 % compared to 20 °C scenario. In order to evaluate the ductility property of FRP bonded wood composite, the equivalent energy elastic-plastic (EEP) estimation of yield point is introduced and ductility ratio is defined in this work (Astm 2005). Based on the typical load-displacement curve, the load of yield point is defined as:

\[ P_y = [\Delta_{\text{failure}} - \sqrt{\Delta_{\text{failure}}^2 - \frac{2w_{\text{failure}}}{K}}] * K \]  

(1)

where \( P_y \) is the yield load; \( \Delta_{\text{failure}} \) is the deflection at failure; \( K \) is the initial stiffness and \( w_{\text{failure}} \) is the energy dissipated until failure. Once the yield load is defined, the corresponding yield deflection \( \Delta_{\text{yield}} \) is determined. Furthermore, in order to determine the ductility level of composite system, the ductility ratio \( \mu \) is defined as:

\[ \mu = \frac{\Delta_{\text{failure}}}{\Delta_{\text{yield}}} \]

(2)

Table 1 summarizes the ultimate load, maximum strain of FRP, energy dissipated until failure, yield deflection and ductility ratio of composite samples under different temperature conditioning. From the ductility ratio in Table 1, we can observe that the ductility ratio decreases slightly when the temperature increases from -5 °C to 20 °C. However, when the temperature keeps increasing to 50 °C, a sharp reduction of ductility ratio, up to 25 % is observed.

From the coupon test of FRP, the ultimate strain for FRP is 1.58 %, while the largest strain of FRP in the four-point bending test is no more than 1.206%, implying that no rupture happens to the FRP during the test. This observation shows that the strength of entire composite system is not limited by tensile strength of FRP. The mechanical properties of wood and the bond performance at the interface are two important parameters governing the mechanical properties of entire system.

Strain Variations of FRP

In Figure 3, the ultimate strain variation of FRP at ultimate load level during four-point bending test are shown. From this figure, it can be seen that the stress transfer from wood to FRP is effective in -5 °C and 20 °C conditioning scenarios. However, for the 50 °C conditioning scenario, the strain on FRP layer is very small compared to the other two scenarios, implying that the interfacial bonding performance deteriorated seriously and the stress transfer between wood and FRP is inefficient. Based on this observation, it can be found that 50 °C temperature has a detrimental effect on the interfacial bonding properties.

Figure 3 The ultimate strain variation of FRP bonded wood sample at ultimate load level during four-point bending test.

CONCLUSIONS

In this paper, experimental tests have been performed to investigate the effect of temperature on the mechanical properties of FRP-wood composite. Experimental tests show that the load carrying capacity of FRP-wood composite decreases around 25.3% when the conditioning temperature increases from 20 °C to 50 °C. Furthermore, when the conditioning temperature is lower than freezing point (0 °C), the deterioration of load carrying capacity is much severer, up to 38.9%. The freezing temperature has a negligible effect on the ductility property of composite system, while the high temperature (50 °C) has a detrimental effect on the ductility of entire composite. Furthermore, 50 °C has a negative impact on the interfacial bonding performance between FRP and wood, reducing the strengthening efficiency of FRP material.
As the wood structures suffer from significant temperature variations throughout different seasons, it is necessary to consider the deterioration of FRP-wood composite caused by temperature in design and maintenance of FRP strengthened wood structures. Our current study successfully demonstrates the temperature effect on the mechanical properties of FRP-wood composite system and this knowledge can act as a foundation for a more reliable design and maintenance strategy for FRP strengthened wood structures.

TEMPERATURE EFFECTS ON CONCRETE SANDWICH PANELS REINFORCED WITH GLASS FIBRE REINFORCED POLYMERS (GFRP)

A. Schmitt 1, M. Haffke 1, V. Carvelli 2 and M. Pahn 1

ABSTRACT

The thermo-mechanical behaviour of sandwich panels was experimentally investigated. The panels had two external concrete layers reinforced with GFRP rebars and an internal expanded polystyrene insulation layer. These are typical for low bearing panels in façade claddings. The heating condition was adjusted, that the internal GFRP rebars in one concrete layer were exposed, for different times, to increasing temperature higher than the glass transition temperature of the resin. This allowed verifying the modification of the mechanical behaviour, in terms of deformability and loading carrying capacity, of the panels with pre- and post-heating bending tests. As main outcome, the elevated temperature effected significantly the insulation layer and provided considerable reduction of the initial global stiffness and of the load carrying capacity.

KEYWORDS

Glass fibre bars, concrete, sandwich panels, thermo-mechanical loading, mechanical testing.

INTRODUCTION

In the last two decades, several investigations showed the advantages of replacing steel reinforcement with FRP (Fibre Reinforced Polymers) rebars in structural concrete components (Hollaway 2012). Many investigations and applications were focused on the GFRP (Glass Fibre Reinforced Polymers) rebars for their non-corrosive and non-conductive characteristics as well as their high strength, low weight and durability (Micelli et al. 2004). One important field of application of GFRP reinforcement are slender concrete structures, because the concrete cover and, as consequence, the thickness of the concrete members can be reduced. Slender layers of reinforced concrete are frequently adopted as the load carrying members of sandwich panels used as façade panels. External cladding sandwich panels made of concrete usually consist of three layers: thin load carrying concrete layer, thermal insulation and thin facing concrete layer. Sandwich panels are frequently adopted in buildings to exploit their structural and thermal efficiency. Several efforts were dedicated to the understanding and optimization of the mechanical behaviour of sandwich panels with different reinforcements. Some investigations were devoted to the mechanical response of steel free sandwich panels having both reinforcement and connectors of GFRP (see e.g. Schmitt et al. 2014). In spite of the interest on sandwich panels in constructions industry, their durability and in particular, their thermo-mechanical behaviour, is not deeply known and investigated. Some investigations were published for understanding the mechanical behaviour of structural concrete beams (see e.g. Carvelli et al. 2013 and Abbasi et al. 2006) internally reinforced with FRP bars after elevated temperatures exposure. Only few experimental studies were dedicated to sandwich panels subjected to elevated temperatures (see e.g. Hulin et al. 2015). The advantages and the potentialities of concrete elements reinforced with FRP rebars, in particular of sandwich panels, require a safe design (Nigro et al. 2014), when exposed to elevated temperature.

The present experimental investigation aims to give a contribution focused on the examination of the residual mechanical performance of steel free sandwich panels. The present study continues the investigation of the authors detailed in Schmitt et al. (2015), in which the attention was focused on the thermo-mechanical behaviour of thin panels reinforced with GFRP bars, considering the influence of the concrete cover and the external surface of rebars. In the present paper, sandwich panels with two thin GFRP reinforced concrete layers were exposed to increasing temperature and bending loading. The heating condition allowed to reach on the bottom internal GFRP rebars temperatures higher than the glass transition temperature. This does not simulate a real fire exposure, but it is an extreme heating condition for low bearing sandwich panels. The consequences of the thermo-mechanical
loading were assessed measuring the variation of the deformability and of the load carrying capacity of the panels with pre- and post-heating bending tests.

MATERIALS AND SAMPLES

The geometry of the sandwich panels is detailed in Figure 1. The length and the width are the maximum for the available heating device. The two concrete layers of thickness 4 cm were reinforced with E-glass fibres reinforced polymer (GFRP) bars. Concrete cover of 10 mm was adopted for the GFRP rebars, named commercially Schöck ComBAR®. The configuration of the reinforcement consists of longitudinal and transverse rebars of nominal diameter 8 mm. In between the two concrete layers, a 6 cm expanded polystyrene insulation layer (typical for façades, named commercially Joma EPS 040 WDV) was placed to reproduce a sandwich panel adopted as external cladding. Point-shaped GFRP connectors of diameter 12 mm were used to link the three layers. They had the same shape of the external surface of the reinforcement, as in Figure 1.

![Figure 1 Specimen geometry and reinforcement]

The number of tests is summarized in Table 1. The GFRP rebars were produced by pultrusion technique using vinyl ester resin with glass transition temperature (T_g) of about 180 °C, according to the producer. They have external ribbed surface, cut into the bar after curing (Figure 1). The main mechanical properties in the longitudinal direction of the rebars are the tensile strength of ≈ 1000 MPa and the elastic modulus of ≈ 60 GPa. The mix for concrete contains for m³: 205 kg of water; 485 kg of cement CEM 42.5 N; 729.6 kg of aggregates 0/2 mm; 891.7 kg of aggregates 2/8 mm; 2 kg of plasticizer (ACE 30). During casting, some specimens were prepared to measure the average mechanical properties of concrete: compressive cubic strength 49.9 MPa, compressive elastic modulus 23.4 GPa and tensile strength 3.1 MPa.

Two panels (named 1 and 2) were loaded with supports span of 140 cm and loads span of 50 cm (see Figure 2) to have the reference mechanical behaviour before heating. The bending loading was applied quasi-statically with an initial speed of 0.5 mm/min for initial cracks monitoring and then of 2 mm/min up to failure, using a jack with a load cell of 50 kN. The width of cracks was measured, maintaining constant the displacement of the jack for less than one minute, at each load step of 2.5 kN. During loading, the deflection of the specimen was measured by five transducers (LVDT), one in the mid span, two 35 cm beside both supports and two at the supports position (see Figure 2).

Second phase: thermo-mechanical loading

In the second phase, quasi-static four-points bending loading was first imposed with same scheme as in the first phase. At the maximum imposed load, the heating device started increasing the temperature on the full bottom surface of the specimen, which was exposed for the time listed in Table 1. The heating on the bottom surface of the samples was applied by the device in Figure 3a. This is an electronically controlled oven with maximum temperature of more than 1000 °C. The temperature was controlled by a thermocouple in the centre of the device.

Figure 3 Heating device (a); Test set-up and external instruments position of second phase (b)

The temperature on the bottom and top surface of the specimen was measured by two thermocouples TC-B and TC-T. Moreover, in two panels (named 3 and 4) one thermocouple (TC-1) was placed mid-span on the bottom of the central rebar to monitor the internal temperature at the bar level. In the panel 5, four more thermocouples (TC-5 to TC-8) were placed at the level of both interfaces between the concrete and the insulation layer. Those allowed the monitoring of the temperature in the thickness of the panel during heating (see Figure 3b).

After the application of the loading, the temperature inside the device was increased from room temperature to the maximum of almost 320 °C for panel 3 and 4 and almost 400 °C for panel 5, with different heating rates. When the temperature in the centre of the device reached the desired maximum, it was maintained constant until the end of the heating phase. The heating phase was about 60 min for panels 3 and 4 and 80 min for panel 5.

The maximum imposed temperature is not as in some real applications of external cladding (e.g. on façade panels the temperature could be below 100 °C in very warm latitudes). It was considered to investigate the thermo-mechanical behaviour under extreme conditions. The maximum temperature in the device was imposed to reach at the rebars level a temperature higher than the glass transition temperature. During loading and heating the deflection of the specimen was measured by five transducers (LVDT) as shown in Figure 2.

Third phase: post-heating mechanical response

In the third experimental phase, after complete cooling, the specimens were quasi-statically loaded using the same four-points bending setup and procedure of the pre-heating tests (see Figure 2) at room temperature. This allowed comparing the mechanical behaviour of the panels, pre and post the thermo-mechanical conditioning.
RESULTS AND DISCUSSIONS

First phase: pre-heating mechanical response

Four points bending tests at room temperature of two sandwich panels (named 1 and 2) provided the reference mechanical behaviour up to failure. The load vs. mid span deflection curves (Figure 4a) show a very similar behaviour of both panels. The two branches shape is quite similar to those recorded for the same load condition of sandwich panels with different reinforcements (Schmitt et al. 2014). An initial branch with the maximum stiffness of the panel up to a load level (= 19 kN), for which the propagation and diffusion of cracking generate a high decrease of stiffness, in the second branch, leading to failure. Looking more in detail the first branch of the two curves in the low range of load, they can be considered linear up to a load level of almost 4 kN (Figure 4b), then the curves had a variation of slope meaning initiation of cracks. This was considered as reference level for loading in the second phase. Both panels failed under compression of the concrete (see Figure 4c).

![Figure 4 Load vs. mid span displacement: complete curves (a); curves in low range load (b); Failure mode (c)](image)

Second phase: thermo-mechanical loading

In the second experimental phase, the thermo-mechanical loading was subdivided in three consecutive steps: mechanical loading; heating with different rates; maintaining the temperature constant in the centre of the device for different exposition times. The bending loading was applied quasi-statically increasing the load in almost 2 minutes up to the maximum resultant of 5 kN (specimen own weight is not included) to impart an initial cracking before heating. The maximum load was estimated assuming the results of the room temperature bending tests in the first phase (see Figure 4b). The heating rate and the exposition time for the three panels (named 3, 4 and 5) adopted in the second phase are listed in Table 1. The effect of two heating rates (20 and 50 °C/min) and two exposition times (60 and 80 min) were investigated.

![Figure 5 Temperature vs. time of panels 3, 4 and 5 on the centre of top (TC-T) and bottom (TC-B) (a) and at mid span on central bar (TC-1) (b); LVDTs displacement vs. time during heating of panel 5 (c)](image)

The temperature on the bottom and top surface of the specimen was continuously measured in the mid span (see Figure 5a). During the exposition time, the temperature on the top (unheated side) was below 30°C, while on the bottom (heated side) there were differences; panel 3 with the lowest heating rate and heating time had a maximum temperature of 225 °C, panel 4 with the highest heating rate and the lowest heating time had a maximum temperature of 260 °C and for panel 5 with the lowest heating rate and the highest heating time a maximum...
temperature of 292 °C was recorded. The diagram in Figure 5b shows the evolution in time of the temperature recorded on the bottom rebar (TC-1). The protection of 1 cm concrete cover allowed to enable maximum temperatures of the rebars in the bottom layer in the range of 195±260 °C. The temperature of the rebars after 40 to 50 min was higher than the resin glass transition temperature, according to the heating rate, and then they were exposed to increasing temperature, higher than T_g, for almost 10, 20 and 30 min in panel 3, 4 and 5, respectively. The measurements of the temperature at the interfaces of the insulation and the two concrete layers were recorded for panel 5 by four thermocouples (TC-5 to TC-8), fixed on two connectors (Figure 3b). The maximum temperature after the heating exposition at the interface of the insulation and bottom concrete layer was almost 181 °C, while at the top interface it was 41 °C. When the temperature at the bottom side of the insulation reached 90 °C, the material underwent a continuous degradation until the evaporation of a large portion of the insulation layer (see Figure 6 after the heating phase). The continuous recording of the LVDTs provided the evolution of the displacement as illustrated in Figure 5c for panel 5. In particular, the initial loading lead to a mid-span displacement of all panels of almost 1.5 mm, while the considered heating rates and exposition times imparted different deformation of the panels. The global deformation of the panels measured after the exposition phase does not seem dependent on the considered heating rates and times, but is proportional to the maximum temperature imposed on the bottom surface. The mid-span displacement after heating of panel 5 is 30 % higher than that of panel 3. After heating and unloading, the maximum residual deflection was 8.5 mm for panel 5. The thermo-mechanical loading of the second experimental phase imparted a cracks pattern on the bottom surface of the panels. The main distribution of the cracks is located, as expected, in the central part of the panels with the constant maximum bending moment. Few longitudinal cracks were observed, mainly in the two external portions close to the supports.

![Figure 6](image_url) Expanded polystyrene layer of panel 4 after heating phase

### Third phase: post-heating mechanical response

The influence of the thermo-mechanical exposition on the mechanical response of the panels was measured in the third experimental phase with four points bending loading up to failure at room temperature. The global response of the panels is detailed in Figure 7a comparing the pre- and post-heating load vs. mid span deflection curves. The different behaviour of the panels is evident, observing the failure loads. Panel 3, subjected to the lowest temperature, had a reduction of the maximum load of about 8 %, while panel 4 and 5, which were heated with higher temperatures, had a failure load 27 % and 30 % lower than the reference panels. This highlights that the reduction of the failure load is not dependent on the considered heating rates and times, but mainly on the maximum temperature recorded on the bottom surface. The influence of the thermo-mechanical exposition is also measurable comparing the initial stiffness of the panels (see Figure 7b), which is defined as the slope of the segment passing through the two points of a curve at load 1 and 4 kN. The stiffness of the panel had a reduction of 22 %, 52 % and 59 % for panel 3, 4 and 5, respectively. The comparison shows, that the higher the applied maximum temperature, the higher is the reduction of the stiffness, regardless of the heating rate and time.

![Figure 7](image_url) Comparison of the pre- and post-heating bending load vs. mid span displacement (a); initial stiffness of the panels (b); rebars in the mid span of the bottom concrete layer after failure in third phase (c)
Two reasons can be attributed to the discussed reduction of the mechanical properties. The first is the damage imparted in the concrete layers (mainly transversal cracks) during the thermo-mechanical loading. In fact, the rebars had, after removing of concrete, the shape in Figure 7c. The bars were not damaged and not broken. They had still a good adhesion with concrete and their external surface was not apparently modified by the elevated temperature. Therefore, the observed level of the damage imparted could have only a marginal influence on the reduction of the mechanical features of the panels. The second reason is the degradation and lack of large portion of the insulation after heating. This is the main responsible of the significant reduction of the mechanical response of the panels. The absence of insulation layer extremely reduced the bond between the top and the bottom layer. Therefore, the structural role of the insulation (Lameiras et al. 2013; Schmitt et al. 2014; Müller et al. 2012) in transferring the shear forces between the concrete layers (sandwich load carrying action) and in giving a contribution to the bending stiffness and load carrying capacity of the panels was completely lost.

CONCLUSIONS

The experimental research was focused on understanding the thermo-mechanical response of steel free sandwich panels reinforced with GFRP rebars. The influence of two parameters was investigated: the heating rate and the exposition time. The limited number of tests does not provide statistically significant results, but they give a clear trend of the mechanical behaviour under the considered conditions. The main outcomes of the research are:

- The imposed thermo-mechanical exposition, up to a maximum in the concrete of 292 °C, created some transversal and longitudinal cracks on the bottom surface of the panels. The GFRP bars were not damaged, had still a good adhesion with concrete and their external surface was not apparently modified.
- When the temperature at the bottom of the expanded polystyrene was about 90 °C, the insulation started melting and the material had a continuous degradation until the evaporation of a large portion of the layer.
- The significant reduction of the mechanical properties (in terms of failure load and stiffness) was mainly related to the max temperature on the bottom surface, regardless of the heating rate and exposition time.
- The main responsible of the considerable reduction of the mechanical response was supposed to be the degradation and lack of large portion of the insulation after heating. The absence of insulation layer reduces the load transfer capacity from the top to the bottom concrete layer (sandwich load carrying action).

The obtained results demonstrate the excellent mechanical behaviour of the thin reinforced concrete layers and in particular of the GFRP rebars exposed to a range of temperature higher than the glass transition temperature of the resin. Moreover, the importance on the global mechanical behaviour of the insulation layers was highlighted to avoid the degradation of the mechanical features after exposition to elevated temperature.

ABSTRACT
This paper investigates the durability of Glass FRP (GFRP) reinforcement exposed to severe environments and subjected to different levels of sustained load. The test matrix was designed to include 92 GFRP specimens exposed to temperatures varying from 20°C to 60°C for 0, 42, 90 and 270 days. A total of 69 specimens were embedded in concrete and submerged in water, whilst the remainders were submerged in alkaline solution with a pH of 12.7. Tensile tests were performed on reference samples and on all conditioned specimens to determine their initial and residual strength and stiffness.

The effect of different exposure conditions and sustained stress on the long term properties of the tested bars is examined and discussed in detail. Exposure to elevated temperatures seems to play a key role in triggering and accelerating the development of critical degradation mechanisms. Moreover, the higher moisture absorption rate corresponds to high reduction on tensile strength and transverse mechanical properties. The effects of both levels of sustained stress (equivalent to 3000 με and 5000 με) seem to be negligible.

KEYWORDS
Composites, durability, GFRP, severe environment, sustained loading.

INTRODUCTION
Over the past three decades, the search for valid alternative to steel reinforcements in concrete structures to prevent corrosion issues has received a lot of attention mainly due to the high cost of maintenance generally associated with critical infrastructure (e.g., bridge decks) (Nkurunziza et al., 2005, Benmokrane and Mohamed, 2013, Almusallam et al., 2013, Demis et al., 2007, Micelli and Nanni, 2004, Dejke, 2001, Robert et al., 2010, Mufti, 2007). Among all different types of Fibre Reinforced Polymer (FRP), Glass FRP (GFRP) bars became the most appealing to civil engineers due to their good mechanical performance and low production costs in comparison to the other FRP bars. However, while the expected service life of an RC structures spans from 50 to 100 years, no reliable information on the long-term performance of in-service GFRP RC structures is yet available.

The physical and mechanical properties of FRP bars can degrade over time due to fatigue, creep, exposure to moisture, high temperature, alkalinity or ultraviolet rays (fib TG 9.3, 2007). The durability of FRP and their long term properties are generally examined through the implementation of accelerated ageing techniques consisting of laboratory tests during which specimens are subjected to mechanical or chemical conditioning along with elevated temperatures to accelerate the onset and development of the degradation processes (Bakis et al., 2002). The exposure conditions are usually selected so as to reproduce the in-service conditions of GFRP bars (i.e., embedded in concrete (moist and alkali environment) under sustained stress).

While previous research mainly focused on studying the effect of individual degradation parameters, this research aims to investigate the long-term behaviour of GFRP bars subjected to couple mechanical and environmental effects, thus representing more closely the in-service conditions of FRP RC.
EXPERIMENTAL PROGRAMME

The experimental programme was designed to study the development of mechanical and physical properties of GFRP bars exposed to alkali (concrete and alkali solution) and moist (tap water) environments as well as sustained stress. The test matrix included 92 GFRP bars with a nominal diameter of 8 mm, made of continuous E-Glass fibres impregnated in a vinyl ester resin and manufactured using the pultrusion process.

The specimens were categorised into four Groups. The unconditioned reference specimens were in Group 1, while Group 2 consisted of stressed and unstressed bare bars conditioned in alkaline solution or tap water at 20, 40 and 60°C. Stressed and unstressed bars embedded in concrete were kept in the laboratory at ambient temperature (Group 3) and immersed in tap water at 20, 40 and 60°C (Group 4). Specimens in Groups 2 and 4 were conditioned for 1000, 2000 and 6480 hours.

The alkaline solution was made of 118.5 g of Ca(OH)$_2$, 0.9 g of NaOH and 4.2 g of KOH in 1 litre of deionised water as recommended by (ACI 440.3R, 2004). The pH level of this solution was periodically controlled and kept constant at about 12.7, which is a representative value for a mature concrete pore solution.

In real applications, structural elements are usually subjected to a service load, which in turn results in a given value of stress being applied to the FRP reinforcement. The stress sustained by the FRP reinforcement can induce micro cracks in the matrix and, in the presence of moisture, promote absorption of the surrounding chemical materials. The chemical interaction between hydroxyl ions and the FRP constituents can consequently increase the rate of the degradation processes in both polymer matrix and fibres. So as to examine this phenomenon, a sustained stress inducing a tensile strain of 3000 με was applied to the FRP bars as recommended by design standards of practice (ACI 440.1R, 2006, CAN/CSAS806-2012). A higher stress inducing a strain of 5000 με was also examined in this investigation to assess the effect of less stringent serviceability limits (e.g. larger crack widths and deflections) on the long term properties of the GFRP specimens.

Two different methodologies were employed to apply a sustained stress equivalent to 3000 με and 5000 με during the whole aging process. For moisture absorption and inter-laminar shear (ILSS) tests, pairs of specimens of Group 2 were tied together at the two ends while a wedge was interposed at mid-length to impose the required curvature and apply the desired stress (Figure 1a). The length of the bars and the size of the wedge were determined according to elastic theory calculations. Conversely, for tensile tests, specimens embedded in concrete (Groups 3 and 4) were placed in a custom made, post-tensioning steel frame equipped with a calibrated spring (Figure 1b).

In this configuration, the aforementioned levels of stress and strains were ensured by simply compressing the spring to the calculated length. Demec points were also mounted on the specimens and used to verify the induced, initial level of strain and monitor strain variation during the whole duration of the conditioning phase.

![Figure 1 Application of sustained stress for specimen of Group 2 (a) and Group 3 and 4 (b). Both pictures were taken after conditioning.](image)

DURABILITY EVALUATION OF GFRP BARS UNDER SUSTAINED STRESS

Characterization of mechanical properties

The mechanical properties of the GFRP bars have been investigated after different durations of exposure, ranging from 1000 to 6480 hrs. The measured mechanical properties were tensile strength, inter-laminar shear strength and modulus of elasticity. The direct tensile tests were performed according to ACI 440.3R-04. Prior to any conditioning, all specimens were fitted with appropriate end anchors filled with epoxy resin that could be mounted directly in the tensile testing machine or in the bespoke post-tensioning rigs (figure 2). Before testing, the bars embedded in concrete were carefully extracted using a hammer and chisel to avoid any damage to the bar. The bars were instrumented with an electronic extensometer placed along their central portion. The extensometer had gage length of 51 mm and an accuracy of 0.025 mm (figure 3). The tests were carried out in displacement control using a universal testing machine. The displacement rate was 1.5 mm/min. The applied load and bar elongation were recorded during the test using a control data acquisition system.
The inter-laminar shear tests were performed according to ASTM (D7028, 2016). The specimens were obtained from FRP bars exposed to a combination of temperature, environments and sustained load, and had a length sufficient to guarantee a clear span of 30 mm and adequate overhanging portion. The span was selected in order to obtain the desired inter-laminar shear failure. The tests were performed in displacement control using a Shimadzu testing machine with a total load capacity of 10 kN. The displacement rate of the crosshead was set to 1.0 mm/min. The ILSS test apparatus is shown in figure 3.

![Figure 2 Sketch illustrating the geometry of a typical tensile test specimen](image)

![Figure 3 Tests set up for tensile strength (left) and ILSS (right)](image)

**Characterization of physical properties**

Physical and microstructural analyses were performed on representative samples, including water absorption, glass transition temperature and high resolution imaging. Moisture absorption measurements were carried out periodically according to ASTM (D7028-07, 2015) and the weights of the GFRP samples were measured monthly to examine the increase due to fluid uptake. The glass transition temperature was measured performing a set of Dynamic Mechanical Analysis (DMA) according to ASTM (D570-98, 2010) using a Mettler Toledo DMA/SDTA861e machine. Moreover, the microstructural analysis was conducted using Scanning Electron Microscopy (SEM) with a high magnification microscope (Phillips XL30 SEM at 20 kV).

**TESTS RESULT AND DISCUSSION**

Table 1 summarizes the results of the mechanical tests along with the measured levels of water absorption after a given duration of exposure to the predetermined environments. The average tensile and ILSS strengths obtained from testing three samples (5 for the control specimens) are reported along with the coefficient of variation and percent rate of retention.

The variation in tensile strength and ILSS for the tested specimens is reported in the following and discussed along with some preliminary observations drawn from the tests used to characterize the physical properties.

Figure 4 Tensile Strength Retention and moisture absorption of unstressed GFRP bars vs duration of exposure

*Con concrete, W water, TEN tensile strength, Abs Absorption rate
Figure 5 Tensile Strength Retention and moisture absorption of stressed GFRP bars vs duration of exposure
*Con concrete, W water, TEN tensile strength tests, Abs Absorption rate

Tensile strength retention

All specimens failed by rupture of the bar and failure initiated within the free length of the specimens without any noticeable slip taking place within the anchorage length. The average tensile strength of the control samples was 1542±28 MPa. It is clear that the tensile strength of the conditioned specimens reduced as the temperature and conditioning time increased. As expected, the highest degradation rate in tensile strength was found for the specimens exposed to a temperature of 60°C. However, the two imposed levels of sustained stress (corresponding to an induced strain level of 3000 με or 5000 με) did not seem to affect significantly overall strength retention.

Inter-laminar shear strength (ILSS)

ILSS is strongly related to the properties of the resin matrix. A summary of the tests results on the ILSS of the tested specimens is reported in table 1 and shown in figure 6, along with moisture absorption to illustrate the effect of moisture uptake.

Figure 6 Inter Laminar Shear Strength retention and Moisture absorption rate for the tested environments
*W in water, WS in Water stressed specimens.
All specimens showed the desired failure mode, which was characterized by the development of a crack perpendicular to the direction of application of the load. However, a combination of horizontal and vertical cracks developed in some of the conditioned specimens, possibly as a result of a relatively high water absorption. In summary, figure 6 shows that higher temperatures of exposure result in a higher reduction in ILSS. Moreover, higher moisture absorption rates correspond to lower ILSS.

**Tests result of physical properties**

The tests results showed that higher temperatures of exposure correspond to an increased weight gain. Moreover, higher moisture absorption rates corresponded to higher reduction in tensile strength and transverse mechanical properties (figures 4, 5 and 6). Unexpectedly, the stressed specimens experienced lower absorption rate than the unstressed counterparts. This may be attributed to the method that was used to induce the desired induced strain (i.e. imposing the required curvature via elastic bending) and the closing of micro cracks within the compression zone of the specimens. No significant microstructural changes were observed from the SEM images. On the other hand, DMA showed a slight reduction in Tg for the samples conditioned in alkaline solution for 2000 hrs.

**CONCLUSIONS**

In this paper an experimental program aiming to quantify the deterioration of GFRP bars in the concrete environment has been reported. Based on the test results presented here the following conclusions can be drawn:

- Among all parameters examined, temperature and moisture were found to be the most important factors affecting the degradation process.
- No significant change in the composite microstructure was observed after 90 days of exposure to the harshest environment (alkaline solution at 60°C).
- The application of sustained stress did not seem to affect significantly the residual mechanical properties.

ABSTRACT

This paper presents the results of experimental investigations of the tensile properties of different types of CFRP plates. Coupon specimens of low, normal and ultra-high modulus CFRP plates were prepared and tested under tensile loading. Four different strain rates were used, including one low strain rate and three high strain rates. Two methods of capturing strain were used: image correlation photogrammetry and foil strain gauges. The results show a significant increase in the tensile strength and elastic modulus. The CFRP coupons were prepared and tested in accordance with the ASTM3039-08 standards.

KEYWORDS

CFRP plates, high strain rate, mechanical properties, CFRP tensile strength.

INTRODUCTION

Carbon fibre reinforced polymers (CFRPs) are commonly used in structural rehabilitation. CFRP is used to strengthen steel structures such as bridges, buildings, trusses, harbour structures, which are usually subjected to different types of loadings with different velocities. A large number of studies have focussed on the strengthening of steel members with CFRP composites, including both experimental and analytical investigations, in order to better understand the behaviour of such applications. The properties of CFRP composites are usually provided by the manufacturer, and these material specifications are measured under static tension or compression loads according to the standards used. These properties can be considered in strengthening applications that are statically loaded. When it comes to high load rates applications, the material properties might differ from the quasi-static loadings. Therefore, there is a problem with studying the bond strength and design calculations without investigating the composites material properties under the desired velocities. A number of experimental investigations have been conducted to study the tensile mechanical properties of various types of FRP under different variables. However, static and dynamic tensile loading are the main loadings used in the research literature. Jacob et al. (2004) presented a review of the strain rate effect on the material properties of FRP composites. The main focus of Jacob et al.’s paper is to review research on the effect of velocity to gauge length ratios, and the effect of these ratios on different mechanical properties of FRP under different applied loads.

There are different methods of performing impact testing on FRP composite materials. The Charpy pendulum, drop mass, hydraulic instruments and split Hopkinson pressure bar are techniques available to obtain the desired strain rate, and each of these techniques can achieve a range of strain rates. These methods are summarised by Deshpande (2006). Harding and Welsh (1983) modified the split Hopkinson pressure bar technique for testing materials with unidirectional fibres such as FRPs under high tensile loading rates. Their research showed that the mechanical properties of glass fibre reinforced polymers (GFRPs) is significantly affected by strain rate for both the 0° and 45° fibre directions. Other studies have focussed on this type of testing using different types of FRP and different strain rates (Adams and Adams, 1989; Adams and Adams, 1990; Lifshitz and Leber, 1998; Barré et al., 1996; Hou and Ruiz, 2000; Majzoobi et al., 2005; Fernie and Warrior, 2002).

This paper presents the mechanical properties of CFRP laminate under high strain rates. Previous studies have been conducted by the authors on the bond properties between CFRP laminate and steel members under high strain rates (Al-Mosawe et al., 2016a; Al-Mosawe et al., 2015; Al-Mosawe et al., 2016b). The properties of three types of CFRP laminates are investigated in this paper: tensile strength, ultimate strain and elastic modulus. Four velocities were used starting from quasi-static up to 5 m/s.
MATERIALS

Three types of CFRP laminates were utilised in this project: low, normal and ultra-high modulus. The tensile strength (MPa) and elastic modulus (GPa) for each type of CFRP are 2800, 165; 2800, 205; and 1500, 460 respectively, as provided by the manufacturer’s specifications. A list of the other properties is shown in Table 1.

SPECIMEN PREPARATION AND TEST SET-UP

Unidirectional carbon fibre reinforced polymer laminate CFK 150/2000, CFK 200/2000 and MBrace 460/1500 were used in this study. The three types were tested under static and dynamic load to investigate the effect of impact load on their mechanical properties. Five samples for each CFRP type were prepared for each test (one static and three dynamic tests), and the samples were prepared in accordance with ASTM: D 3039/D 3039M-08. Steel tabs were glued at both ends of the specimen as shown in Figure 1, to reduce the stress concentration and distribute the force uniformly to the CFRP specimens. These tabs were sand-blasted and cleaned with acetone, a thin layer of adhesive was applied on their surface, and then they were attached at both ends of the CFRP laminate on both sides. The far end surfaces of the CFRP were also cleaned with acetone, to ensure they were free of any dust or contaminants.

![Figure 1 (a): specimen for dynamic test, (b) specimen under quasi static load; (c) the image correlation technique system](image)

The procedure for specimen preparation was similar for static and dynamic testing, apart from the specimens’ dimensions; the gauge length was 150mm for the static and 50mm for the dynamic testing. This difference in gauge length was used to achieve the desired strain rate values.

Four strain rate values were used, starting from quasi-static tests at 2.22×10⁻⁴ s⁻¹, to impact tests at 67, 86 and 100 s⁻¹. MTS 250kN machine was used for the quasi-static testing, while a drop-mass rig was utilised to test the coupons under impact load. The desired strain rates for impact testing were achieved by dropping a mass of 156kg from different heights (0.575, 0.975 and 1.3m). For the impact tests, a strain gauge was mounted at the centre of the coupon to measure the strain development while testing (see Figure 1a). However, for the quasi-static testing, two methods were used to measure the strain: a conventional strain gauge and photogrammetry image correlation. The photogrammetry image correlation technique (see Figure 1c) has been shown to be efficient in previous research by comparing its strain readings with the strain gauge reading at the same location in CFRP-steel double strap joints (Al-Mosawe et al., 2015). Following the manufacturer’s instruction for using this technique, all coupons were painted white along the gauge length, and then each coupon was painted with black dots using a fine marker, as recommended in the manual of the VIC-3D correlated solution camera. The camera captured the strain that developed on the coupons while loading, Figure 1b shows painted specimen under loading.
RESULTS AND DISCUSSION

It is common for the actual properties of FRP to differ slightly from the manufacturers’ properties, due to the fact that the manufacturers provide the design properties or the minimum mechanical properties of the composite materials. Below are the details of the experimental results for all types of CFRP under the different loading rates.

Effect of high strain rate on stress-strain relation

The ultimate stress varies among the different strain rates, and the effect of high strain rate on the stress-strain relationship is shown in Figure 2 below.

![Figure 2 stress-strain relationship for CFRP laminates](a) 2.22×10⁻⁴ s⁻¹, (b) 67 s⁻¹ (c) 86 s⁻¹, (d) 100 s⁻¹

As shown in the figures above, a sudden failure occurred (at the point where the plots end), indicating that CFRP laminate is an elastic brittle material. The stress-strain behaviour is similar for all strain rates with slightly different values.

Effect of high strain rate on tensile elastic modulus

The results show that there is a significant impact on the tensile modulus of all CFRP types under high strain rates, as shown in Figure 3. The elastic modulus increased by up to 20% under high strain rates. The influence of high strain rates on the elastic modulus of CFRP was varied among the different research (Lifshitz and Leber, 1998; Harding and Welsh, 1983; Adams and Adams, 1990; Hou and Ruiz, 2000; Al-Zubaidy et al., 2013). The variations in the influence rate among all studies can be attributed to the type of FRP used and the strain rate values.

Effect of high strain rate on ultimate tensile stress

Figure 2 shows the linearity behaviour of CFRP composite materials, while the ultimate strength of all CFRP types significantly increased under the high strain rates. Figure 4 shows that the tensile strength increased by up to 55% under high strain rates. This percentage is higher than that found by the other researchers mentioned above, and
this variation may be attributed to the type of CFRP used. In addition, the type of matrix used to laminate fibres may also have some influence on these rates.

**Effect of high strain rate on ultimate longitudinal strain**

The effect of high strain rates on the ultimate longitudinal strain was significant for low and normal modulus CFRP. However, there was an insignificant increase in the ultimate strain for ultra-high modulus CFRP, as shown in Figure 5. The lack of understanding of the effect of high strain rates on longitudinal strain is due to the limited number of studies focusing on this. In the present research, the strain rate sensitivity to fibres is the reason for this behaviour.

![Figure 3: Effect of strain rate on the Young’s modulus of CFRP](image)

![Figure 4: Effect of strain rate on the ultimate tensile strength of CFRP](image)

A comparison of the current test results of CFRP laminates and previous research with CFRP sheet are carried out in this research. The comparison is made with the study held by Al-Zubaidy et al. (2013), normal CFRP sheet was used in this research to investigate its engineering properties under a range of strain rates. Three of the strain rate values are matching those used in this research, so it is worth to plot the results in figures to have better understanding. Figure 6a, 6b and 6c are showing the comparison of the strain rate vs the elastic modulus (GPa), Tensile strength (MPa) and ultimate strain respectively. The results of this research agreed very well with those found in CFRP sheet. The behaviour of the increase in material properties with the increase of strain rate can be attributed to the strain rate dependency of CFRP fibres, where FRP laminate has about 66% fibres and the rest is matrix as mentioned in the manufacturer properties.
Figure 5 Effect of strain rate on the ultimate tensile strain of CFRP

Figure 6 Comparison of the material properties between CFRP laminate and CFRP sheet under high strain rates.

CONCLUSION

The mechanical properties of three types of CFRP: low, normal and ultra-high modulus, were investigated. The properties were measured under high strain rates to study their influence on tensile strength, ultimate strain and elastic modulus. Four strain rates were used in this study: $2.22 \times 10^{-4}$, 67, 86 and 100 s$^{-1}$. The results show a significant increase in the engineering properties under high strain rates, the tensile stress being increased by up to 55%, while the elastic modulus and the ultimate strain increased by up to 20% and 35% respectively under high strain rates. Similar behaviour of material properties was observed for CFRP laminates and CFRP sheets.

EFFECT OF SHEET VOLUME ON IMPACT RESISTANT CAPACITY OF RC BEAM STRENGTHENED WITH AFRP SHEET

ABSTRACT
In this study, in order to investigate effects of the sheet volume on impact resistant capacity of the RC beams strengthened with Aramid Fiber Reinforced Polymer sheet (AFRPs), weight-falling impact tests were conducted taking sheet volume and falling height of the weight as variables. In addition, Poly-Ethylene Telephthalate FRP sheet (PFRPs) was also used to absorb the impact force and/or restrain rupturing of the AFRPs combining with AFRPs. An elastic modulus of PFRPs is less than one tenth that of AFRPs, but the ultimate strain is larger than four times that of AFRPs. The results obtained from this experiment are as follows: 1) the mid-span deflection of the RC beams can be reduced due to bonding AFRPs; 2) the impact resistant capacity of the RC beams can be increased corresponding to an increase of sheet volume; and 3) the axial strain concentration and rupturing of AFRP sheet can be restrained due to increasing sheet volume and/or using PFRPs combining with AFRPs.

KEYWORDS
RC beams, AFRP sheet, PFRP sheet, sheet volume, impact resistant capacity.

INTRODUCTION
In recent years, various Fiber Reinforced Polymer sheet (FRPs) bonding methods have been applied for retrofitting and/or strengthening existing Reinforced Concrete (RC) structures. On the other hand, impact resistant structures also need to be strengthened, because some structures have been deteriorated under severe environmental conditions. However, an effective strengthening procedure for this kind of structures has never been established yet. In our previous works, Aramid FRP sheet (AFRPs) bonding method has been proposed as one of strengthening method for impact resistant structures, because AFRPs has many advantages such as light weight, high tensile strength, flexible, and ductile properties.

Until now, our research group conducted falling-weight impact test of the RC beams strengthened by means of AFRP sheet bonding method (Kurihashi et al. 2015). In consequence, it is confirmed that the deflection of the beams and the crack width around the loading point can be reduced by applying the proposed strengthening method. However, when the input impact energy was increased, the RC beams tend to reach ultimate state with sheet rupturing. To establish an appropriate strengthening method for existing impact resistant RC structures, it is important to solve AFRPs rupturing mechanism and develop a restraining method.

From these points of view, in this study, in order to investigate effects of the sheet volume on impact resistant capacity of RC beams strengthened with AFRPs, falling-weight impact tests were conducted taking unit mass of AFRPs and falling height of the weight as variables. In addition, Poly-Ethylene Telephthalate FRP sheet (PFRPs) was tried to use as absorbing material for restraining rupture of AFRPs, in which PFRPs was bonded combining with AFRPs. Because the elastic modulus of PFRP sheet is less than one tenth that of AFRPs, even though the ultimate strain is larger than four times that of AFRPs.

EXPERIMENTAL OVERVIEW
Specimens
Specimens used in this experiment were listed in Table 1. In this table, the nominal name of specimen was designated in order of strengthening procedure (N: case of without strengthening, A1/2/3: cases of bonding AFRPs with nominal tensile capacity of 600, 1,200, and 1,800 kN/m, respectively, AP: case of bonding AFRPs with 600 kN/m nominal tensile capacity combining PFRPs with 600 kN/m nominal tensile capacity) and setup falling height H of the weight. Here, the estimated free falling height Hr of weight was evaluated using measured falling velocity of the weight just before impacting the upper surface of the RC beam. In this experiment, the AFRPs bonded for the beams A1/2-H3.0 were finally ruptured, and those for the other beams were not ruptured but debonded partially.

Figure 1 shows dimensions of the beam, layouts of rebar and FRP sheet. The beams have a rectangular cross section of 250 × 200 mm (height × width) and a clear span length of 3.0 m. The axial rebars of D19 (SD345) were placed at the upper and lower edges. These rebars were welded to steel plates placed at the both edges so as to reduce the anchoring length of rebars. Stirrups of D10 (SD295) were placed at the intervals of 100 mm. The FRPs was bonded onto the tension-side surface of the beams leaving 50 mm between the supporting point and the end of the sheet as shown in Figure 1. In the cases of beams A3/3AP, AFRPs with 1,200 kN/m or PFRPs with 600 kN/m tensile capacity were bonded as the first layer, respectively. And then, AFRPs with 600 kN/m tensile capacity was bonded as the second layer. Curing period for bonded FRPs was taken about 1 week under an atmosphere with temperature of 20 degrees Celsius.

Table 2 shows material test results for concrete and axial rebar, and calculated load-carrying capacity of each beam. The calculated load-carrying capacity of the beam was estimated following Japanese concrete standard (Japan...
Society of Civil Engineers, 2005) and using material properties of concrete and FRPs obtained from the test results, and nominal values for FRP sheets. Especially, flexural load-carrying capacities of the beams were estimated assuming perfect bonding between concrete surface and FRPs up to calculated ultimate state. Also, shear-bending capacity ratio was evaluated dividing calculated shear load-carrying capacity by flexural one. It is seen that these values for all specimens were greater than 1.0. This means that whole beams considered here will be statically reached ultimate state with a flexural failure mode.

**Test procedure**

Experimental setup is shown in Figure 2. Falling-weight impact tests were conducted following a single loading method, in which a falling-weight was dropped just one time from the predetermined height. Mass and diameter of the weight were 300 kg and 200 mm, respectively. Loading point was limited at the mid-span of the beam. Also, each beam was pinned supported and was pinched on its top and bottom surfaces at the lines of 200 mm inside from the both edges. The impact and reaction forces were measured using load-cells for impact loading. Based on our previous research works, ultimate state of the beam was defined as follows: 1) the residual deflection was reached up to 2% of the span length; and/or 2) FRP sheet was completely debonded and/or ruptured.

Table 3 shows a list of material properties of FRP ses used in this experiment. Here, it is seen that an elastic modulus of PFRPs is less than one tenth that of AFRPs, but the ultimate strain is larger than four times that of AFRPs. Measuring items were the impact force $P$, the reaction force $R$, the mid-span deflection $\delta$, and the axial strains of AFRPs. These output data were continuously recorded by using digital data recorders with a sampling time of 0.1 ms/word. Also, failure behaviour around the loading point was recorded by using a digital high-speed camera with the intervals of 1 ms/frame.

**EXPERIMENTAL RESULTS AND DISCUSSIONS**

**Time histories of impact force, reaction force, and deflection**

Figure 3 shows time histories of the impact force $P$, the reaction force $R$, and the deflection $\delta$ for all specimens. From Figure 3(a), it is observed that the time history of the impact force $P$ consists of a predominant first half-sine shape with about 3 ms duration time and subsequent high-frequency components, irrespective of sheet volume, sheet material, and falling height $H$ of the weight. The maximum impact forces for strengthened RC beams were larger than that for not strengthened one.

From Figure 3(b), it is seen that configurations of the time history of the reaction force $R$ for all beams were composed of two components: a sinusoidal half shape with about 35 to 50 ms duration time; and a high frequency component with a period of about 5 ms. In the case of falling height of the weight $H = 2.5$ m, duration times of
main component for the strengthened beams tend to be smaller than that for the beam N. This means that the flexural rigidity of the strengthened RC beams can be upgraded due to bonding AFRPs. In the case of \( H = 3.0 \) m, duration times of the beams A3/AP were shorter than those for the beams A1/A2. This means that the flexural rigidity of strengthened beams was increased corresponding to an increase of sheet volume and a rupture of the sheet could be restrained due to increasing sheet volume or combining with PFRPs. Also, in the cases of \( H = 3.0 \) and 3.5 m, comparing the duration time between beams A3 with AP, it is seen that the case of beam AP is slightly larger than the case of beam A3.

From Figure 3(c), it is observed that configurations of the time history of the deflection \( \delta \) for all cases show a damped sinusoidal shape after unloaded and the maximum/residual deflections tend to be restrained corresponding to an increment of the sheet volume. In the case of \( H = 2.5 \) m, it is seen that as maximum deflections of the beams A1/2 were smaller than that of beam N, the deflection can be reduced due to bonding FRPs. In the case of \( H = 3.0 \) m, it is seen that the deflections of the beams A1/2 were larger than those of the beams A3/AP, because the beams A1/2 reached the ultimate state with sheet rupturing. Also, in the cases of \( H = 3.0 \) and 3.5 m, comparing configurations of the time history of the deflection between beams A3 and AP, maximum value and duration time of the time history for beam AP were greater than those of beam A3. This means that the flexural rigidity of the beam AP may be less than that of the beam A3. Also, the bonded AFRPs in the case of the beam AP-H3.5 was partially ruptured as shown in Fig 4.

From these results, it is confirmed that the deflection of the RC beams subjected to impact load can be restrained by bonding FRPs. Also, the effect was increased corresponding to an increment of the sheet volume and/or combining PFRPs.
Transitions of strain distribution of FRP sheet and failure behaviour of RC beams

Figures 5 show transitions of the strain distribution of AFRPs and failure behaviour of the beams around the loading point for the beams A2/A3/AP-H3.0 at the elapsed times from 1 to 20 ms from the beginning of the impact. From these figures, it is observed that until the elapsed time of \( t = 4 \) ms, flexural and diagonal cracks were developed, and strains of the AFRPs were gradually increased around the loading point for all beams. At the elapsed time of \( t = 8 \) ms, these cracks were widely opened, and the strains of the AFRPs were distributed in the whole span. After the elapsed time of \( t = 9.5 \) ms, in the case of the beam A2-H3.0, the upper concrete cover has been crushed, and the strain at the mid-span reached about 1.5\%. On the other hand, in the case of the beams A3/AP-H3.0 at the elapsed time of \( t = 12.0 \) ms, the upper concrete cover has been crushed similarly to the case of the beam A2-H3.0, and also AFRPs was partially debonded due to peeling action of the critical diagonal crack developed in the lower concrete cover near the loading point. Maximum strain was about 1.25\% and not concentrated but distributed in the region of around the loading point.

Finally, in the case of the beam A2-H3.0 at the elapsed time of \( t = 10.0 \) ms, many cracks were observed in the lower concrete cover, and then AFRPs was ruptured around the loading point. On the other hand, in the cases of the beams A3/AP-H3.0 at the elapsed time of \( t = 20.0 \) ms, the sheet debonded area and large strain developed area were widely spread toward both supporting points.

From these results, it is confirmed that the strain concentration and rupturing of sheet can be restrained by increasing sheet volume and/or combining with PFRPs.
CONCLUSIONS

To investigate effect of the sheet volume on impact resistant behaviour of the RC beams strengthened with bonding AFRPs, falling-weight impact loading was conducted taking unit mass of AFRPs and falling height of the weight as variables. In addition, PFRPs was also applied combining with AFRPs to absorb the impact force and/or to restrain rupturing of the AFRPs. From these experiments, following results were obtained:

1) The mid-span deflection of the RC beams can be reduced due to bonding AFRPs in flexure;
2) The impact resistant capacity of the beams will be increased corresponding to an increase of the AFRPs volume; and
3) Axial strain concentration of the AFRPs and rupturing of the sheet can be restrained by increasing of sheet volume and/or applying PFRP sheet in combination with AFRPs.

ABSTRACT

The durability of fibrous composite materials used as strengthening systems in civil engineering is of primary importance in order to calibrate design guidelines and to assess the design life of the strengthened structure. Recent applications of Fibre Reinforced Mortar (FRM) systems, used as external strengthening in masonry and concrete buildings, have shown that dry fibres may be used as long reinforcement within a cementitious or lime-based mortar. This situation is quite different from FRP (Fiber Reinforced Polymers) composites in which, typically, an epoxy resin acts as a protection for the fibres, which are not in direct contact with the pore solutions of the substrate. In this study an extensive campaign was conducted with the aim of evaluating possible methods for the assessment of the durability of fibrous reinforcement in alkaline environment.

Two different configuration of reinforcement were studied: dry fibrous reinforcement and industrially pre-cured fibrous reinforcement (with different polymer resins). This choice was done since at the moment different reinforcement systems are used in FRM systems, which can be in forms of dry fibres or FRP grids. Glass fibres having different chemical composition (E-glass, AR-glass), basalt fibres, steel fibres, aramid fibres and carbon fibres were tested and used as benchmark. Four different alkaline environments were chosen for the accelerated exposure, according to the existing technical recommendation and scientific literature. In this perspective the presence of different ions and pH levels were accounted. Different exposure times were considered, from 168 up to 4320 hours; the wet environments were maintained at different temperatures in order to see possible acceleration effects. The comparison was made in terms of residual tensile strength, since all unexposed and conditioned specimens were tested up to failure under uniaxial tensile forces. SEM microscopy images are presented to show the damage at fibre level which was observed in vulnerable fibres.

INTRODUCTION

In the last years new inorganic matrices were used, in place of epoxy resin. They are made of lime mortar, cement mortar or polymer added cement/lime mortar. Fibrous reinforcement systems which are immersed into this environment need to be studied in terms of durability due to the high alkalinity of the interstitials pore solutions. In fact pH values, in interstitial solution present within the pores of the young cementitious matrix, may be comprised between 12.5 and 13.5, depending on the chemical species which are present. The reinforcing types most commonly used in this field are constituted by: fabrics, soft meshes or nets (glass, carbon, polyaramid, natural fibres) which are embedded directly into the inorganic binder (cement or lime). Preformed FRP grids, plates or bars, commonly constituted by glass or carbon fibres and thermosetting resins are used as alternative solutions. As regards the exposure in an alkaline environment, object of this study, it is crucial to identify the possible vulnerability of reinforcement systems, especially those more sensitive made with glass or basalt fibres. In these cases the chemical sensitivity of the material forming the reinforcement, could lead to a chemical damage, even severe, of the reinforcement itself, with consequent reduction of the mechanical properties at macroscopic level. To assess and measure this potential sensitivity, laboratory tests were conducted by immersing dry and cured fibrous materials in aqueous solutions with pH between 12 and 13.5, by varying the exposure time or speeding up the diffusive effect of such solutions through a increase of temperature of the alkaline bath. In order to simulate several possible service conditions, alkaline solutions may have different chemical composition, containing varying percentages by weight of alkali hydroxides such as Na(OH), K(OH), Ca(OH)₂. This choice was done by considering previous literature that testifies that for the glass and basalt fibres different degradation mechanisms
have been identified (Gao et al. 2003, Purnell and Beddows 2005, Butler et al. 2010,) that can be summarized in the following cases: massive corrosion of the filaments due to attack by OH- ions, rupture for static fatigue due to growth of existing surface defects aggravated by OH- ions in the vicinity of the edges of the defects, densification due to the precipitation of crystals, which go to fill the spaces between the filaments of the fiber with subsequent embrittlement. The glass fibres normally used in the composite industry (E-glass) have demonstrated a remarkable sensitivity to alkaline attack, resulting in poor durability. The mechanisms of chemical attack in an alkaline environment are classifiable in two modes: leaching due to diffusion of alkaline ions that cause a dissolution of the glass fibres; etching due to breaking of the bond Si-O-Si, which forms the main structure of the glass fiber, because of the attack lead by the alkaline chemical species. When the fibres are used in a composite polymer matrix, the protective role of resin is important too, which should not degrade in order to maintain its mechanical role. As regards the resins the most dangerous of degradation mechanism is hydrolysis of the ester groups present within the polyester resins and vinyl ester (Chen et al. 2007). The vinyl ester resins have a much lower concentration of ester groups and thus a reduced sensitivity to hydrolysis compared to conventional polyesters. Epoxy resins have no ester groups and therefore are much less sensitive to hydrolysis, thus they are commonly used in structural composites. Furthermore, the durability of FRP products made from E glass fibres, in an alkaline environment, is reduced compared to the use of AR glass fibres, and this may change also depending on the resin used for the impregnation. Laboratory tests are often conducted with the aim of accelerating the effects, in order to simulate long exposure times in situ. This is done by increasing the temperature of the alkaline bath. This change in test temperature strongly affects on durability, and various studies show that accelerated aging tests (T=50-60 °C) seem to enhance the degradation processes of Glass FRP (GFRP), as found by Bennokrane et al. (2001) and Micelli and Nanni (2004).

In the present paper the results of an extensive experimental campaign are presented. Dry reinforcing fibres (glass, carbon, basalt, polyaramid, steel) and impregnated fibres (glass and carbon), were subjected to tensile tests after accelerate aging in alkaline bath, following different ageing protocols. The values of the residual tensile strength are compared; local damages at fibre level will be also shown through SEM electronic microscopy.

EXPERIMENTAL PROGRAM

For the evaluation of the durability of the fibres in alkaline environments it was decided to choose the experimental variables based on the tests already carried out in the literature and according to existing guidelines in the civil engineering field. The residual tensile strength of the fibres was chosen as reference parameter to compare possible effects of mechanical degradation, even if an electronic microscopy was also used to observe the surface of the fibres after conditioning. This choice was followed since it is well known that durability in terms of structural design is the ability of the tested materials to maintain the mechanical properties after a certain period of exposure in a certain aggressive environment.

All samples of the same material were extracted from the same coil, in order to make meaningful comparisons, and purify possible systematic errors due to differences in production batches. Thus the fiber content (typically expressed in TEX unit g/km) for each type of material is identical in each sample. Due to the possible error in determining the real cross section of the specimens, residual capacity is expressed in terms of ultimate tensile load (kN). For the execution of the tensile tests recommendations of the CNR DT 203 (CNR 2006) were used for the preparation of the samples and the UNI EN ISO 527/4 with regard to the mechanical tests. The minimum number of repetitions for each type of sample was chosen equal to 5, in order to make the experimental the results statistically significant.

Four alkaline environments were used for the long-term simulated ageing of the fibres. The first wanted to simulate immersion in a lime mortar, the second the presence of a cementitious mortar, and were taken from existing literature. The other two environments were not directly related to the application of structural strengthening systems in civil structures, but were studied in order to detect the sensitivity according to the available standard protocols provided by ETAG and ASTM. The following formulations were used, with content of chemical species expressed in weight %:

- Environment A - lime mortar (Waldron et al. 2001): 0.16% Ca(OH)_2 - pH =12.6
- Environment B - cement (Micelli and Nanni 2004): 0.16% Ca(OH)_2, 1% Na(OH), 1.4% K(OH) - pH = 13
- Environment C - ETAG 029 / Annex A (2013) : 0.2% K(OH) - pH = 12.5
- Environment D - ASTM E 2098 (2006) :5% Na(OH) - pH = 14

The experimental protocol is evidenced in Table 1, in which exposure times, temperatures and conditions are summarized for the dry fibres.
For the dry five specimens, per each exposure/test protocol and per each material were prepared. Dry fibre bundles were cut with a length of 580 mm, after the conditioning period the ends of the dry fibre specimens were impregnated with epoxy resin for a length of 100 mm in order to better grip them inside the universal testing machine.

During the conditioning the pH level was measured daily, and the following changes were recorded: environment A - lime mortar T=20°C: pH = 12.6 ± 0.2 for the first 30 days, then a reduction until pH= 12.0 ± 0.2 was recorded after 90 days; environment A - lime mortar T=45°C: pH = 12.6 ± 0.2 constant after 60 days; environment B - cement pH = 12.8 ± 0.2 constant after 60 days in all cases; environment C - ETAG 029 / Annex A : pH = 12.5 ± 0.2 for the first 30 days, then a reduction until pH= 11.0 ± 0.2 was recorded after 90 days; environment D - ASTM E 2098: pH = 13.5 constant after 30 days. The following dry fibres were conditioned in alkaline bath:
- Glass Fibres E - TEX: 4800 g/km
- Glass Fibres AR 1 - TEX: 2400 g/km (Alkali resistant – presence of ZrO₂)
- Glass Fibres AR 2 - TEX: 2400 g/km (Alkali resistant – presence of ZrO₂)
- Carbon Fibres - TEX: 1600 g/km
- Basalt Fibres 1 – extracted from a dry net with a grammage of 200 g/m²
- Basalt Fibres 2 – extracted from a dry net with a grammage of 200 g/m²
- Polymaramidic Fibres (PBO) - extracted from a dry net with a grammage of 200 g/m²
- Steel strand - extracted from a dry net with a grammage of 670 g/m²

Glass fibres AR-1 and AR-2 differ for the chemical composition, having different content of ZrO₂. E-glass and Basalt fibres 1 and 2 are related to different manufacturers. PBO fibers are the only available for structural strengthening of civil and heritage building; steel strands were also taken from a commercial product that is used for structural strengthening of concrete and masonry structures.

As it regards pre-cured impregnated strands, they were cut from FRP grids produced through an industrial process that controls the curing of the polymeric resins. Three different meshes were tested:
- Mesh with 50% E glass + 50% AR glass fibres in a vinylester -epoxy matrix
- Mesh with 100% AR glass fibres in a vinylester -epoxy matrix
- Mesh with 100% carbon fibres in a bisfenolic matrix

All meshes were produced by using strands of 9600 g/km, and the fiber content (% mass) inside the composite strands was 67%. For impregnated fibers ten specimens per each exposure/test protocol and per each material were prepared and tested. The ageing program for pre-cured FRP strands is illustrated in Table 2 of the following section, which will report also the experimental results by comparison of mechanical tests.

EXPERIMENTAL RESULTS

Dry fibres

The results of the tensile strength performed on control specimens (unconditioned) highlighted a coefficient of variation (COV%) between 3% and 12%, thus it should be considered the range of the experimental error. In Figures 1 and 2 the residual tensile strength is plotted, at different exposure periods, for the different dry fibrous reinforcements that were tested after ageing.
Form the results in Figure 1 it is clear that different vulnerability was found for the different materials and for the different environments, as expected from the experience in the field. E glass fibers and basalt fibers demonstrated to be highly sensitive to the attack of alkaline ions, while the protection offered by the ZrO$_2$ in AR glass fibres strongly mitigated the chemical attack, on both AR-1 and AR-2. This is clearly evident in the environments A and B which are of major interest in the field of FRM-strengthened construction. In the case of lime mortar bath (environment A) the tensile strength of E-glass and basalt fibres had the same maximum drop of more than 30%. In the case of cement solution (environment B) the tensile strength of E-glass had a maximum drop of 76%, while for the case of basalt it was 35%. Environment C confirmed the same trend, even if exposure time was shorter. The case of environment D demonstrated to be very aggressive for all the fibres except for steel and carbon fibres which remained totally unharmed. Even if it is known that concentrations of alkaline ions as same as those used are not realistic, it is considered a valid “stress test” to compare the different susceptibility of the different chemical composition of the fibres.

![Figure 1](image1.png)

**Figure 1** Strength retention after alkaline exposure of dry fibers at T=20°C

The results plotted in Figure 2 are referred to tests after accelerated ageing by increasing the temperature at 40°C during the exposure. The effects of the temperature were very strong since all fibres, except carbon (steel was not tested due to its insensitivity) had a significant reduction of final strength, even if E glass and basalt fibres remained those much more vulnerable respect to AR glass and PBO.

In both cases of ageing at low and high temperature the cementitious simulated environment demonstrated to be more aggressive respect to lime simulated bath. This is due to the presence of different ions, which act as responsible of the damage growth on the surface of the fibres. It is known, in fact, that environments that contain in calcium ions would seem that, after the attach of these calcium ions to the Si-O- group that is formed (chemical degradation mechanism), a surface layer that acts as a barrier to the diffusion of ions OH- is formed. This occurrence delays the process of damage growth. This beneficial effect was not seen in alkaline environments in which there was the presence of sodium or potassium ions.

The SEM microscopy images of Figures 3 show the damage in E glass fibres produced by the attack of the alkaline ions with reference to the environment A at 40°C after 30 days. Figure 4 illustrates how this damage is not present on AR-1 glass fibres; this is due to the presence of zirconium oxide which has commonly a weight content between 16% and 20%. In these cases, during the exposure in an alkaline bath, a layer of oxide is present on the surface of
the fibres, which greatly increases the chemical resistance against alkaline attack. This chemical barrier allows to slow down very significantly the spread of the hydroxyl OH- that would cause the breakage of the glass filaments.

**Figure 2** Strength retention after alkaline exposure of dry fibers at T=45°C

**Figure 3** SEM Microscopy: E-glass dry fibres (A environment)

**Figure 4** SEM Microscopy: AR1-glass dry fibres (A environment)

**Pre-cured impregnated fibres**

The results of the durability tests on pre-cured specimens allowed to strongly highlight the important role of the matrix as protective binder in the composite structure. It was expected that when the matrix is not penetrated by the diffusion of alkaline solutions, fibres damage should be less severe than the cases of dry fibres. This evidence was found also in this experimental study, even if different fibres and different resin composition were used in order to test possible solutions used in the real field. In these cases, in addition to hydrolysis, the deterioration of the matrix could be present due to phenomena of plasticization and / or swelling caused by the diffusion of the alkali solution within the resin itself. This could lead to a reduction of the capacity of the resin to transfer the loads between the fibres which translates into a mechanical decay of the entire composite. The alkaline attack may also
take place at the fibre-resin interface, and also in this case the macro-mechanical properties of the composite would strongly decrease. The permeability of the resin typically depends from the type of resin (macromolecular composition) and the degree of crosslinking. In this study the resins that were used were cured through a controlled industrial program at temperatures that go from 100 °C to 120 °C, which means that the glass transition temperature and degree of crosslinking are remarkably higher than those cases in which the resin is cured on site. The results in Table 2 show that the loss in tensile strength is negligible, except for the case of environment B after 40 days, in which the strength had a drop of 28%.

CONCLUSIONS

A study on the durability of fibrous reinforcements was presented. Dry fibres strands and pre-cured strands were subjected to ageing in different alkaline environments. E-glass and basalt fibres demonstrated to be more sensitive and vulnerable respect to the other fibres type. AR glass confirmed their ability to resist also in lime or cement simulated alkaline baths. The presence of the vinylester-epoxy resin in pre-cured glass fibres specimens allowed to strongly reduce the effects of the alkaline attack in lime simulated environment.

ABSTRACT

Fibre Reinforced Polymer (FRP) has been widely used for reinforcement or rehabilitation to the upper structure. Currently, some research has investigated the application of FRP underground structure which refers to reinforcement of the structure or substitution of traditional material. Due to the corrosion of steel bar or deterioration of concrete in harsh environments, there is a need to replace some steel reinforced concrete piles which leads to the study of composite piles including FRP piles. However, not much has been done to examine the application of FRP in geotechnical structures. This paper presents an overview of FRP in geotechnical application with focus on FRP reinforced piles. Furthermore, the geotechnical utilisation in shield construction and further investigation of the FRP pile are highlighted. It is expected that this review could provide practical information for geotechnical engineers.

KEYWORDS

FRP bar, FRP slice, reinforcement, geotechnical application, shield construction.

INTRODUCTION

Fibre Reinforced Polymer (FRP) is a composite material which contains fibre that can provide high tensile strength and resin. This material is also known as fibre-reinforced plastics, or advanced composite materials (ACMs) (Bank & Wiley, 2006). FRP is well known for its high ratio of strength to weight, high ratio of longitudinal/transversal Young’s and high ratio of longitudinal/transversal shear modulus (Pecce, 2001). It can be categorized into Aramid-FRP (AFRP), Basalt-FRP (BFRP), Carbon-FRP (CFRP) and Glass-FRP (GFRP) depending on the materials of fibre, and due to this, the FRP product is more flexible to change the material properties via designing volume ratio of fibres to resin and selecting the types and orientation of fibre. It has been widely applied in aerospace, automotive, industrial and recreational products before the application in civil engineering construction. The FRP composite products in the market are mostly manufactured into FRP sheets and FRP bars for construction purposes. FRP bars usually include GFRP anchor (ribs) and GFRP grille (Zhang et al. 2001). There is a large amount of research focus on the analysing the structural behaviours of beams, walls with consideration of FRP sheet application (Mostofinejad & Mohammadi Anaei, 2012; Mohammed et al. 2013; Mostofinejad & Tabatabaei Kashani, 2013; Mosallam et al. 2015). A notable method utilising the confinement to concrete columns by FRP has been studied and the results show that methodology could enhance strength when the structure suffers axial loading (Kwan et al. 2015; Lo et al. 2015; Youssf et al. 2015). The application history of the FRP composite materials has surpassed 80 years. However, these pass projects mostly refer to the rehabilitation or strengthening of the structure members such as beams and columns. This paper presents an overview of FRP application in geotechnical works.

DEVELOPMENT AND INVESTIGATION OF FRP PILE

There are wide utilisations of piles whereby some issues occur when piles are located in harsh environments especially in marine or coastal conditions. The piles with traditional materials could be destroyed due to corrosion of steel, deterioration of timber and degradation of concrete as shown in Figure 1. The deterioration of the timber, concrete, and steel piling systems costs the United States nearly 2 billion dollars per year for repair and replacement (Hassan & Iskander, 1998). In 1998, the Federal Highway Administration (FHWA) initiated the project on the use of the Fibre-reinforced Polymer pilings as the replacement of traditional piles under the background of a waterfront rehabilitation project which one goal was the replacement of up to 100,000 bearing piles for the lightweight structures.
The development of concrete piles has a long history. Engineers are now facing the problem relating to piles, that even though the piles are made of concrete and steel which possess good rigidity and high strength, damage still occurs as shown in Figures 2 and 3 which depict the damage of concrete piles photographed in Gold Coast and Adelaide in Australia, respectively.

The application history of the FRP piles is approximately three decades. Dated back to April 1987, the first prototype recycled pile was driven at The Port of Los Angeles (Juran & Komornik, 2007). This replacement of creosote-treated timber piles successfully avoided the threat of marine borers. As early as 1998, the Empire State Development Corporation (ESDC) undertook a waterfront rehabilitation project known as Hudson River Park. That project was involved replacing up to 100,000 bearing piles for lightweight structures (Juran & Komornik, 2007), the concrete-filled FRP composite piles then were employed by Virginia Department of Transportation (VDOT) in 2000 for an entire bent of the new Route 40 Bridge over the Nottoway River in Sussex County, Virginia (Pando, 2003a; Pando et al. 2004).
Even though this material is very expensive, the overall cost in the long run is more economical than the traditional materials of concrete and steel, due to advantages of low management cost and long service life. Ballinger pointed out that although the cost of FRP composite materials may be higher, the cost of labour and use of equipment necessary for construction work may be lower due to their lighter weight (Pando, 2003b). Aside from the cost, there is a growing concern in the environmental and health impact of using treated timber and steel painted with solvent or heavy-metals coatings (Guades et al. 2012). These poisonous materials threatened the marine borers which lead to the engineers starting to replace these timber piles with FRP piles which are made of fibre and plastics or resins. Robinson and Iskander (2008) pointed out those using recycled plastics to manufacture FRP piles utilises material which may have been otherwise landfill and can be more economical in aggressive environments when life-cycle costs are considered. According to the data from EPA (2006) that less than 10% of the 13.7 million tons (equal to loading of 122GN) of plastic containers and packaging produced annually in the U.S. are recovered by recycling (Brent & Iskander, 2008).

Many researchers have started to examine the FRP piles. Most of the researchers paid attention to: the drivability, driving efficiency, durability, and surface friction between FRP and soils; effect of the hammer; and resistance of the soil. The research of the driving hammer effect was conducted using wave equation analysis which considered the effects of weight and velocity of the hammer and pile property. This showed that the single-acting steam hammer was more efficient than the diesel hammer as it could drive the composite deeper with the same number of blows (Iskander & Hassan, 1998). A modelling study simulated via the software program Microwave, showed that both hollow and concrete-filled FRP piles could be driven by a heavier hammer (Ashford & Jakrapiyanun, 2001). Moreover, the soil resistance to driving which included side friction and end bearing resistance was also been investigated using the wave equation analysis program (WEAP), and the results from the entire spectrum of the study demonstrated that, for the drivability, there was more substantial difference in friction and end bearing conditions for concrete-filled FRP and concrete piles (Mirmiran & Shahawy, 1996). The outcome of a study which researched the interface behaviour between sand and FRP (Fam, 2000) concluded that FRP exhibits similar relationships between peak interface friction coefficients and the relative roughness for a given granular material (Pando et al. 2002).

A review on the driving performance of FRP composite piles pointed out that the types of composite piles are Steel Pipe Core Piles, Structurally Reinforced Plastic Piles (SRP), Concrete-filled FRP Piles, Fiberglass Pultruded Piles, Fiberglass Reinforced Plastic Piles, Hollow FRP Piles and FRP sheet Piles as shown in Figure 4 (Guades et al., 2012). A further study of Pando (2003b) emphasized that Composite products are available in the market, which are steel pipe core piles, structurally reinforced plastic matrix piles, concrete-filled FRP pipe piles, fiberglass pultruded piles, plastic lumber piles, hollow FRP piles and FRP sheet piles.

Due to these results obtained from investigation, notable research of behaviours of FRP composite piles under vertical loads was conducted to determine the stiffness, flexibility, settlement and bearing capacities. Through this research, in-situ static and dynamic tests were conducted with onsite Standard Penetration Tests (SPT) and Cone Penetration Tests (CPT). 4 types of FRP piles static and dynamic load tests were conducted in Elizabeth, New Jersey which were concrete filled fiberglass shell piles (Lancaster Pile, Figure 5), polyethylene piles reinforced...
with steel bars (PPI Pile, Figure 6), polyethylene piles reinforced by fiberglass bars (SEAPILES, Figure 7) and solid polyethylene piles (American Ecoboard Pile, Figure 8). The tests have shown possible applicability of plastic piles to traditional axial loading applications and the further work of long term creep performance and durability of these piles was highlighted (Robinson & Iskander, 2008). Concrete-filled FRP piles came into notice and were considered the best FRP piles to resist upper loading. From a different perspective, the other types of FRP piles showed inadequate capacity, for example, the steel pipe pile is mostly used under the conditions of being exposed to water, which means the FRP is actually only used for protection away from corrosion. Further example like SRP, is mainly used in fendering applications and regarded as potential load-bearing piles (Guades et al., 2012). FHWA proposed the conclusion that the FRP composite piles can be used effectively as vertical load-bearing piles and represent an alternative for deep foundation construction, especially in waterfront environments and aggressive soils (Juran and Komornik, 2007).

Additionally, many researchers started to investigate the FRP composite piles that suffered from lateral loading. The comparison tests between FRP tube pile filled with concrete (no steel reinforcement) and prestressed concrete pile were conducted and the results showed that, after the statnamic test, the FRP tube pile responses was much less stiff than the prestressed concrete pile response (Pando & Filz, 2004). A similar research agreed that the concrete filled GFRP tube pile was more flexible, which depicted a larger displacement at equivalent lateral loads and led to the reduced service load capacity of the GFRP pile (Weaver et al. 2008), and it was also concluded that the concrete filled GFRP piles could be adequately modelled using traditional p-y curves and classical beam theory. The displacement behaviour of high strength glass fibre reinforced composite bored piles was researched and results were obtained from inclinometer and survey measurements, it was concluded that those two measurement methods were the same. Furthermore, the measured displacement was much higher than the pre-load test calculations and the post-load test analysis indicated an 85% reduction in soil strength was needed for predicting the deflection of the FRP pile (Thomann et al. 2004). The limitation of this tests equipment which is used for
providing the lateral loading is mostly applied forces from pile head without considering distributed loading along the pile length.

THE GEOTECHNICAL APPLICATION OF FRP BARS

FRP anchorage in slope reinforcement
A large amount of research focused on the investigation of reinforced concrete (RC) structures with externally bonded FRP application for the purpose of strengthening and repairing. One of the limitations of this technology though is the propensity of the FRP to prematurely de-bond at strains well below its rupture strain (Zhang et al. 2012). So some researchers conducted tests to design the FRP anchors and provided the criterion for optimal assessment. Other perspectives of the anchorage are the application of FRP bolt or FRP anchor bolts which are used for slope treatment in expansive soils. The reason for using FRP bolt is that traditional main governance methods of expansive soil slope is to use steel anchor bolt and frame beam or grid, but they are easily corroded and the durability is poor (Liu, 2014). Through comparison between the FRP anchor bolt and steel bolt and analysis, the author pointed out that even though the maximum crack widths were different, and the pulling resistances were almost equal.

Others application projects used for slope reinforcement is reported by Luo, where the technology of GFRP reinforcement anchor was adopted in the project of Changji Expressway built for the purpose of red sandstone slope reinforcement during construction in 2008. This proposed reinforcement system used GFRP bolts with 28mm diameter and the results demonstrated the slope was overall stabilized (Luo, 2014). Luo also provided another GFRP anchor application used in an underground retaining project in which GFRP bolts replaced the Chinese traditional HPB325 bolts and the result was successful after the pull-out tests.

FRP bars in shield construction
A Tunnel boring machine (TBM) is one of the most efficient equipment used for tunnelling, however TBM cannot easily break the walls or piles which are used for retaining the earth pressure. As shown in Figure 9, 2 yellow coloured blocks are the areas of the train entrances of the subway station, where the steel reinforced retaining structures are located. The old way to solve that problem is utilizing manual work which is dangerous to the workers and time consuming. The project of Yuantong subway station in Nanjing city suffered a human loss during breaking the retaining structures in 2007, where the soil layers collapsed and. In this accident, the ground cracked and extended to 150 meters (Liu et al. 2014).

The application of GFRP bars are the most commonly used reinforcement during shield tunnelling construction. The replacement of traditional steel reinforcement with GFRP reinforcement in concrete structures (pile or retaining wall) successfully solves the problems mentioned above. It is because GFRP shows brittle behaviour when loading reaches and surpasses failure conditions, as the TBM can directly cut the retaining structures. This technique is widely accepted in China and there are numerous projects that have applied GFRP to fully or partially replacing the traditional reinforcement. Some projects with GFRP geotechnical application (retaining wall) are Shanmei subway station, R2 in Dongwan city (Ming, 2011), Shenzhen Subway, R5 in Shenzhen city (Zhang et al,
FURTHER RESEARCH TO BE INVESTIGATED

Some investigations of the FRP composite piles that suffered with axial loading were conducted. However, the FRP slice confined piles lack research due to research only being focused on the FRP tube or FRP inside reinforcement. Therefore, further research considering geotechnical application of FRP laminar and investigating of the laminar layers and orientation of fibre is required.

In practice, laterally loaded piles can be classified as active piles or passive piles, with regard to the loading transferring direction between the piles and the surrounding soils (Beer, 1977). To the best of my knowledge, there is no research considering the passive FRP composite piles suffering soil movement. Furthermore, there are no proposed equations for determining the capacity of FRP piles which consider the fibre orientation and FRP reinforcement ratio.

As cases mentioned in shield construction, the GFRP bar reinforced concrete passive piles successfully replaced the traditionally reinforced concrete passive piles in deep excavation construction and create convenient condition for the TBM. However, there has been no deflection and stress investigation. Moreover, there is a limited data analysis associated with FRP laboratory tests.

Generally, the FRP composite piles are still experience brief time spans and the data obtained from onsite field tests are limited. More data needs to be recorded for the engineers in the future.

CONCLUSIONS

This paper has presented an overview of the FRP geotechnical application followed by a brief historical development of FRP material. Some of the projects are illustrated and the future research required is presented. The limitation of the vertical loaded FRP piles is that, there is no test conducted for the piles on FRP laminar application and there is no consideration of the layers and fibre orientation. For the lateral loaded pile, tests were mostly applied loading from the pile head and there was no research of the passive piles suffering from soil movement. Furthermore, the FRP bars application technology successfully replaced the conventional steel material in shield construction. However, there is still a lack in research and data analysis.

(Former researcher at ISISE - Institute for Sustainability and Innovation in Structural Engineering, University of Minho, Portugal), Email: esmaeeli_civil@outlook.com

ABSTRACT

Hybrid Composite Plate (HCP) is a novel retrofitting element which is tailored to be significantly free of the shortcomings identified in commonly used strengthening systems (e.g. FRP and TRM), mainly durability and connection reliability issues. HCP utilizes the synergetic advantages of Strain Hardening Cementitious Composite (SHCC) and Carbon Fiber Reinforced Polymer (CFRP) for the retrofitting of deficient RC members. Sufficient bearing capacity of SHCC offers the possibility of using mechanical fasteners to attach HCP to the RC substrate. This paper reviews the development of HCP and discusses its retrofitting performance based on experimental tests executed on the RC beams strengthened in shear or flexure and on the repaired RC beam-column joints. Moreover, following the results of the single-lap shear experimental tests and finite element analyses performed on the connection models, some aspects of HCP-RC connection are highlighted.

FRP, SHCC, repair and strengthening, flexural and shear, beam-column joint, bond stress-slip.

INTRODUCTION

A combination of Strain Hardening Cementitious Composite (SHCC) and FRP was recently adopted in the development of a thin prefabricated retrofitting element, designated Hybrid Composite Plate (HCP) (Esmaeeli, 2015). HCP was tailored in response to the shortcomings of the existing strengthening systems such as FRPs or textile reinforced mortars (TRMs). Bond degradation, premature debonding or detachment, vulnerability to impact loads and vandalism are examples of the drawbacks limiting a more extended use of FRP systems. Mechanical anchors, made of metallic or FRP materials, are proposed by several researchers to prevent/delay FRP debonding/detachment (Grelle and Sneed, 2013). Besides a high cost, the risk of corrosion and the rupture of FRP due to stress concentration at the anchored regions are disadvantages of using metallic fastening elements. Anchors made of FRP are susceptible to the drawbacks of the FRP-bonded systems. It is believed that Near Surface Mounted FRP (NSM-FRP) is less prone to the shortcomings identified in externally bonded (EB) FRP systems. Nevertheless, this solution has lower application versatility than EB-FRP (e.g. dependency on cover thickness and soundness, and on the width of the element). In the case of TRMs, generally premature debonding at the interface between the matrix and the retrofitted member or between the matrix and the fibers, restricts their retrofitting efficiency (Triantafillou and Papanicolaou, 2005). Furthermore, installing several layers of fabrics increases the in-situ workmanship job, which results in higher retrofitting costs. Moreover, excessive deflection and wide crack openings adversely affect the efficacy of the TRMs in enhancing serviceability performance of the concrete structures. Prefabricated plates made of fiber reinforced cementitious composites (FRCs), attached to the RC elements by means of adhesive, anchors or a combination thereof, have also been attempted as durable retrofitting alternatives (Alaee and Karihaloo, 2003, Misir and Kahraman, 2013). However, the retrofitting efficacy of these plates is restricted to an optimum strip thickness. This paper reviews the development of HCP and its retrofitting applications following the six years investigations performed in the scope of the PhD thesis of the Author since late 2009 (Esmaeeli, 2015).

MATERIAL-STRUCTURAL CONCEPT OF HCP

HCP combines the potential structural effectiveness of prefabricated SHCC reinforced with CFRP, in retrofitting of RC structures. As illustrated in Figure 1, CFRP is bonded onto the face of the SHCC plate, either in the form of sheets, designated as HCP(S), or in the form of laminates (bonded onto the pre-swan grooves), designated as HCP(L).
The thickness of SHCC plate may vary from 15 mm to 25 mm. SHCC is a composite made of a cementitious matrix reinforced with short randomly dispersed fibers, capable of developing a higher tensile strength than their first cracking strength. An appreciable amount of ductility under tensile loading is one of the most desired characteristics of SHCC, which originates from the formation of multiple diffused fine cracks before the SHCC attains its ultimate tensile strength. If SHCC is properly designed, before reaching its ultimate tensile strength, a self-controlled crack width mechanism retains the average crack width fine enough, generally below 100 µm. Thus, this cracked SHCC remains sufficiently impermeable. However, the ultimate tensile strength of SHCC is usually less than two times of its matrix tensile strength. CFRP, the other HCP constituent, has a high tensile strength with an almost linear-elastic response up to its tensile rupture. Hence, CFRP offers a negligible ductility. Therefore, as depicted schematically in Figure 2, HCP utilizes the synergetic advantages of CFRP and SHCC, namely strength and ductility, in the retrofitting of RC structures. Thanks to the bearing capacity of SHCC, this thin prefabricated plate can be attached to the concrete substrate by means of only mechanical anchors. However, depending on the retrofitting demand, the HCP-RC connection can be made of only adhesive or a combination of adhesive and mechanical anchors.

The FRP bonded face of HCP is placed in contact with the retrofitted RC member. This means that SHCC acts as a protective cover for the CFRP constituents. Therefore, this system is expected to endure a relatively higher temperature than a conventional FRP system. Furthermore, up to very close to the rupture strain of CFRP material only fine diffused cracks form in the SHCC, which potentially assures a long-time performance for the HCP’s constituents. Hence, as compared to the FRP strengthening techniques, HCP is more suitable for the repair applications or for the strengthening of RC members subjected to an aggressive environment, a relatively high temperature or considerable temperature variations, and the risk of vandalism or impact. As the detachment of HCP connected to RC elements by means of both adhesive and anchors is expected to be prevented or at least significantly delayed, this system offers an enhanced connection reliability, specially suitable for the strengthening of RC elements demanding a remarkable upgrade in their load carrying capacity. This technique is also appropriate where the concrete cover has a poor quality, since anchors are expected to transfer a proportion of the interlayer shear stresses to the element’s core, beyond the level of the main steel reinforcements. Furthermore, the proposed technique is independent of the concrete cover thickness. If increasing the shear capacity of the RC member is the strengthening objective, the notable contribution of SHCC plate in resisting shear stresses is combined with tensile contribution of FRP elements, which significantly enhances the shear strength of the RC member. In comparison to TRM, a superior bond strength at the interface of HCP constituents (CFRP and SHCC), and at the interface of HCP and concrete is attainable.
DEVELOPMENT OF HCP AND ASSESSMENT OF ITS RETROFITTING EFFICACY

Development of HCP was attempted in the scope of the PhD research work of the author, which was started in late 2009 and finalized in 2015.

**SHCC Characteristics**

The SHCC developed for the fabrication of HCP was composed of a finely graded cementitious matrix reinforced with randomly dispersed short Poly Vinyl Alcohol (PVA) fibers. 2% of PVA fibers (fraction of the total composite volume) were mixed into a fresh cementitious matrix which was rheologically adjusted to achieve a self-compacting composite. Portland cement type I 42.5R, silica sand and fly ash - materials available at the north Portugal – were used as the constituents of the matrix. These ingredients were proportioned taking into account the micromechanical demands of PVA-SHCC (Wang, 2005). Detailed information about the development of SHCC, including mix proportions, mixing procedure and methods of rheological and mechanical characterizations, can be found in (Esmaeeli et al., 2012) and in Chapter 4 of (Esmaeeli, 2015). Figure 3 depicts the typical tensile stress-strain response of the SHCC used in the development of HCP, which was characterized by means of direct tensile testing of thin SHCC prisms. As the typical mechanical properties of the PVA-SHCC, used in this study, were in average 2.75 MPa, 3.71 MPa, 18420 MPa and 35.2 MPa, respectively, and was about 1.54%.

![Figure 3 typical tensile stress-strain response of the SHCC used in development of HCP](image)

**Strengthening of Shear-Deficient RC Beams**

The results of the first series of three-point bending tests executed on shear strengthened RC beams showed that adhesively bonded HCP<span>1</span> plates are significantly efficient in increasing the shear strength and ductility of RC beams (Esmaeeli et al., 2013). However, the detachment of the HCP<span>1</span>, although much delayed as compared to that of the externally bonded CFRP sheets, highlighted the need for a further improvement in HCP-RC connection, such as adding mechanical anchors. Following this observation, author also hypothesized the concept of HCP<span>L</span>, SHCC plate with CFRP laminates bonded onto the cut grooves on its surface, to assure that: a) compatible materials, the strengthening plate (SHCC) and the concrete, are bonded to each other, b) a more efficient interfacial bond between CFRP and SHCC can be achieved (such as in NSM-FRP), and c) the post-cracking strain-hardening of SHCC contributes to stress transfer between cracked SHCC and CFRP-laminate. Figure 4 demonstrates the test setup, the configuration of the shear-deficient as-built beam and the strengthened ones along with their descriptions for the beams tested in the second series of the experiments. Moreover, two types of Plate-RC connection were studied: adhesively bonded versus connection by means of a combination of adhesive and chemical anchors. The force-deflection results obtained from these tests are shown in Figure 5. Moreover, the crack pattern at the failure of the beams strengthened with HCP<span>L</span> or SHCC plates, among others, are shown in Figure 6. Additional information about this experimental work, including material properties and the details of the strengthening systems, is available in section 4.5 of (Esmaeeli, 2015). Independent of the connection system, both types of HCPs were capable to alter the shear-tension failure mode, occurred in the other specimens, to a flexural failure mode. However, due to the scale-effect, utilizing the full shear strengthening potential of the HCPs was restricted to this flexural failure mode. Although the improvement in the deflection ductility in the case of HCP strengthened beams was more notable than that of the beam strengthened with adhesively bonded U-shaped CFRP sheet, the extent of this enhancement was a function of the type of the connection. The main advantage of adding chemical anchors to the adhesive-based connection of the strengthening plates, within the context of the study performed on the retrofitting of short-span beams, was hindering the sliding of the beams’ longitudinal tension bars. The effect of this restricted sliding was reduction in the rate of the post-peak load-decay in the case of retrofitted beams failed in flexure (HCP retrofitted ones), and higher shear capacity in the case of the retrofitted beam failed in shear (the...
beam retrofitted with SHCC plates). Visual inspection of the specimens at the end of their testing revealed that the debonding of HCP occurred only in the case of the adhesively bonded HCP\textsuperscript{LJ} plates.

Figure 4 the configuration of the shear-deficient as-built beam (left), the configuration of the strengthened beams (middle), and specimens' labels and descriptions (right)

Figure 5 load-deflection response of beams strengthened with adhesively bonded schemes along with the as-built beam (left), and beams strengthened with adhesively bonded plates versus those with a combination of adhesive and chemical anchors (right) - for the beams' nominations refer to Figure 4.

Figure 6 crack pattern of the beams strengthened with the SHCC or HCP\textsuperscript{LJ} plates at their failure considering the two different types of connection: adhesive versus a combination of adhesive and chemical anchors

**Flexural Strengthening of RC Beams**

The load-deflection responses obtained from four-point bending tests executed on a series of flexurally under-reinforced beams retrofitted by attaching HCP\textsuperscript{LJ} to their soffit and on the as-built beam are depicted in Figure 7. The description of each beam is presented at the right side of this figure. The number of CFRP laminates in the structure of HCP\textsuperscript{LJ} (two vs four laminates), the type of HCP\textsuperscript{LJ} connection (chemical anchor, adhesive, or a combination thereof), and the layout of chemical anchors (staggered vs one row) were the investigated parameters. As compared to the results of the as-built beam, all of the adopted strengthening schemes resulted in a superior response in terms of the load and deflection at the onset of cracking, yield load of the tension steel bars, and ultimate load. In the case of the connection by means of only chemical anchors, the bearing capacity of HCP\textsuperscript{LJ} was sufficient to mobilize up to 74% of the tensile strength of two CFRP laminates to the RC beam, corresponding to 72% gain in the ultimate load of the as-built beam (the splitting failure in HCP\textsuperscript{LJ} is shown in the left side of Figure 8). This type of connection resulted in deflection ductility of 5.3 which was the largest as compared to the other types of connections. The staggered configuration of the anchors was more efficient than one row of them in delaying the progress of detachment in concrete cover (detachment path is shown in the right side of Figure 8). This layout of anchors in combination with epoxy adhesive provided a significant increase of 167% in the flexural load carrying capacity as compared to that of the as-built beam (corresponding to 83% mobilization of tensile strength of four CFRP laminates), with a satisfactory deflection ductility of about 4.0. There were no cracks visible,
to an unaided eye, on the surface of the strengthening layer, while several cracks along the loading span on the lateral faces of the beams were already existed.

Repair of Severely Damaged Beam-Column Joints

To experimentally assess efficacy of HCPs for enhancing seismic performance of RC structures, two full-scale severely damaged interior beam-column joints were repaired by attaching 25 mm thick HCPs to their critical regions, and they were tested. While cross-shape HCP_L plates were attached to the front and rear faces of both specimens, to one of the specimens also L-shaped HCP_O plates were fixed to the lateral faces of the beams and columns at each corner. These plates were attached by means of adhesive and chemical anchors. Similarly to the test configuration at their virgin state, these repaired specimens were subjected to simultaneous constant axial load and lateral reversal cyclic load, imposed on the top of their column. According to the tests results, both retrofitting schemes resulted in a superior performance in terms of hysteretic response, lateral load carrying capacity, energy dissipation capacity, beams flexural resistance and degradation of the secant stiffness as compared to the test results in their virgin state. A four-sided retrofitting solution altered the joint shear failure occurred in the other specimen and the virgin ones, to the failure caused by forming plastic hinges at the interfaces of the beams and the joint, and consequently the longitudinal CFRP laminates on the beams region ruptured (the failure mode of each of these repaired specimens are shown in Figure 9). By adopting a four-sided retrofitting solution, an increase of 48.3% in the lateral load carrying capacity, 84% in energy dissipation capacity and 22.2% in initial secant stiffness, as compared to the seismic performance of its virgin state, were obtained.

Figure 9 Damages at the strengthened beam-column joints at their failure, two-sided solution (left), and four-sided solution (right) (Esmaeeli et al., 2015)

HCP_L-RC Connection

A combination of experimental tests and finite element modellings was utilized to firstly characterize the local bond stress-slip laws at the interface of the SHCC and CFRP laminate and at the interface of the HCP_L and
concrete. The calibrated FE model was then extended to identify the pull load capacity of the HCP\textsuperscript{L(L)} as a function of the bond length and the stiffness of CFRP laminate, and further to optimize the parameters affecting the connection between HCP\textsuperscript{L(L)} and concrete - chapter 7 of (Esmaeeli, 2015). Following the results of this investigation, it was found that for an adhesively bonded HCP\textsuperscript{L(L)}, cohesive failure of SHCC is the prevailing failure mode. This mode of failure restricted the connection capacity to 65% (24kN) of tensile capacity of a single CFRP laminate. Thus, the use of anchors to further mobilize the tensile capacity of HCP\textsuperscript{L(L)} was found inevitable. If cohesive failure in SHCC is prevented, a CFRP-SHCC bond length of 90 mm is sufficient to mobilize the full tensile capacity of a single CFRP laminate (S&P laminate CFK 150/2000: 1.4×10 mm²). The effective CFRP-SHCC bond lengths for single- and double-CFRP configurations were identified as 200 and 250 mm, respectively, which correspond to maximum pull forces of 39.5 kN and 57.5 kN. Taking into account both the FE results and the practical considerations, a distance of 25 mm between groove and anchors is proposed. In the case of HCP\textsuperscript{L(L)} adhesively bonded to the RC block, with two rows of single-CFRP laminates, addition of a single anchor (200 mm far from the bottom edge of the plate) increases the pull force capacity by 41%. However, doubling the stiffness of the CFRP-laminates adversely affects this efficiency (only around 20% increase). Finally, for an HCP\textsuperscript{L(L)} composed of two rows of double-CFRP laminates bonded on an SHCC plate of 18 mm in thickness, both optimized width and height are 250 mm. This HCP\textsuperscript{L(L)} can mobilize 108 kN pull force to the concrete substrate if it is connected by means of adhesive and two chemical anchors.

CONCLUSIONS

The assessment of the retrofitting efficacy of HCP confirmed its suitability to upgrade variety of structural demands of the RC elements, such as increasing the shear and flexural capacity of RC beams, and enhancing seismic performance of beam-column joints. The bearing capacity of HCP is sufficient to be attached by means of chemical anchors and adhesive, ensuring a high HCP-RC connection reliability. Moreover, from the observations of the experimental tests it was found that the cracks widths in the SHCC, at least up to the serviceability limit of the flexurally strengthened beams, remain fine enough to be sufficiently impermeable. Thus, the constituents of cracked HCP are well protected against severe environmental conditions. The SHCC is also expected to protect the adhesive used to bond FRP and HCP from a relatively high temperature, temperature variations, and vandalism. However, the long-term durability, creep and fatigue performances of the HCP strengthened RC members need to be investigated.

ABSTRACT

The use of Glass Fibre Reinforced Polymer (GFRP) bars for internally reinforcing concrete structures has been growing to overcome common problems of steel reinforcement, such as corrosion. The Dundas Point Boardwalk in Applecross, Western Australia is subject to a harsh marine environment and remedial works to the foundation system which included corroded steel piles were focused on achieving an extended design life and addressing the ongoing corrosion issues encountered in marine environments. In stage one of the boardwalk repair, sixteen concrete columns and eight concrete footings were constructed, all internally reinforced with GFRP bars. The design of the footings and columns was performed using Canadian Code CAN CSA S806-12 and ISIS Canada’s guide ‘ISIS Educational Module 3: An Introduction to FRP-Reinforced Concrete.’ As the boardwalk decking was constructed using steel supporting members, attention was paid to detailing the concrete to steel connections in order to avoid moisture ingress and bimetallic corrosion. This connection was designed using GFRP threaded bolts embedded into the concrete columns and connecting the supporting steel members. Contractor feedback highlighted the ease of workability with the GFRP bars and all research suggests that there is no reason that a design life in excess of 75 years for the concrete elements cannot be achieved.

GFRP bars, compression members, durability, reinforcement, corrosion.

INTRODUCTION

Background of Dundas Point Boardwalk

Dundas Point Boardwalk is approximately 250 metres long, between 2.5 and 7 metres in width, and is located on the southern side of the Swan River Estuary near the north and western sides of Dundas Point in the City of Melville, Western Australia. The majority of the boardwalk is in the tidal zone of the Swan River and receives constant wetting and drying of its support structure. The boardwalk is used for foot and bike traffic only.

The boardwalk was designed and constructed in the 1990’s utilising steel universal column (UC) piles encased in concrete a minimum of 200mm below ground level at the time of construction. This supported steel framing on which a timber deck was laid. All steel members including piles and steel framing were hot-dipped galvanised.
Steel thickness measurements were performed on a selection of the steel piles. They were assessed in accordance with AS 1627.0-1997: ‘Metal finishing - Preparation and Pretreatment of Surfaces.’ All piles were classified as suffering from Grade H corrosion – ‘Large portion of surface is covered with rust, pits, rust nodules and non-adherent paint, pitting is visible.’ The results of the thickness measurements were extrapolated through a detailed non-destructive visual inspection to give an assessment of all 76 of the boardwalk piles. These results showed that 48% of the piles were between 20-30% corroded, 34% of the piles were 30-40% corroded and 5% of the piles exhibited more than 40% corrosion.

Due to funding limitations, it was decided to only remediate a 41 metre section of the boardwalk at the southwestern corner with the remainder of the required works programmed into the City of Melville’s future works programme.

Background to GFRP

Fibre Reinforced Polymers (FRP) are composite materials that can be used to strengthen concrete structures. They are made of fibres of a particular material selected, embedded in a polymeric resin. The most common fibres used in FRPs are glass, carbon or aramid. FRPs can come in woven sheets, which attach to the outside of reinforced concrete structures to offer strengthening, usually for remediation purposes. FRPs are less commonly produced as reinforcing bars.

Advantages of GFRP bars include; having high tensile strength, being corrosion resistant, nonmagnetic and lightweight with low thermal and electrical conductivity. This suite of characteristics is useful in many situations. GFRP bars are well suited for use in corrosive environments, in structures required to have a very long design life, in hospitals near MRI machines, for example, and provide easy workability because they are lightweight.

Disadvantages of GFRP bars include; no yielding before failure, low transverse strength compared to steel, low modulus of elasticity and possible durability issues of glass fibres in high alkaline environments. These characteristics need to be understood with guidelines to manage risk associated with these properties in concrete.

In 2001, the American Concrete Institute (ACI) released their first standard detailing recommendations of the use of FRP bars in reinforced concrete (RC). “Guide for the Design and Construction of Structural Concrete Reinforced with FRP Bars” is the most current standard and was published in February 2006. ACI Committee 440 has chosen not to offer recommendations on the use of FRP bars in compression members due to the lack of experimental data at that time. The Canadian Code CAN CSA S806-12 does include the use of GFRP in concrete compression members but ignores the contribution of GFRP when considering axial capacity.

Objectives

Experimental research at University of Western Australia was undertaken by the writer in 2012 who compared the performance of axially loaded concrete columns reinforced with GFRP bars to traditional steel reinforcement “The Study of FRP Strengthening of Concrete Structures to Increase the Serviceable Design Life in Corrosive Environments.” The results concluded that the same axial capacity could be achieved using the same area of reinforcement providing the GFRP transverse reinforcement spacing was lowered to approximately half that of the steel equivalent. That study led to the decision to construct concrete columns in an active project not only to achieve a corrosion resistant solution which would be economically beneficial, but to also monitor the performance of the columns, validating the findings of previous research.

INITIAL DESIGN PHASE

Constraints

The project brief stipulated that remedial works undertaken must yield a similar appearance as the existing boardwalk. This therefore set column sizes at 300mm in diameter and required them to have a black exterior. The same size and arrangement of steel framing was to be used to support the decking. Whilst keeping to these aesthetic requirements, the Client required a design life of over 25 years. The portion of boardwalk being replaced was 23 years old.

In the existing northeastern section of the boardwalk, there is pile support for the riverside of the boardwalk, with the steel cross beam which connects being supported in a recess into the limestone retaining wall on the land side. This connection was unstable as the retaining wall was rotating due to erosion issues below the boardwalk. This meant that new supports were needed to avoid reliance on the retaining wall for support.
Proposed Solution

The proposed solution included the replacement of pile supports whilst keeping a portion of the embedded steel UC pile to provide added anchorage of the element into the ground. The existing concrete encasement to piles was to be fully removed and replaced with a durable GFRP reinforced concrete solution. Whilst the existing steel UC pile was engaged, its requirement was designed out in the final design. This meant that a new footing would be required to support the concrete columns.

It was proposed that to eliminate the corrosion vulnerable column to superstructure connection, GFRP bolts would be cast into the new columns. This was deemed necessary as the steel framing for the decking was to be replaced and treated with an ultra-high build epoxy painting system so as to achieve a system that could be maintained over time and give a long design life of 20-25 years in a harsh marine environment.

Where the boardwalk cross beams were embedded in the limestone retaining wall adjacent, it was proposed to support them on new GFRP reinforced concrete columns identical to the replacement columns.

In the original construction there was a 300mm deep layer of sand extending up from the base of the concrete encasement of the steel piles. Over time this had been eroded away, in some cases exposing the limestone base below. This meant that two arrangements of footings were required to be designed, one founding on sand areas of the site and one founding on limestone.

Figure 2 Steel Cross Beam Embedded in Retaining Wall.

Figure 3 Proposed Column and Footing Design.
**FINAL DESIGN**

**Columns**

The final design of the columns included six 15.88mm GFRP longitudinal bars (1.68% area of reinforcement) with ligatures at 100mm centres made from 9.53mm GFRP bars. Although the bars are non-corrosive, it was decided that a pour blocker would be used in a 40MPa concrete mix to minimise concrete degradation. This was used with the intent of achieving a design life of the columns in excess of 75 years.

As there was the requirement for the new columns to look the same as the existing, permanent fibre cement formwork 300mm in diameter was specified and then painted black. This allowed for easy forming and yielded a neat appearance.

The existing steel piles were nominated to be cut back to leave an 800mm lap to be embedded in the replacement column. Following this they were to be cleaned to a Class 2.5 finish according to AS 1627.4 using grinding to remove the bulk rusted layers followed by wet abrasive blast cleaning or a blasting / washing / blasting sequence to achieve effective removal of soluble salts. Surface chlorides were tested to ensure that they were less than 50 micrograms per square centimetre. Where otherwise, they were to be re-washed with inhibitor solution then re-blasted prior to coating with a corrosion inhibiting priming paint.

**Footings**

The strip footings were designed to be able to support the loads through the new columns without the need for the engagement of the existing steel pile. One strip footing is used to support a pair of columns. The footing is 2.5 metres long, as required due to the placement of the columns, 600mm wide and minimum 250mm deep. The footing has bottom reinforcement, with six, 15.88mm GFRP bars equally spaced over the long span and four, 15.88mm GFRP bars over the short span. Six starter bars extend from the footings which would lap onto the main column reinforcement.

Due to the variable site conditions, the strip footing could be slightly altered for each case. Where sand is present, the footing and column are to be constructed with 500mm of sand above the top of the footing to allow for future erosion, or until bedrock is encountered. Where bedrock is exposed, the footing is to be recessed 250mm into the bedrock.

**Connection to Steel Framing**

The connection detail between the new columns and the steel cross beams which support the decking is critical. As this zone was prone to the deposition of salts, GFRP bolts were assessed as the best material for fixing the columns to the steel. Four 24mm diameter GFRP threaded rods were anchored 1 metre into the new concrete column. The new steel UC cross beams which were fabricated had additional plates welded to the bottom flanges in order to allow for these bolts to be accommodated. Due to the high grade paint specification used, EPDM washers were used to protect the steel from the nut and washer fixings.

As there was a gap between the top of column and the underside of the steel cross beam, two ‘U-bars’ were fabricated from 15.88mm GFRP and cast into the top of the column. This allowed for a non-shrink structural epoxy grout to be used to infill the gap and be engaged by the remainder of the concrete column. The grout could then be tapered to the steel cross beam to minimise pooling of any moisture.
CONSTRUCTION PHASE

Footings

The existing steel UC piles were successfully cut back and cleaned via abrasive blasting and thorough wire brushing. Chloride tests were performed on five of the sixteen steel sections with all tests yielding results under the allowable 50 micrometres per square centimetre. The steel was then painted with the appropriate corrosion inhibitor within four hours of the chloride tests being undertaken. This ensured that no excess chloride deposition took place between the testing and painting phases.

The footings were formed and GFRP reinforcement and starter bars laid as per Airey Taylor Consulting drawings and specifications. All footings encountered bedrock and therefore all footings were recessed into the bedrock. Rock boulders would be placed at the base of the footings to assist in limiting erosion, protecting the retaining wall structure adjacent to the boardwalk. The Contractors noted the ease of laying the reinforcement due to its lightweight. Plastic zip ties were used to tie bars together.

Columns

Once the footings were cast and cured, the column reinforcement cages, which were assembled on site, could be installed and the permanent formwork positioned and propped correctly. Timber plates were used to position the GFRP threaded rods at the correct height whilst the columns were poured. The installation of GFRP reinforcement was completed in the same way that traditional steel reinforcement is.

Finished Boardwalk

Following installation of the steel framing, a composite decking was installed and the original hardwood handrails were reinstalled. After the remediation of the boardwalk reclaimed beach sand was placed over the top of the footings with a geotextile placed on top of that with additional rock armouring and beach re-nourishment. This was to aid in protecting the surrounding structures.

The construction phase was carried out in line with the final design and construction administration was performed by the writer throughout to ensure this was the case. The Client was very pleased with the outcome and the fact that the remediated portion of the boardwalk looked very similar to the existing, although now with a design life of 75 years for the columns and footings, minimizing their future maintenance costs in a very inaccessible area.
The Contractor had no issues with the placement of GFRP and advised that it was similar to working with steel reinforcement but lighter.

![Figure 7 New (left) vs Old Boardwalk (right).](image)

**COST ANALYSIS**

Cost estimates were gathered from steel reinforcing suppliers in Perth for the fabrication and delivery of equal volumes of steel reinforcement compared to the GFRP bars specified. The steel estimates were approximately $4,000 whereas the fabrication and delivery (via air freight) of GFRP came in at $7,866. The price supplied for the same amount of GFRP but delivered via sea was $6,810.

The difference of approximately $4,000 is less than 1.5% of the total project cost which tendered for the amount of $275,772.28 + GST. This was considered to be negligible, whilst the advantages in corrosion resistance and extended time prior to first maintenance are significantly increased.

**CONCLUSIONS**

Previous experimental research performed by the writer in 2012 concluded that concrete compression members reinforced with GFRP bars gave comparable capacities to concrete columns reinforced with traditional steel. This research was the basis of the design of the Dundas Point Boardwalk.

The use of GFRP reinforcement in compression members is not recommended by current guidelines and the Dundas Point Boardwalk is the first project in Australia known to have used the technique. This is considered a big step in the acceptance of GFRP as reinforcement not only in compression members but in all concrete structures in Australia. Whilst there are many projects overseas which utilize this material, Australia has been slow to adopt it, and as all things new, people want to see it used in projects before confidence can grow.

The additional 1.5% of the total project cost was assessed as a negligible outlay in order to achieve concrete members which are expected to give good in service duty for over 75 years. The lack of maintenance required will allow for this slight start-up price increase to be recouped multiple times over the life of the structure.

The Client was receptive to the use of GFRP reinforcement at the concept design phase of the project, and the Contractor had no negative feedback whilst using the material and commended the workability of the product. This project, the ease with which it was executed, and the attenuated durability expected will give confidence to others to adopt the material.

FLEXURAL DESIGN OF LIGHT RAIL GUIDEWAY GIRDER USING ULTRA-HIGH-PERFORMANCE FIBRE-REINFORCED CONCRETE AND GLASS-FIBRE-REINFORCED POLYMER

D. Hubbell and P. Gauvreau
Department of Civil Engineering, University of Toronto, Canada

ABSTRACT

Many of the challenges preventing widespread use of Glass-Fibre-Reinforced Polymer (GFRP) composites in the construction industry can be overcome by using GFRP in combination with Ultra-High-Performance Fibre-Reinforced Concrete (UHPFRC). To illustrate the potential of this material combination, a design study of a light-rail guideway girder is undertaken. It is shown that a girder designed with UHPFRC and GFRP can equal the performance of a conventional prestressed concrete girder while weighing half as much and potentially simplifying the construction process. UHPFRC and GFRP acting compositely are together able to overcome many of the challenges to designs using of each material on its own. GFRP structures require very high safety factors for sustained loads to protect against creep effects, and their low elastic modulus and lack of plasticity often mean that serviceability requirements dictate design rather than ultimate capacity. Compositely acting UHPFRC adds stiffness and keeps sustained stresses in the GFRP low at service load levels, while providing some plasticity at ultimate limit states. Fabrication of voided cross-sections entirely composed of UHPFRC is difficult given the low viscosity of wet UHPFRC, and the very slender structural elements enabled by its high-performance properties lead to questions regarding resilience. Compositely acting GFRP has the potential to significantly enhance the ductility and resilience of UHPFRC, and it can act as a structural, stay-in-place form to facilitate fabrication.

KEYWORDS

GFRP, UHPFRC, hybrid structures, guideway structures.

INTRODUCTION: GFRP IN CONSTRUCTION

The high strength and corrosion resistance of GFRP make it an attractive material for use in the construction industry. However, relatively low stiffness, nearly elastic behaviour to failure, and susceptibility to creep and fatigue present challenges for engineers designing with GFRP. Most current applications of GFRP in the construction industry use GFRP in place of steel in traditional reinforced concrete or steel girder-concrete deck composite systems. Such systems always face challenges stemming from the low stiffness of GFRP in comparison to steel, and its lack of any tensile yield plateau to give ductility to the structure.

This suggests that the structural systems that have evolved using steel and concrete may not be as well suited to hybrid composites involving GFRP (the term “hybrid” is used to refer to composites which consist of two or more compositely acting composite materials). The high stiffness and ductility of steel complement the brittle, relatively soft mechanical properties of concrete in a mutually beneficial way. The properties of GFRP do not seem to be so compatible with conventional concrete.

Combining materials into structural composites gives designers the ability to use the strengths of one material to offset the weaknesses of the other. Both GFRP and conventional concrete are approximately elastic to failure in tension, both are susceptible to creep, and both have a relatively low stiffness. As a result, any structural system using these two materials will inevitably suffer from these same weaknesses. In seeking a material partner for GFRP with which it can achieve a symbiosis similar to that which exists between steel and concrete, one must look for a material that can replace the stiffness and ductility that GFRP lacks. Ultra-High-Performance Fibre-Reinforced-Concrete (UHPFRC) possesses these enhanced properties and promises to be a good match for GFRP.

While many other researchers have explored structural components using polymer composites acting compositely with conventional concrete (Chang, 2006), only a few research projects to date have explored the potential of this material combination. Keller et al. (2007) tested UHPFRC-GFRP sandwich panels with a lightweight concrete...
core. El-Hacha and Chen (2012) have tested hybrid composite beams consisting of pultruded GFRP sections acting compositely with UHPFRC and Carbon-Fibre Reinforced Polymer (CFRP).

The potential of GFRP-UHPFRC hybrid composites will be demonstrated here through a brief description of the UHPFRC mix that has been developed at the University of Toronto, followed by a design study for a light-rail guideway girder.

ULTRA-HIGH-PERFORMANCE FIBRE-REINFORCED CONCRETE

UHPFRC is a dense cementitious composite reinforced with short steel fibres. The composition of the UHPFRC developed at the University of Toronto (Shao & Gauvreau, 2015) is detailed in Figure 1 along with its basic mechanical properties, which are used in the design study to follow. It has a lower compressive strength than many mixes, a compromise that has been consciously made in favour of lower cement content and a lower volume of fibres.

Despite its many impressive characteristics, UHPFRC has, like GFRP, seen relatively limited use in construction. Aside from cost there are a number of challenges preventing its widespread acceptance:
1) It is a highly self-consolidating mix. Its low viscosity is required in order to achieve a good distribution of fibres, but becomes problematic for the fabrication of voided cross-sections. The void form must be fixed in place in some way, and there will be hidden surfaces and enclosed volumes where air could become trapped, forming unwanted voids.
2) Related to these difficulties, and because the fibre distribution and tensile strength can be influenced by the method of casting, UHPFRC is best suited to precast construction. However, a simple and effective means of connecting precast UHPFRC components does not yet exist.
3) The resilience of UHPFRC structures can be called into question due to the very slender elements that its high cost demands, and its high performance permits. Girder webs and flanges, which could be 100 mm or less in thickness, would be susceptible to damage from accidental impacts on a construction site.

These problems can be overcome by combining UHPFRC with a second material, such as GFRP. The GFRP can act as a stay-in-place form to simplify fabrication, it can provide a means of transmitting forces across construction joints, and it can add reinforcement to enhance the structure’s resilience against impacts.

DESIGN STUDY: A LIGHT-RAIL TRANSIT GUIDEWAY GIRDER

The preliminary design of a guideway girder to support a light-rail transit line provides an effective example to illustrate the potential of GFRP-UHPFRC hybrid composite structures. The girder has a straight alignment, is simply supported, and spans 30 m. Only the flexural behaviour of the girder is studied in detail. A cross-section designed and developed by the authors using UHPFRC and GFRP is shown in Figure 2e. For comparison, four other designs are also considered and presented in Figure 2:
a) Prestressed concrete box girder
b) Steel U-girder with a compositely acting concrete deck
c) GFRP acting compositely with conventional concrete rather than UHPFRC
d) UHPFRC post-tensioned with external unbonded tendons

In all cases, a perfect shear connection between materials is assumed, producing fully composite behaviour. Achieving this behaviour in reality may not be a trivial matter. However, the assumption allows a plane-sections analysis that is sufficiently accurate for the purpose of comparing the global behaviour of the designs.

The light rail vehicle loading is simplified to a uniformly distributed load of 18.5 kN/m for fatigue and service checks, and 22.8 kN/m for ultimate capacity checks. A superimposed dead load of 5 kN/m is included to account for barriers, emergency walkway, rails, conduits, and all other permanent attachments. The self-weight of the girders ranges from 12.4 kN/m to 25.5 kN/m. For a 30 m simple span, applying load factors of 1.2 for dead loads and 1.7 for live loads, the factored moment demand ranges from 6710 kNm for the GFRP-UHPFRC girder to 8480 kNm for the prestressed concrete girder. The fatigue moment range is 2080 kNm.

The primary service requirement for a guideway girder is that it must have adequate stiffness to avoid problems with vibration. If this requirement is satisfied, it is likely that static deflection and crack control limits will also be satisfied. Detailed analysis of train-structure dynamic interaction can be very complex, but a simple check of natural frequency can be used at the preliminary design stage to ensure that resonance between the dominant structural and loading frequencies is avoided. A train car with a bogie spacing of 12 m, travelling at 25 m/s (a typical maximum speed for light rail systems) would create a cyclic load effect with a frequency of $25/12 = 2.1$ Hz. Other characteristic lengths, such as the train and span lengths, will be longer, contributing lower-frequency components to the fluctuating load. Therefore, if the natural frequency of the guideway structure is kept above 2.5 Hz, the risk of encountering problems with resonance later in the design process will be low.

Ultimate limit states requiring attention at the preliminary design stage are the static ultimate capacity, fatigue, and in the case of GFRP structures, creep failure. Buckling is neglected in this study; stiffening elements could be added as necessary to the slender steel webs of (b) and GFRP webs of (c) and (e).

The relative efficiencies and problems associated with each structural system can be compared with reference to the moment-curvature response for each cross-section, shown in Figure 3. These diagrams are derived without material resistance factors in order to allow a clear comparison between materials governed by different regulatory codes. Each of the designs is briefly discussed below.

(a) Prestressed Concrete

This cross-section is based on the design used for the Vancouver Expo Line guideway girders (Mills, 1986). It has a typical moment-curvature response for a prestressed concrete girder, maintaining the uncracked section stiffness under service loads before cracking and ultimately failing in a ductile manner by yielding of the prestressing strands. By properly proportioning prestressed and mild steel reinforcement it is generally possible to design a section, like this one, that efficiently meets both serviceability and ultimate limit state requirements. Since this cross-section has been successfully used for guideway structures, it serves as a baseline for evaluating other design concepts.

(b) Steel-Concrete

A steel U-girder acting compositely with a concrete deck is able to satisfy the strength and stiffness requirements with a 20% reduction in weight and a span-to-depth ratio of 26.1 compared to 21.9. However, the design is governed by the natural frequency limit, and careful detailing would be required to avoid fatigue concerns. The ultimate capacity of the section is well beyond the ULS demand – the increased lightness and slenderness has been purchased at the cost of a less efficient use of materials. Decreasing the capacity without reducing the stiffness is not possible due to practical limits on the thicknesses of the webs and flanges of a welded girder.

(c) GFRP-Concrete
This is as close to an all-GFRP solution as is possible. The concrete deck is required for rail attachment and would also help with geometry control of the track bed. The design is unsatisfactory in a number of ways. The section depth must be increased to 1.8 m in order to achieve the required natural frequency, which creates a span-to-depth ratio of 16.7, seriously compromising the aesthetics of the structure. This increased depth is necessary to control the effects of fatigue. As designed, the stress in the GFRP varies from 35 MPa to 65 MPa, or 13% of the ultimate tensile strength (UTS). The thickness of GFRP is 22 mm throughout; this could be increased to allow a higher span-to-depth ratio, but fabrication becomes more challenging with thicker GFRP plate.

(d) Prestressed UHPFRC
Setting aside the challenges discussed above of fabricating a UHPFRC box girder and ensuring its resilience, a UHPFRC girder, post-tensioned with external, unbonded tendons, could be an interesting option. Flexural behaviour very similar to that of the conventional prestressed concrete girder can be achieved with a girder that is 35% lighter. Furthermore, the UHPFRC girder has a span-to-depth ratio of 30, which would be a noticeable improvement in the slenderness of the structure. However, the costs of on-site erection and post-tensioning work would be similar to conventional construction. Therefore, the benefits may not outweigh the higher material costs, even if the afore-mentioned challenges could be overcome.

(e) GFRP-UHPFRC
This cross-section has been designed and developed by the authors at the University of Toronto. The GFRP shell would be supported at its end points in an unshored condition while the UHPFRC is cast. In this way, the GFRP carries all of the dead load, and the UHPFRC is able to remain uncracked under typical service loads. Because the UHPFRC provides most of the stiffness under service loads, it is possible to dimension the GFRP primarily for ultimate limit states, leading to a more efficient use of materials than is possible when designing with GFRP alone. Moment is plotted in Figure 3 relative to the curvature in the UHPFRC, which is zero under the dead load moment of 1970 kNm. The residual uncracked capacity is enough to withstand most of the live load stresses. Sections nearer to the supports will have a lower level of pre-load in the GFRP and may exhibit more cracking in the
UHPFRC under live load. A small amount of cracking in the UHPFRC would be beneficial to the damping of the system. The maximum permanent tensile stress in the GFRP from dead load is 85 MPa (17% of UTS), within recommended limits for avoiding creep rupture (Greenwood, 2002). Because the UHPFRC remains largely uncracked under live loads, the stress range in the GFRP is only 15 MPa (3% of UTS), and the maximum fatigue stress is thus 100 MPa (20% of UTS). These stress levels indicate that fatigue is likely to be a significant factor as the design is refined, but they are not so high as to preclude a viable solution for a reasonable service life. The extent to which fatigue is a problem also depends on the fatigue performance of UHPFRC, which is not yet well understood. A programme of fatigue testing of UHPFRC under cyclic tensile loads is underway at the University of Toronto to address this question.

The GFRP box shell could be fabricated by vacuum infusion, a process that has been successfully used for bridge girders in the past (Hurtado, 2012), and which allows girders to be fabricated with arbitrary curve or twist to accommodate the required track alignment. The casting of UHPFRC slabs into this shell would be a simple matter in comparison to casting a girder of the same geometry entirely out of UHPFRC.

CONCLUSIONS

GFRP-UHPFRC hybrid composite girders display structural behaviour that is superior to that of girders designed using either material on its own. The GFRP-UHPFRC system is able to match the performance of a prestressed concrete girder while cutting the girder weight in half. Specific benefits of the material combination include:

1) The stiffness and ductility of UHPFRC in tension is able to offset the relatively low stiffness and lack of ductility in GFRP.
2) By having UHPFRC carry most of the load under service conditions, fatigue stresses in GFRP are kept manageable without the need for far more material than is required for ultimate capacity.
3) Vacuum infusion of the GFRP allows fabrication of girders having arbitrary alignment or superelevation, an especially important consideration for guideway structures. The GFRP sets the geometry of the girder, and provides a stay-in-place form for the UHPFRC, overcoming the difficulties of casting complex geometries with a very low-viscosity concrete.

Work is on-going at the University of Toronto to continue to explore and characterize the behaviour of this promising new structural composite system.

ABSTRACT

A lighthouse, 32 meters high and entirely made of fibre reinforced polymers (FRPs), was manufactured by ACCIONA Infrastructure in Madrid (Spain), and was installed in only two hours in the north extension of Valencia Port (middle east of Spain), in February 2015. This five-storey structure, which weighs 19 tons, is formed by eight carbon FRP circular hollow columns made by pultrusion and positioned at the vertices of an octagon. The 5 storeys are glass FRP and polyurethane octagonal sandwich panels made by resin infusion. An FRP spiral staircase is placed in the centre of the structure, going from its base to its top. To increase the lateral stiffness of the structure, between each couple of consecutive storeys, its carbon FRP columns are connected along the structure perimeter by horizontal glass FRP pipes which form in this way four octagonal rings. Once the FRP lighthouse was installed, its wind induced vibrations were recorded by a set of accelerometers strategically placed to determine its dynamic response. Previously, a numerical simulation of the structure was performed to assess its natural frequencies and mode shapes and to compare them with those determined experimentally.

KEYWORDS

FRP structures, free vibrations, dynamic response.

INTRODUCTION

In the marine environment, to minimize maintenance costs, the use of FRP materials for the construction of durable and lightweight civil structures is an attractive and promising alternative to traditional materials, such as steel or steel reinforced concrete. Because of the particular mechanical behaviour of FRP structures and the increased interest on this technology, many experimental and numerical research projects have been carried out in the last years, most of them focused on the static response of FRP structures, but very few in the field of dynamic response. In the case of the FRP lighthouse presented in this paper, the flexibilities of the connections between structural elements have an important influence on the flexural-torsional vibration response of the structure, so an adequate numerical model can be calibrated based on the experimental results from free vibration testing.

DESCRIPTION OF THE STRUCTURE

The lighthouse (Figure 1) is a five-storey structure supported by eight carbon FRP circular hollow columns whose centre lines, at the lower storey (S1), pass through the vertices of an octagon inscribed in a circumference of 4.15 m diameter and, at the upper storey (S5), through those of an octagon inscribed in a 3.75 m diameter circumference. These 32 m long columns, manufactured by pultrusion with epoxy resin (Figure 2a), have an outer diameter of 250 mm and a wall thickness of 20 mm. The 5 storeys, manufactured by resin infusion with vinylester resin (Figure 2b), are 200 mm thick sandwich panels with 10 mm thick glass FRP skins and a polyurethane core with a density of 70 kg/m³. The storeys are placed every 6 m and each one has a different octagonal geometry depending on its position in the structure. A spiral staircase is placed in the centre of the structure, going from its base to its top. The steps are manufactured by RTM and have a sandwich structure made of glass FRP skins and a polyurethane core (Figure 2c). Each step has a 200 mm rise and is formed by a ring with 500 mm inner diameter connected to a 900 mm length trapezoidal platform, with a variable tread width. The steps rings, vertically aligned along the lighthouse central axis, form a cylindrical space which is filled with reinforced concrete, providing a stiffening
core to the structure. To increase the lateral stiffness of the structure, the carbon FRP columns are connected by four octagonal rings placed between each two consecutive storeys. Each of these rings is formed by eight glass FRP pipes placed along the structure perimeter. The glass FRP pipes, manufactured by pultrusion, have an outer diameter of 190 mm and a wall thickness of 20 mm. The connections between columns and the horizontal glass FRP pipes are made by FRP rhomboidal diaphragms having a thickness of 42 mm (Figure 2d).

![Figure 1 The FRP lighthouse](image)

![Figure 2 Parts of the lighthouse during their fabrication: (a) columns; (b) storeys; (c) steps; (d) rhomboidal diaphragms](image)

The base of the lighthouse is a 4 m high reinforced concrete box with an octagonal prismatic shape. The lower ends of the lighthouse columns are embedded in the 1.10 thick box’s bottom slab. The 0.35 m reinforced concrete slab which forms the box ceiling is perforated to permit the eight carbon FRP columns and the central reinforced concrete core to pass through it. Neoprene bearing collars are placed between the FRP columns and this concrete slab to restrain the horizontal displacement of the columns at this level.
NUMERICAL SIMULATION

Model description

A three-dimensional finite element model of the whole structure is developed using SAP-2000 v16.1.1. The carbon FRP columns, the glass FRP pipes and the central core column are modelled with frame elements, while the storeys and the rhomboidal diaphragms are modelled with shell elements. Each column is fixed at its base, while its contact with the top slab of the concrete box is modelled with a set of linear elastic springs radially connected to the columns frame elements and having a stiffness equivalent to that of the neoprene bearing collar. Each structural element is characterized by the elastic parameters (\(E_x\), \(E_y\), \(G_{xy}\), and \(\nu_{xy}\)) and the specific weight taken from Table 1. Although carbon FRP columns and glass FRP pipes are orthotropic materials, the transverse elastic modulus \(E_y\) is not used in the model since these parts are modelled with frame elements. The spiral staircase steps are not modelled since it is assumed they do not contribute to the stiffness of the structure. Nevertheless their masses are considered adding them to the frame elements which model the concrete core below S5.

Modal analysis

A modal analysis of the numerical model of the structure is carried out to obtain the vibration modes and the corresponding frequencies, with the aim to compare them with those measured experimentally. The first ten vibration modes in the numerical model are presented in Table 2.

EXPERIMENTAL ANALYSIS

In May 2015, three months after the installation of the lighthouse, wind induced vibrations in the structure are recorded by a set of accelerometers strategically placed to determine its dynamic response. Eight unidirectional DeltaTron Accelerometers Type 4508 are used, connected to its corresponding data logger Bruel&Kjaer LAN-XI 51.2 kHz - Type 3050. At each storey, but at the lowest one (S1), two unidirectional accelerometers are placed, one oriented along X-axis and the other oriented along Y-axis (Figure 4).
At storeys S3, S4 and S5 each pair of accelerometers is fixed to a 5 kg steel block placed on the storey top surface near one of the carbon FRP columns, as it is shown in Figure 4a. At storey S2 the accelerometers are fixed to small L profiles bonded to the storey top surface near the centre of the structure (Figure 4b).

Different data records are registered in order to compare the results of each measurement to detect possible random differences between them. The experimental vibration frequencies are determined by the Fast Fourier Transform (FFT), which converts the accelerations recorded in the time domain to the frequency domain. The measurements are made with a sampling frequency of 100 Hz. The choice of this frequency for data processing is set after analyzing several measurements with a higher initial frequency and after the observation that there are no excited frequencies in the structure higher than 50 Hz. As an example, Figure 5 shows the registered accelerations and the corresponding Fast Fourier Transform for the pair of measuring points (X-axis and Y-axis) in storey S2 during one of these data records. After processing all the data records, the first ten frequencies shown in Table 3 are almost the same in most measurements with very little differences between them, so it can be assumed that the first ten global modes of vibration of the structure correspond to these excited frequencies.

From these results, the first five experimental modal shapes can be compared to those obtained numerically. The first vibration mode recorded experimentally, with a frequency of $f_{1,exp} = 1.309$ Hz, corresponds to the second vibration mode in the numerical analysis, a flexural mode with a frequency of $f_{2,num} = 1.241$ Hz. The second vibration mode recorded experimentally, with a frequency of $f_{2,exp} = 2.979$ Hz, corresponds to the third vibration mode in the numerical analysis, a torsional mode with a frequency of $f_{3,num} = 2.907$ Hz. The third, fourth and fifth vibration modes recorded experimentally, with a frequency of $f_{3,exp} = 3.922$ Hz, $f_{4,exp} = 6.178$ Hz and $f_{5,exp} = 9.307$ Hz, respectively, correspond to the fifth, sixth and ninth vibration modes in the numerical analysis, corresponding to a flexural mode with a frequency of $f_{5,num} = 3.679$ Hz, $f_{6,num} = 6.350$ Hz and $f_{9,num} = 9.375$ Hz, respectively. In Figure 6 the first five vibration modes in the numerical model with a frequency very similar to that obtained experimentally are presented, and are compare in Table 4.

CONCLUSIONS

The experimental analysis carried out based on acceleration measurements has proven to be a good technique to obtain useful information about the structural behaviour of the lighthouse from the free vibration of the structure.

The analysis of the wind induced accelerations by FFT identifies the first five modes of vibration of the structure, and the corresponding experimental frequencies are 1.309 Hz, 2.979 Hz, 3.922 Hz, 6.178 Hz and 9.307 Hz. The frequency analysis is completed with a Finite Element Model, with frequencies very close to those obtained experimentally. This model allows identifying the experimental modal shapes, where the first mode corresponds to the first flexural mode and the second one to the first torsional mode, being the following modes the second, third and fourth flexural modes, respectively.

Although for a global structural analysis the use of isotropic linear elastic constitutive laws adopted for frame elements (carbon FRP columns, glass FRP pipes and central core column) is accurate enough, a more detailed analysis taking into account the shear deformability effect would be required, especially of those parts influenced by the stiffness of connections.

The use of FRP materials in the construction of singular structures in aggressive environments is a promising technique that has been validated through many projects worldwide, as for example the lighthouse presented in this paper. This structure has met the quality and structural requirements imposed to these type of projects, not only for its static behaviour, but also for its dynamic response.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to the laboratory technicians and engineers of ACCIONA Infrastructure Research Centre of Madrid involved in this project, for their participation in the design, manufacture and testing of the structure.

It is worth mentioning that this structure has been awarded at the JEC World 2016 Innovation Awards in Paris in the Infrastructures category with the title "All-composite lighthouse marine navigation aid".

ABSTRACT
Since the late 1990’s there have been a number of bridges in the United States that have been built or rehabilitated using FRP materials. A number of these projects occurred within the state of Missouri between 1999 and 2012. To assess durability behavior of existing bridges, some samples with reinforcing bar including GFRP bars are extracted from several older FRP bridges like Southview Bridge in varying climates to examine their performance after a decade or more under field conditions. This paper presents several analytical methods like Short Bar Shear (SBS) test, Glass Transition Temperature ($T_g$) test, and Resin Content Measurement [Burn off testing (i.e. resin)] for FRP rebars, and PH Measurement for concrete to evaluate the both physical and chemical properties of GFRP bars and concrete with time under field environmental conditions. This paper is intended to provide a possible path forward to collect important field data on FRP reinforced structures with a view to create a database of field data to better understand the long-term behavior of FRP bars used in the field.

KEYWORDS
FRP, SBS, $T_g$, burn off testing, PH measurement.

INTRODUCTION
Corrosion of steel reinforcement is a major problem with traditional steel reinforcement used in bridge decks. In the last decade, the non-corrodible glass fiber-reinforced polymer (GFRP) bars have made them more attractive to civil engineers and construction companies to replace conventional steel bars due to their lower cost, higher tensile capacity, and lower weight. They can mitigate or prevent the corrosion problem of reinforced concrete (RC) structures, especially members and elements such as bridge deck slabs exposed to aggressive environments (Ghatefar et al. 2014). GFRP composite materials cannot be corroded by nature like their steel counterpart. However, concrete structures reinforced with GFRP materials are still susceptible to other forms of deterioration due to harsh environments involving deicing chemicals, sulfate salts and alkalis, which can readily infiltrate concrete through cracks (ISIS Canada 2006).

The state of Missouri has had a number of FRP projects for both strengthening of existing deficient bridges and new FRP bridge construction due to their corrosion resistance, high strength to weight ratio and rapid installation processes. Validation of the long-term durability performance and the comprehensive development criteria/guidelines are needed before FRP system will gain widespread acceptance throughout the engineering and civil infrastructure community in the United States. Therefore, many of the Missouri demonstration projects like the Walker Street Bridge and the Southview Bridge have included on-going monitoring and load testing to validate these systems and demonstrate their long-term durability performance (Holdener et al. 2008).

Some concrete cores involving GFRP bars were extracted from the Southview Bridge slab deck using GFRP bars for top and bottom mats and CFRP reinforcement for internal post-tensioning of the bridge deck. This bridge is located in Rolla, Missouri (Southview Drive on Carter Creek), U.S.A. One lane of the bridge was already built using a conventional four-cell steel reinforced concrete box culvert. One lane and sidewalk needed to be added. This additional lane was constructed using FRP bars as internal reinforcement in 2004 (Fico et al. 2006).
There are limited results whether the GFRP bars are deteriorated after long-term field exposure to concrete. As a result, these results cannot explain completely the properties of GFRP bars extracted from concrete structures. In this paper, therefore, SBS test, Resin Content Measurement (Burn off Testing), Glass Transition Temperature ($T_g$) test for GFRP bars, and PH Measurement of concrete cylinders with different locations were performed to determine whether epoxy and concrete were deteriorative with time and to suggest a possible path forward to creating a database of suggested test methods on field collected samples. The secondary objective of this study is to further illustrate whether the properties of GFRP bars will change after several years exposure to concrete environment, and provide a direction or guideline of long-term performance of FRP system so that this system can be applied widely to civil engineering. It should also be noted since these structures were constructed, manufacturers have made improvements their FRP product so any observations noted in this work certainly may not be reflective of bar products produced today with improvements seen in the resin systems.

EXPERIMENTAL PROGRAMS

Short Bar Shear (SBS) Test

Number 6 GFRP bars (0.75 in. (19 mm) diameter) that were manufactured by Hughes Brothers were extracted from some cylinders that were from Southview Bridge in Rolla, Missouri. Figure 1 shows the samples of GFRP bars. According to limitations and requirements of ASTM D4475-02 (Reapproved 2008) (ASTM D4475-02 2008), Short Bar Shear (SBS) test was performed. The test set-up is illustrated in Figure 2. The purpose of this test is to measure the inter-laminar shear properties of GFRP bars, and to compare to the values that manufacturer reported. Shear behavior would change if resin or epoxy in GFRP bars is destroyed or deteriorated under seasonal in-situ field exposure.

![Figure 1 Samples of GFRP bars](image1)

![Figure 2 Set up of SBS test](image2)

Resin Content Measurement (Burn off Testing)

GFRP bar samples were cut and weighed approximately 0.011 lb (5 g). Burn off testing was conducted based on ASTM D2584-11 (ASTM D2584 2011). Firstly, some samples were weighed, then placed on a substrate and re-weighed. The samples on the substrates were heated in the muffle furnace at 600°C (1112°F) until all resin had disappeared. The samples were then cooled and weighed again including the substrate. Resin contents of these samples were calculated and compared to the original values. The purpose of this test is to determine whether epoxy of GFRP bars is deteriorative after long-term field exposure to concrete.

$T_g$ Measurement of GFRP bar

The glass transition temperature ($T_g$), an important physical property of the matrix, is not only an indicator of the thermal stability of the material but also is an important indicator of the structure of the polymer and its mechanical properties (Mufti et al 2007). The ideal temperature for heat treatment application depends on the thermal behavior of each composite, such as $T_g$ analysis and initial degradation temperature (Miyazaki et al 2009). The $T_g$, therefore, can successfully be used as a reference to sign the ideal heat treatment for photo-irradiated resin compositions. According to ASTM E1640-13 (ASTM E1640 2013), TA instrument was used to perform $T_g$ measurement. Some powders of FRP samples were obtained from interior and surface of GFRP bar to evaluate:

1. the thermal behavior of epoxy;
2. the difference between interior and exterior of GFRP sample.

The samples were heated until 200°C (392°F).
PH Measurement of Concrete

The initial pH value of concrete surface is approximately 13. The value at the exposed surface will fall due to the reaction of carbon dioxide from the atmosphere and alkalis in the concrete. The process is known as carbonation. Depth of carbonated concrete will continue to develop over time. Because the carbonated concrete can allow corrosion of reinforcing bars, it may be important to determine the depth of carbonated concrete. This test was followed ASTM F710 (Section 5.2.1) (ASTM F710 2011). First, the concrete surface was ground by sand paper, and cleaning the surface. Distilled water was placed on this surface. PH paper was used to measure pH value. It was compare with the pH value that concrete surface was not ground.

EXPERIMENTAL RESULTS AND DISCUSSIONS

Short Bar Shear (SBS) Test

In order to perform this test, the specimen length was 3.5 in. (89 mm) based on ASTM D4475-02. The Instron 4400 Series Universal Testing Machine (UTM) was used to do this test. The same rate of loading, 0.05 in./min (12.7 mm/min) was used. The specimen was center-loaded. The center-to-center distance between two supports was 2.25 in. (57.2 mm). The ultimate failure load and displacement of the inter-laminar shear test were recorded. Figure 5 illustrates the experimental load-displacement curve of GFRP sample.

![Figure 5 Load-displacement relationship](image)

The ultimate load at failure and final deflection were 2913 lbs and 0.274 in (6.96 mm) respectively. Figure 6 shows the failure specimen after the test. There was some deformation of the specimen directly under the loading head at the beginning of loading due to the low stiffness and strength of resin compared to fibers of this GFRP bar. This can explain that the curve of load-displacement have a lower slope at the beginning of this relationship, but there was an increase in slope after the original deformation as showed in Figure 5. Finally, the load decreased suddenly because the crack started from the mid-plane under the loading head. The failure of the specimen occurred. The GFRP bar could still carry some load because of flexural strength of the sample after ultimate failure. At the same time, the crack width also increased gradually. This specimen showed a vertical plane of failure (plane of load) with crack perpendicular to the cross-section of the rod as illustrated in Figures 6 and 7.

![Figure 4 Failure GFRP specimen](image)

![Figure 5 Cross section of GFRP](image)
According to ASTM D4475-02, shear strength was determined by the equation (1):

\[ S = 0.849 \frac{P}{d^2} \]  

(1)

where S is the apparent shear strength, P is the breaking load, and d refers to the nominal diameter of the FRP bar. Due to lack of the original test data of the SBS prior to construction of this bridge, this paper referred to the interlaminar shear strengths of control and in-service specimens that were extracted from Sierrita de la Cruz Creek Bridge (built in 2000, located 25 miles Northwest of Amarillo, Texas) to serve as a comparison. Table 1 illustrates the results.

Conversion Units: 1 in = 25.4 mm, 1 lb = 4.448N, 1 psi = 0.0069 MPa

These GFRP bars were produced by the same manufacturer at different periods. Even if there were no original data of SBS to refer for Southview Bridge, the in-service samples still suggests that shear strength of GFRP bar shows a decreasing trend compared to average results of control for the Sierrita de la Cruz Creek Bridge. It may suggest that the GFRP bar was deteriorative under the long-term exposure to concrete environment. However, the chemical composition of fiber/resin, different ratio of fiber and resin, or other parameters may vary for different production lots. The shear strength of control samples for Sierrita de la Cruz Creek Bridge can only be considered as a reference. Additional SBS tests will be needed to investigate the interlaminar shear property of GFRP bars so it is suggested that a suite of tests be done at the time of construction to set a baseline for future sampling.

Burn off Testing

First of all, the muffle furnace without GFRP samples was heated until 600°C (1112°F). Secondly, three small samples with substrates that were obtained from two GFRP bars were put into the muffle furnace to heat until all resin had disappeared. The duration of this test was about 7 hours. The content of resin was calculated. Samples prior and after burn off testing are illustrated in Figure 6.

![Figure 6 Samples prior (left) and after (right) burn off testing](image)

Detailed information of GFRP samples before and after test is illustrated in Table 2.

Conversion Units: 1 g = 0.0022 lb
From Table 2, it can be observed that the percentages of resins have no difference between these samples. This paper also referred to the test data of the control specimens (80.5%) and in-service samples (79.7%) of Sierrita de la Cruz Creek Bridge. The average fiber content of GFRP samples for the Southview Bridge shows a lower fiber content compared to the control and in-service samples of Sierrita de la Cruz Creek Bridge. However, they were still above the minimum fiber content standard requirement of 70% by mass based on AC 454 (AC 454 2015).

**T<sub>g</sub> Measurement of GFRP bar**

Moisture in the matrix would reduce T<sub>g</sub> of the resin through plastification if the Van der Waals bond between the polymer chains is broken. The swelling stresses are able to result in permanent damage in the epoxy of GFRP bar such as matrix cracking, hydrolysis, and fiber-matrix de-bonding when the composite material uptakes moisture or alkalis present (Mufti et al 2007).

Differential Scanning Calorimetry (DSC) was used to evaluate the T<sub>g</sub> of the resins of surface and interior of the GFRP bar. It was found that the surface and interior of GFRP bar presented temperatures of 95.3°C (203.5°F) and 92.3°C (198.1°F) respectively.

**PH Measurement of Concrete**

Two different locations of concrete were selected to measure the pH values. The concrete of the first spot that was not ground by sand paper was the transition zone between concrete and GFRP bar. The fresh distilled water was put onto this surface. The pH value of this location was evaluated by pH strip and was about 9 as illustrated Figure 7.

In addition, the second location was selected as illustrated Figure 8. This concrete surface was ground and cleaned. The same fresh distilled water was still utilized and put onto the ground surface. The pH value of this location was 12 showing variation in the measured values.

The pH value of the ground surface was in agreement with the report from University of Miami (Gooranorimi et al 2016).
CONCLUSIONS

Durability of GFRP bars in existing FRP bridge structures exposed to the field environment is studied by using physical and chemical tests including SBS test, burn off test, and $T_g$ measurement of GFRP bars, and pH measurement of concrete. Concluding remarks are summarized as follows:

- According to ASTM D4475, short bar shear (SBS) test is performed in order to study resin properties of GFRP bars exposed to concrete environment. The horizontal shear strength results may provide a measure of resin damage. Micelli and Nanni (2004) studied transverse properties of GFRP rods. The results showed that failure loads of these rods decreased after they were exposed to alkaline solution. In this study, therefore, GFRP bars might be affected by hydroxyl ions (OH$^-$) in concrete. It is necessary that more SBS tests of GFRP bars need to be conducted to further investigate this property of resin to obtain more accurate results. Furthermore, FTIR evaluation will be conducted as supplemental investigation.

- Fiber content by mass should be more than 70% based on the report of manufacturer (Hughes Brothers), which was verified through this evaluation post installation.

- According to the manufacturer report, the glass transition temperature ($T_g$) or the temperature at which the resin changes from a “glassy state” and begins to soften is 110°C (230°F), which is higher than the results measured in this study. It is necessary that more investigation such as EDX microscopic studies be undertaken to better understand any changes in the chemical characteristics.

These measurements above cannot prove whether in-service GFRP bars have deteriorated after 11 years of service as concrete reinforcement in the Southview Bridge. In order to understand sufficiently their properties, SEM and EDX analyses will be performed to investigate whether there are some damage of glass fiber, resin, and fiber-matrix interface and identify existing chemical elements in GFRP bars as phase II work. In addition, Fourier transform infrared (FTIR) spectroscopy will be conducted in subsequent study to investigate the amount of OH$^-$ in GFRP sample.

ABSTRACT

This paper summarizes the deployment of fiber reinforced polymer (FRP) composites in the form of fabric, laminates, and rod panels over the past fifteen years on twenty eight reinforced concrete, prestressed concrete, and steel bridges throughout Kentucky. The field applications of FRP composites include: (1) retrofit of PC beams in shear using unidirectional carbon fabric; (2) flexural strengthening of concrete and steel beams using CFRP laminates; (3) retrofit of cracked ends of PC I-beams using carbon fabric; (4) retrofit of cracked PC box beams using carbon fabric; (5) retrofit of impacted PC beams with CFRP Rod Panels; (6) retrofit of cracked concrete pedestals using carbon fabric; and (7) retrofit of impacted concrete piers and pier caps using carbon fabric. This paper highlights eight case studies, each of which includes an in-depth discussion of the retrofit techniques used.

KEYWORDS

CFRP, beam strengthening, bridge retrofit, carbon fabric, laminates, rod panels.

INTRODUCTION

Fiber reinforced polymer (FRP) composites — especially carbon FRP fabric and laminates — are becoming the primary choice to strengthen damaged structural components or upgrade structures. FRP materials have several benefits, including a high strength-to-weight ratio, resistance to corrosion, can be adhesively bonded, and higher moduli of elasticity than concrete. The low transportation and handling costs of FRP materials, as well as their low application and labor costs, reduce overall project expenditures when they are used. Compared to traditional repair methods, FRP is less disruptive to regular service during the repair process. Furthermore, repairs that employ FRP contribute minimal additional dead load to the structure.

Table 1 lists, in chronological order, all of the bridge retrofit projects carried out by the authors. Specifics on the damage type, the repaired/strengthened member type, and retrofit material are provided as well. Several of the bridge retrofit projects highlighted in Table 1 include the first field application of CFRP Rod Panels (CRPs), the second field application of Ultra High Modulus (UHM) CFRP laminates for steel girder strengthening, and the first civil engineering applications of quasi-isotropic braided triaxial carbon fabric. The following sections discuss selected projects from Table 1 in more detail, where the applications have been categorized based on the type of deficiency and/or strengthening carried out along with the type of material used.

</table>
SHEAR STRENGTHENING
KY 3297 Bridge, Carter County

A routine inspection on this 3-span bridge revealed that significant diagonal shear cracks up to 29 mm wide and 1.8 to 2.4 m long had formed in all precast prestressed box beams (Fig. 1) at both ends of Span 2. Subsequent inspections revealed that the shear cracks in Span 2 were propagating at an alarming rate, and new shear cracks were also developing in Spans 1 and 3. In addition, the re-evaluation confirmed that the box beams were under-reinforced in shear. The retrofit was performed in two phases: (1) crack repair; and (2) application of CFRP fabric. The application of CFRP fabric was expected to strengthen and compensate for the shear deficiency.

When the cracks were initially discovered, the bridge had an estimated remaining life expectancy of three to five years. The application of the CFRP system only required the use of light construction kits and tools; no heavy machinery was used throughout the entire process. Another positive aspect of this particular project was that the impact on daily traffic was kept to a minimum while work was being performed underneath the bridge. When the project was carried out in 2001, the cost for the repair and 3 years monitoring was US$ 105,000, whereas replacing the superstructure would have cost, at minimum, US $600,000. Fifteen years after the retrofit, no crack movement or new cracks have been reported on the bridge.

FLEXURAL STRENGTHENING
KY 3 (Louisa-Fort Gay) bridge, Lawrence County

The Louisa-Fort Gay Bridge is a 12-span continuous bridge structure consisting of composite concrete deck-steel girder spans and reinforced concrete (RC) girder middle spans that comprise an intersection for traffic coming from three different directions. Bridge inspection indicated that flexural cracks had developed in the RC girders due to heavy coal truck loads. Weigh-in-motion scales measured trucks that weighed in excess of 1000 kN. Further evaluation confirmed that most of the reinforced concrete girders were stressed beyond the allowable service limits specified by the American Association of State and Highway Transportation Official Specification (AASHTO, 1998). The amount of CFRP laminates needed to strengthen the beams was determined via moment-curvature analyses (Choo and Harik, 2007). Figure 3 captures the underside of Span 4 following the laminate application. Similar to the Carter County bridge, there were minimal impacts on daily traffic during construction. The cost savings were considerable — the retrofit and three years of monitoring cost just US $195,000. Alternatively, it would have cost over US $2 million to construct a new bridge. The experience gained through the project on
application of CFRP laminates over long spans, considering man power, equipment and work time of epoxy adhesives, was instrumental in the development of CFRP Rod Panels that facilitates modular construction.

KY 32 Bridge, Scott County

The KY 32 Bridge over Lytles Creek, is a single span steel girder bridge with a non-composite reinforced concrete bridge deck. A load posting of 124.6 kN (14 ton) was on the bridge before strengthening. While ultra high modulus (UHM) CFRP laminates were considered for improving the load carrying capacity of the beams, a preliminary analysis indicated that, due to the non-composite deck, the increase would be minimal and the laminates would not be used in an effective manner. To utilize the laminates more effectively, shear studs were post installed between the steel girders and the concrete deck to make the bridge deck act partially composite with the girders. The number and location of the shear studs were evaluated to obtain maximum partial composite action while using the fewest number of studs. After the shear studs were set into place, UHM CFRP laminates were applied to the top and bottom of the bottom flange of the steel girders (Fig. 3). Field tests were conducted before and after the installation of the shear studs to verify the effectiveness of post installed shear studs (Peiris and Harik, 2015a). Field tests were carried out after the laminate application to determine the increase in the load carrying capacity and the reduction in maximum deflection after the strengthening. The combination of post-installed shear studs and UHM CFRP laminates increased the bridge’s load rating factor from 0.46 to 1.21, which permitted the removal of the load posting.

PC I-BEAM END STRENGTHENING

I-65 Elevated Highway Bridges, Louisville KY

A number of vertical cracks located near or at the supporting piers developed on many of the AASTHO Type II prestressed concrete (PC) girders between Jacob Street and Chestnut Street. Preliminary investigations indicated that the cracks may have developed due to shrinkage and temperature loading. The cracks were especially apparent at piers with fixed restraints, where the axial shortening of girders is prevented. Prior to retrofitting, the two widest cracks on two PC girders were instrumented with linear variable displacement transducers (LVDTs) to monitor the vertical and longitudinal movements. The bridge was monitored over a period of six months. The readings indicated that the cracks were very active but stable. This permitted the design of a simple and cost effective retrofit that will be continuously monitored from a remote location. A single layer of unidirectional carbon fabric was applied along the length of the beam at the crack locations, while additional strengthening in the form of vertical U-wraps were added at locations with multiple cracks and concrete spalling. After the repair, the two crack locations that had been monitored previously were again instrumented with LVDTs to gauge the repair’s effectiveness (Fig. 4).

The repair caused no traffic disruptions and utilized no heavy equipment. The carbon fabric retrofit extended the service life of the structure. Alternatives to the retrofit included the construction of new piers, the extension of existing pier caps, or replacement of the damaged section of the I-65 expressway. Given the number of crack locations, any one of these alternatives would have cost more than US $1 million. The combined use of remote monitoring and using lightweight CFRP fabric for the retrofit was the most cost effective and efficient solution to repair the cracked girders.
PC BOX BEAM STRENGTHENING
KY 100 Bridge, Simpson County

The two span PC box girder bridge on KY 100 over the CSX railroad had multiple beams with several cracks close to the abutments and the center pier. The cracks were thought to be due to uneven settlement of the abutments/pier, leading to slight out-of-plane twisting of the superstructure. Most of the cracks were primarily diagonal, originating from the top of the beam. However, several vertical and horizontal cracks, as well as inclined cracks, were also present. While bi-axial carbon fabric was initially considered for the retrofit, in order to address the cracks in multiple directions, a quasi-isotropic braided triaxial (0°, +60°, -60°) carbon fabric was used to strengthen the beam. Figure 5 shows a retrofitted PC box girder following application of the carbon fabric. The triaxial carbon fabric facilitated the use of a single layer of fabric to achieve the required amount of strengthening in multiple directions, reducing construction time, material, and labor costs.

IMPACTED BEAM RETROFIT
Sunny-side Gotts Road Bridge, Warren County

An AASHTO Type III precast girder of the four span bridge on Sunnyside-Gotts road over Interstate 65 was damaged by an over-height truck impact. The damaged section spanned the two right lanes of the northbound three-lane interstate highway. The over-height truck impact produced considerable concrete spalling, severed two prestressing strands, and damaged several wires in two more strands (Fig. 6). The retrofit replaced the lost concrete and installed CFRP Rod Panels (CRPs) to replace the capacity loss due to the damaged prestressing strands. CRPs were attached to the structural member as externally bonded reinforcement. Each panel is approximately 1.2 m long and is made of a number of small diameter rods that are attached to a glass fiber mesh, which is intended to facilitate handling of the panels and to retain a uniform spacing between rods. In the field, the panels were connected through a finger joint lap-splice to form a continuous externally bonded reinforcement and fulfil the strengthening length. CRP 195 panels, with CFRP rods of 4 mm diameter able to carry 867 kN (195,000 lbs) per 300 mm (1 ft) width of panel, were selected for the strengthening.

Because the bridge was over a major interstate, the retrofit was carried out at night to minimize traffic disruption. The use of CRPs provided several advantages over regular CFRP laminates due to the location and nature of the retrofit being over multi-lane traffic. Because CRP construction is modular, the retrofit could be stopped after installation of any CRP panel as long as the splice length of the last panel was kept void of epoxy. This is advantageous when impact damage spans multiple lanes of traffic, where the retrofit can proceed in stages, with strengthening occurring over one lane at a time. Using the CRPs also meant application could be executed with a two-person crew working out of a truck mounted mobile platform or man-lift. This eliminated the need for a larger crew and multiple pieces of access equipment or scaffolding that would be required for a similar retrofit using CFRP laminates.

CONCRETE PEDESTAL STRENGTHENING
Pier 6, I-65 Elevated Highway Bridges, Louisville KY

Bridge Pier 6 is located at the intersection of Main Street and Hancock Street. The six interior pedestals of the eight reinforced concrete pedestals showed signs of damage; with one in particular experiencing severe loss of concrete cover and exposure of reinforcing steel. The damage to the concrete pedestals was attributed to de-icing...
agents falling through the expansion joints over the piers. The pedestals posed a unique challenge as they were irregularly shaped (i.e., neither circular nor rectangular). Their unique shape rendered traditional wrapping techniques obsolete because the expansion of the pads would not have been confined by such wrapping. To surmount this obstacle, a prism (i.e., one of the corners) was sheared off of the bearing pad so that it could be confined by the wrapping. The objective of using carbon fabric wrapping was to improve concrete confinement and thus increase the pedestal’s load carrying capacity. Figure 7 shows a pedestal after loose concrete had been removed.

**IMPACTED CONCRETE PIERS**

**Elrod Road Bridge, Warren County**

The pier column of Elrod Road Bridge over Natcher Parkway was impacted by a truck, which resulted in cracking of the column and pier cap. The primary retrofit involved wrapping unidirectional carbon fabric around the column. An additional layer of triaxial carbon fabric was wrapped over the joints of the unidirectional fabric for confinement (Figure 8). The strengthening is expected to increase the load carrying capacity of the column more than 300%, from 2448 kN when unconfined to 8105 kN for the confined column.

![Figure 7 Deteriorated pedestal](image1)

![Figure 8 Carbon fabric application](image2)

**CONCLUSIONS**

FRP composites were used to retrofit several bridges in Kentucky because they offered significant economic advantages over other retrofitting alternatives. Carbon fabric wrapping was found to be an effective method for retrofitting for shear, concrete piers, pier caps and pedestals, and deteriorated or damaged PC and RC beams. CFRP laminates proved to be an efficient strengthening technique for RC and steel beams where the underside of the bridge is easily accessible. CRPs were efficient for retrofitting impacted and deteriorated concrete bridge beams with limited access. Based on the success of the projects listed in Table 1, FRP retrofit, where applicable, has become the primary choice for retrofits in Kentucky.

ABSTRACT

An inspection path for highway bridges has been developed using pultruded GFRP members. The proposed bridge inspection path is a trussed girder type with a sandwiched panel floor made of GFRP and urethane foam. In this study, the inspection path with 10-m long span was developed and fabricated in order to apply to a steel plate girder bridge with a long interval of cross beam. The validity and usability of structural design was investigated by various loading tests using a full-scaled model. As a result of static loading test, it was found that the deflection limitation of 1/600 for the span length was roughly satisfied, and the result of some vibration test demonstrated that the uncomfortable vibrations did not occur. Therefore, it was confirmed the developed trussed-girder-type inspection paths had the required rigidity and safety, and was feasible to the practical use.

KEYWORDS

GFRP, inspection path, trussed girder, sandwich panel slab, static, dynamic and impact loading test.

INTRODUCTION

In Japan, many highway steel bridges are suffering from aging and need maintenance procedure. Current maintenance system of bridges requires close visual inspection once every five years (MLIT 2014) and installation of inspection paths is required. In particular, an inspection path using pultruded GFRP trussed girder has been developed for the highway bridges in order to effectively utilize the advantages of FRP (Ishii et al. 2016). The proposed bridge inspection path is a trussed girder type with a sandwiched panel floor made of mainly GFRP and urethane foam to increase the rigidity and reduce the weight. In addition, extension of the distance between the panel points with the same length and angle of diagonal member makes it possible to be applicable to various span.

Recently, the application of a steel plate girder bridge with the long interval of cross beams as the distance between them of 10m is gradually increasing to reduce cost associated with fabrication and construction. Considering such circumstance, an inspection path that its span is expandable to maximum span of 10m is required.

Therefore this paper deals with the serviceability and the safety of the inspection path with 10-m long span in order to apply to a steel plate girder bridge with a long interval of cross beam.

OUTLINE OF TRUSSED INSPECTION PATH WITH 10-M LONG SPAN

Design conditions of inspection path

Table 1 shows the design conditions of the inspection path. Nippon Expressway Company determines the standards for a FRP inspection path by references to existing FRP inspection path and R & D (Furuya et al. 2015). In this study, this standards were applied and the design live load (3.5kN/m²), the vertical and horizontal loads to a handrail and the required size for serviceability are shown in Table 1. The value of the deflection limitation for
inspection paths is 1/100 for a span length in this standards. However, considering the serviceability, the value of 1/600 for a span length was used in this study. The value is also used for a general footbridge (JSCE 2011).

### Proposed trussed girder type with a sandwiched panel floor

Figure 1 shows the general view of GFRP trussed inspection path with 10-m span length. GFRP channel profiles of C75 (H75×B40×t5.0 mm), which are composed of roving glass fibres, are used for upper and lower chords, diagonal and vertical members. GFRP square pipes of SP60 (H60×B32×t4.0 mm) are used for a horizontal member which is non-structural member. All the GFRP members are pultruded.

The floor slab is made of lightweight sandwich panels and Figure 2 shows the cross sectional view of sandwich panel floor slab. It is fabricated as follows: First, two GFRP channel profiles of C75 as a lower chord place on both sides and 2 mm thick continuous-molding GFRP skin plates are fixed on the top and bottom of lower chords. Then, interior of the floor slab is filled with hard urethane foam as a core material. Finally, toe-plates cut out from GFRP channels of C100 (H100×B50×t5.0mm) are fixed to both edges of the upper surface of the floor slab to prevent instruments and tools from falling down. It also affects to reinforce the joints and increase section rigidity.

GFRP angle members cut out from GFRP channels of C75 are installed at the panel points of the lower chord to reinforce the joints. The panel points are connected with stainless steel (JIS SUS305) blind rivets and adhesives. It is effective method for connection of closed section. Table 2 shows the material properties by coupon tests. The material test was conducted on the basis of Japanese Industrial Standards (JIS).

PERFORMANCE VERIFICATION TEST FOR INSPECTION PATH

Evaluation of deflection under design live load

In order to evaluate the deflection under design live load, the static loading test was conducted as Figure 3. Sandbags equivalent to 3.5kN/m² were placed on the floor slab and its vertical deflection was measured.

Figure 4 shows the distribution of vertical deflection under design live load. The maximum deflection was 17.11mm at the center of the span. It was found that the experimental values were slightly larger than the analytical values based on FEA. However, the value of deflection limitation (L/600) for the span length was roughly satisfied.

Analytical evaluation of safety under design live load

In order to examine the safety of GFRP trussed inspection path with 10-m span length under design live load, FEA was conducted. According to the results of GFRP trussed inspection path with 6-m span length in previous study (Ishii et al. 2016), it has been found that relationships between the applied load and displacement at the center of the span are shown in Figure 5. When the applied load was approximately 50 kN, the shear failure occurred at the panel point of the upper chord as shown in Figure 6. Figure 5 shows that the analytical result is different from the experimental result after shear failure. Therefore, maximum load of GFRP trussed inspection path with 10-m span length was evaluated by the maximum shear strain of 8484 (×10⁶) in previous study. In addition, it has been found that the experimental axial strains at the panel point of the upper chord was sufficiently smaller than the failure strain in material test.

The deformation of GFRP trussed inspection path with 10-m span length under design live load is shown in Figure 7. The focused point in Figure 7 also shows the panel point of the upper chord where the maximum shear strain was confirmed. Figure 8 shows the analytical relationships between the applied load and the shear strain at the focused point. From the result in Figure 8, the applied load which was compatible with the shear strain of 8484 (×10⁶) was 60.47kN. Therefore, it was found that the predicted failure load was 60.47kN. Also, the predicted failure load was 2.94 times higher than the design live load of 3.5kN/m².
Vibration characteristics of inspection path

In order to examine the vibration characteristics of the inspection path, some vibration tests were conducted. Figure 9 shows set-up of the vibration test. Sandbags weighing 20kg, 40kg and 60kg respectively, were hanged at the upper chord level of 1.1m in height, and then dropped on the center of the floor slab as free vibration method. Natural frequency was measured with accelerometers at under surface of the floor slab and the upper chord.

The first natural frequency calculated by vibration tests is shown in Table 3. The minimum natural frequency was 5.43Hz, which was higher than that of uncomfortable vibrations to humans (the range of 1.5Hz to 2.3Hz). Therefore, it was confirmed that natural frequency of the proposed inspection path satisfied the vibration serviceability.

Safety of handrail member under static load

Using the inspection path for safety checks, workers will lean on or step on its handrail. Considering such circumstance, in order to examine the safety of handrail members, the vertical and horizontal static loading tests were conducted. Sandbags equivalent to 0.59 kN/m were placed between the panel points of the upper chord as Figure 10 (a). The maximum strain of each member under the vertical static load was measured. Moreover, the maximum strain of each member under the horizontal static load was also measured with the concentrated load equivalent to 0.39 kN/m. Its load was statically applied to the panel point of the upper chord by using a screw jack as Figure 10 (b).

**Resistance of handrail member to impact load**

In order to examine the resistance of the handrail member to impact load as the maximum applied load considering the accidental fall of inspectors, impact loading test was conducted as Figure 11. The conceptual diagram of impact loading test is shown in Figure 12. A sandbag weighing 85 kg was connected to the handrail through a safety belt and dropped from upper chord level.

As a result, Figure 13 shows the damage to a handrail member after impact loading test. A crack occurred at the corner located between the upper flange and the web of the upper chord. However, there were no failure of members and no damage to panel points. Additionally, the handrail member prevented the sandbag as an inspector’s weight from falling to the ground.

Table 5 shows the measured maximum strain under impact load. From the result in Table 4, each measured strain was smaller than the failure strain of 15,000 (×10⁶) confirmed by material test. Therefore, it was confirmed that handrail members possessed sufficiently safety for the fall of inspectors.

CONCLUSIONS

In this study, the inspection path with 10-m long span was developed and fabricated in order to apply to a steel plate girder bridge with a long interval of cross beam. The performance verification test using a full-scale model was conducted to confirm the serviceability and the safety of the inspection path. The following conclusions were obtained:

(1) In static loading test under design live load, it was found that the deflection limitation of 1/600 for the span length was roughly satisfied. Also, the estimated strength of the proposed inspection path by FEA was sufficiently higher than the material strength under the design live load.

(2) In some vibration tests, the minimum natural frequency was higher than that of uncomfortable vibrations to humans. It was confirmed that the natural frequency of the proposed inspection path satisfied the vibration serviceability.

(3) In vertical and horizontal static loading tests, the strength of the handrail member possessed sufficiently higher strength under its design load.

(4) In impact loading test considering the accidental fall of inspectors, partial damages occurred at handrail members. However, it was confirmed that handrail members did not fall and possessed sufficiently safety for the fall of inspectors.

Therefore, it was confirmed the developed trussed-girder-type inspection paths with 10-m long span possessed the required rigidity and safety, and was feasible to the practical use.

ABSTRACT

This paper presents a project in Hong Kong for bridge strengthening using fibre-reinforced polymers (FRP) and this is the first case approved by the local authority. Old structures often need repair and strengthening to stay in a serviceable condition and this paper reports on the strengthening of a 30-year old pre-stressed concrete bridge to satisfy the new building regulations in Hong Kong. Due to site constraints, a combination of post-tensioning and fibre-reinforced polymeric technology was used. In this paper, the design basis is presented and details for implementation are highlighted, including selection for materials, method of installation, fire proofing, full load testing and monitoring. To demonstrate the success of the works, full load-testing and several long-term monitoring techniques were designed and installed including optical fibre strain measurement. Since the completion of the strengthening works, long term monitoring has been carried out. The long term monitoring results show that the FRP is in a good condition after 5 years.

KEYWORDS

FRP, bridge, strengthening, long-term monitoring.

INTRODUCTION

Swire Bridge is located at the Main Campus of the University of Hong Kong. This bridge was constructed in 1970s. It consists of a two-lane carriageway and a footpath and serves as the main vehicular and man access to the eastern part of the campus from the central part. The total length of the bridge is 52.5m. It consists of three continuous spans supported by two end abutments and two intermediate piers. The main span is 22.5m and the two side spans are 15m. The bridge deck is constructed with prestressed concrete with internal tendons passing through the bridge deck. Bridge piers and abutments are conventional reinforced concrete structures and they are supported by bored piles.

Swire Bridge is an emergency vehicular access and truck access. Current trucks and emergency vehicles can weigh 28ton or more. However, the bridge is designed to resist a live load of 20 ton originally. Therefore there is a need of upgrading the bridge to accommodate the latest live load requirement.

A design check was conducted to assess the existing capacity of the bridge, including overall stability and load capacities of different structural elements. Design check results showed that while the bridge was of sufficient overall stability and loading capacity to resist the increased load in the ultimate limit state, the bridge deck failed to pass the serviceability limit state requirements. For example, the tensile stress would excess of the allowable value of 2.4MPa. It was anticipated that the bridge deck would be of excessive deflection and have potential cracking problem. Excessive deflection and cracks would affect the durability of the structure by allowing corrosive substances, e.g., oxygen and moisture, penetrating into cover of concrete. The risk of corrosion of steel reinforcement would increase. Severe steel corrosion would lead to delamination of concrete cover and spalling problems, reducing the life of the bridge deck. In extreme case, if the existing prestressing tendons are corroded, the prestressing force would reduce, causing detrimental effects to the loading carrying capacity.

To control the potential deflection and cracking problems in the bridge deck at service load, a combination of prestressing and fibre-reinforced polymeric (FRP) technology was used, the latter of which formed the first project case approved by the Hong Kong building authority. Due to the pioneer nature of the project, full load-testing and several long-term monitoring techniques were designed and installed including optical fibre strain measurement. In this paper, the design basis is presented and details for implementation are highlighted, including selection for
materials, method of installation, fire proofing, full load testing and monitoring. Finally the test results are presented and long-term monitoring data discussed, from which some preliminary conclusions are drawn.

**STRENGTHENING DESIGN CONSIDERATIONS**

**Strengthening Methods Selection**

During the project design stage, various strengthening methods were considered with a view to increase the bridge’s performance in deflection and cracking at service load. The potential strengthening methods include span shortening, installation of additional steel frame or additional concrete layer, strengthening with fibre-reinforced polymeric (FRP), additional prestressing, etc. Each method has its own characteristics and hence strengths and shortcomings. During the selection process, preference was given to the method with minimal visual impact and ease of application. Span shortening and additional steel frame would cause substantial change in bridge’s appearance and hence are rejected. Additional concrete layer would affect road profiles of adjacent access roads and it is not preferred to have extensive modification works to these adjacent roads. FRP strengthening is the most preferred method since it can maintain the original appearance of the bridge and the application method is simple. However, FRP strengthening is able to resist additional load only. To reduce deflection and control cracks caused by existing dead loads, the method of prestressing is preferred. Therefore, after careful considerations, both FRP and prestressing technologies are selected as a combined strengthening solution. By adopting this strengthening method, the cracking and deflection of the bridge will be better controlled. Under extreme loading conditions, the bridge will not be subject to excessive deflection and cracking. Corrosive substances such as carbon dioxide and moisture cannot penetrate through concrete cover into steel reinforcement and prestressing tendons. The durability of the bridge is hence better assured and the service life is extended.

**Strengthening Materials**

The two common FRP materials for structural strengthening applications are glass fibre reinforced polymer (GFRP) and carbon fibre reinforced polymer (CFRP). Typical tensile properties of FRP materials can be found in design guidelines in Concrete Society – Technical Report No. 55 Design Guidelines for Strengthening Concrete Structures using Fibre Composite Materials, Second Edition. In general, tensile strength and modulus of CFRP are higher than those of GFRP. To satisfy the performance requirement, the higher stiffness material, i.e., CFRP, is preferred, so that the composite section has a higher overall stiffness against bending and hence deflection and crack control.

Consideration is also given to durability performance. Both GFRP and CFRP do not have corrosion problem since they are non-metallic materials. The identified deterioration mechanisms of FRP materials are degradation due to ultra-violet light and damage in case of fire. In this case, a fire insulation layer is used to protect the installed FRP against fire and block the ultra-violet light. Since that the durability performances of two FRP materials are similar but CFRP has a better loading performance then GFRP. Therefore CFRP is adopted for this project.

For the prestressing tendon, prestressing bars with higher tensile load capacity are selected. To prevent corrosion, heat shrinkable plastic tubes are adopted. The plastic tubes serve as physical barriers which block water and moisture from going into the steel surface so that corrosion will not occur.

**Strengthening Design**

According to Buildings Regulations of Hong Kong, any structural alternation and additional works shall be approved by Buildings Department. To obtain this approval, submissions with full justifications are needed. The required submissions include structural strengthening design, quality control proposal, materials’ durability data, etc.

This project involves a bridge structure and therefore the bridge’s structural analysis is in accordance with “BS 5400 – Steel, Concrete and Composite Bridges” and “Highways Department – Structures Design Manual”, both of which are design manuals common adopted in Hong Kong. For the design of FRP, since there is no available British Standards or Hong Kong standards, two design guidelines, namely “Concrete Society – Technical Report No. 55 Design Guidelines for Strengthening Concrete Structures using Fibre Composite Materials, Second Edition” and “The International Federation for Structural Concrete – Bulletin 14 Externally Bonded FRP Reinforcement for RC Structures” are adopted. As a conservative approach, the FRP design is checked against these two design guidelines so that requirements from both guidelines are satisfied. It was calculated that, after strengthening, the tensile stress of the concrete structure would be the allowable limit of 2.4MPa.
The adopted FRP material was a carbon fibre reinforced polymer plate of 1.4mm thick. The tensile strength of the material was 2,510MPa with a Modulus of Elasticity of 139GPa.

Quality control and durability of the materials are two main concerns during the approval process, especially the FRP material since this material is the first time being approved by the Buildings Department of Hong Kong. As parts of the approval conditions by Buildings Department, a series of quality control tests on the FRP system is required, including tensile tests for tensile strength, pull off tests for adhesion, tapping tests for void identification, verification load test and structural health monitoring, etc. Among these tests, verification load test and structural health monitoring are discussed in more details in the following text.

**SYSTEM INSTALLATION AND VERIFICATION LOAD TESTS**

The installation of strengthening systems started in 2008 and was completed in July 2009. The installation was in accordance with the following procedure. References were made to “Concrete Society – Technical Report No. 55 Design Guidelines for Strengthening Concrete Structures using Fibre Composite Materials, Second Edition” and “Concrete Society – Technical Report No. 57 Strengthening Concrete Structures using Fibre Composite Materials: Acceptance, Inspection and Monitoring”. Some photos showing different steps of installation and the verification load tests are also given.

(i) Conduct verification load test before strengthening systems’ installation
(ii) Conduct tensile test for FRP material as quality control
(iii) Construct anchorage blocks for prestressing bars, which were reinforced concrete blocks attached to the existing bridge structure.
(iv) Install prestressing bars and stress them in stages
(v) Install corrosion protection system to prestressing bars
(vi) Install CFRP plates on bridge soffit (Figure 1).
(vii) Conduct quality control tests to CFRP plates, including pull off tests, tapping tests, etc.
(viii) Conduct verification load test after strengthening systems’ installation (Figure 2 & 3)
(ix) Install optical strain gauge system
(x) Apply a proprietary fire rated fire protection layer to CFRP plates
(xi) Completion of works (Figure 4)

PERFORMANCE MONITORING

The method of FRP strengthening was the first time approved by the Buildings Department in Hong Kong. Due to the pioneer nature of the works, a comprehensive structural health monitoring programme is implemented to monitor the structural health of the bridge and the strengthening system, including visual inspection, pull off test and optical strain monitoring.

Visual inspection is carried out to the whole bridge soffit, including the external prestressing system and CFRP system, with the aid of binoculars if necessary. If defects are observed, such as spalls, cracks, signs of corrosion, they will be recorded.

Pull off tests are carried out to verify the bond strength of CFRP plates over time. In addition to the required CFRP plates in accordance with the design, extra CFRP plates are installed at the bridge soffit, known as the Sacrificial Zone. Pull off tests are conducted to the CFRP plates at the Sacrificial Zone at the required time. Bond strength of CFRP plates are then determined.

Pull-off tests were carried at Year 2 and Year 5, i.e. 2012 and 2015. The test locations are shown in Figure 5 below.

![Figure 5 Locations for pull-off test](image1)

Optical strain gauges are installed on the CFRP plates at six locations as required by the Buildings Department. The strain gauges’ locations are shown in Figure 6 below. Cables from sensors are routed to a termination box located at the soffit of the East Span. During a standard monitoring, a readout unit is connected to the sockets on the test station and send optical signals to the sensors for measurement. Monitoring results are displayed on the laptop computer connected to the readout unit. The data obtained are wavelengths in the unit of nano-metre (nm). With formulas and parameters from the optical strain gauge supplier, the measured wavelengths are then converted to change in strains.

![Figure 6 Locations of optical strain gauges](image2)
Selection of Strain Gauges

During the selection of strain monitoring method, several types of strain gauges were considered, including electrical resistance gauge, demountable mechanical gauge and optical strain gauge.

An electrical resistance gauge is in the form of a flat grid of wires mounted on a thin plastic sheet. Strain is measured by means of changes in electrical resistance resulting from extension and compression of the gauge. Electrical resistance gauge is the most common type of strain gauges. However, an electrical strain gauge is made of metal or alloy which is prone to corrosion. It is not suitable for the use in an exposed environment for a prolonged period. Therefore this type of strain gauge is not adopted for this project.

A demountable mechanical (demec) gauge consists of a sensitive dial gauge mounted on a steel bar with a pivoted pointer at one end. This gauge is used to measure the relative movement between two studs attached to the surface concerned. When there is a relative movement, the studs cause the pivoted pointer to rotate which turn causes the dial to change. This method would depend on the skills of the technicians since the readings would be affected by the force pressing onto the studs. This method also requires accesses to the bridge soffit which is not available. Therefore this method is not adopted.

One of the most common types of optical strain gauges is Fibre Bragg Grating (FBG) sensors. A FBG sensor consists of an optical fibre containing a grating. During measurement, a light source with a range of different wavelengths is sent in the fibre. The wavelength corresponding to the grating pitch is reflected by the grating while all other wavelengths pass through the grating undisturbed. Since the grating period is strain dependent, measuring the reflected wavelength is able to determine the strain. An optical fibre is made of quartz, which is a non-metal and does not have corrosion protection. This type of sensors is suitable for outdoor conditions and is more durable. Considering that the monitoring programme will last for ten year, this monitoring technique is adopted.

Monitoring Frequencies and Acceptance Criteria

The monitoring frequencies of the above monitoring methods are summarized in Table 1 below:-

<table>
<thead>
<tr>
<th>Item</th>

</tbody>
</table>

Monitoring Results

Strengthening works of the bridge were completed in July 2010 and the structural health monitoring then started. Up to end of 2015, monitoring results of the first 5 years have been obtained.

Visual inspection showed that the conditions of the bridge soffit and the installed strengthening works appeared in good conditions. No signs of defects were observed during each visual inspection. Both the CFRP plates and the fireproofing system remained intact on bridge without any cracks, delamination or spalling.

Pull-off tests carried out at sacrificial zones in 2012 and 2015 are shown in Table 2. The average pull-off strength is 2.07 and 3.90MPa. Therefore, the results satisfied the 1.5MPa requirement by the Buildings Department. It indicated that, the adhesive of the CFRP was still in good condition without degradation after 5 years.

Optical strain monitoring has been conducted for five years. The changes in strains over time are shown in Figure 7 below. The changes in strains range between -0.048% and 0.005% and are well below the limit of 1.8%. Therefore, all visual inspection, pull-off test, and strain monitoring results show that the strengthened bridge is of good conditions.

CONCLUSIONS

In this paper, a case study of extending a concrete bridge’s service life using FRP strengthening and external prestressing is presented. Structural health monitoring is being implemented to the strengthened bridge. Monitoring results for the first five years are obtained successfully. The results show that the strengthened bridge is in good condition. It is concluded that the adopted strengthening system is effective.

ABSTRACT
In the last years, significant research in the context of bond of near-surface mounted (NSM) fibre reinforced polymer (FRP) systems in concrete has been conducted at the Department of Civil Engineering of the University of Minho. This paper presents a brief summary of the major results obtained in that research, namely in terms of durability, quality control and design topics. Accelerated ageing tests on NSM FRP bond specimens were conducted to simulate different environmental conditions. A new method was developed and applied to investigate the evolution of the adhesive stiffness and the bond behaviour of NSM systems for different curing conditions used for quality control of FRP installations. Regarding the bond design, two existing guidelines’ formulas were adapted to the partial safety factors framework.

KEYWORDS
Concrete, NSM, CFRP, Bond, Durability, Design.

INTRODUCTION
The near-surface mounted technique (NSM) is one of the most effective techniques to strengthen concrete structures in flexure, which presents several advantages when compared to the externally bonded reinforcement (EBR) that preceded it. The use of fibre reinforced polymer (FRP) as reinforcing material in the context of the NSM technique has significantly evolved in the last decades, both in terms of scientific investigations and practical applications (Coelho et al. 2015; Sena-Cruz et al. 2015).

One of the most critical aspects regarding the NSM technique is related to the bond behaviour of the composite system, i.e. the stresses transfer between concrete and the FRP reinforcement. To better understand that behaviour, bond tests have been carried out worldwide. Despite the existence of a manifold of test setups, those can be grouped in two main types: (i) direct (DPT) and (ii) beam (BPT) pullout tests (Coelho et al. 2015). The effectiveness and reliability of FRP-based strengthening systems depends fundamentally on the bond between the composite material and the concrete substrate. In recent years, the application of thermosetting resins in civil engineering applications has largely increased, mainly for their use in structural strengthening systems such as FRP reinforcements. The most common resins employed as structural adhesive for bonding FRP to structural elements to be strengthened are two-component epoxy resins (ACI 2008; Coelho et al. 2015; Sena-Cruz et al. 2015).

The lack of a comprehensive, validated, and easily accessible database about the durability and long-term performance of FRP systems (such as NSM FRP and EBR FRP systems) used in civil infrastructure applications has been identified as a critical barrier to widespread acceptance of these systems/materials by structural designers and civil engineers (Al-Mahmoud et al. 2014). Furthermore, the importance of developing procedures for quality control of FRP reinforcements, installation procedures and strengthening systems is recognized by several design guidelines (e.g. FIB 2001; ACI 2008). The development of methodologies could be essential to the definition of monitoring protocols for FRP installation and it could allow to quantitatively evaluate of its installation. Despite the significant research that has been conducted in the structural behaviour of NSM as a strengthening technique, there is not enough knowledge about the durability and quality control of NSM FRP systems, a critical aspect that must be taken into account when designing a structural strengthening. With the aim of improving the knowledge on these relevant issues, experimental research was developed.
Finally, in the absence of design formulations to estimate the bond strength of NSM FRP systems based on the Eurocodes philosophy, a design proposal was developed based on existing guidelines that were adapted to the partial safety factors framework.

**BOND DURABILITY OF NSM CFRP SYSTEMS**

**Experimental Programs, Test configuration and Materials**

In order to contribute for bridging the gap on the knowledge on durability of bond behaviour of NSM CFRP-concrete systems, an extensive experimental program composed of 23 series (each one composed of 4 specimens) of DPT tests was carried out to study the effects of different environmental conditions. In addition, the mechanical characterization of the involved materials was also assessed over the time. The specimens were firstly exposed to different environmental conditions for different periods of time ranging between 4 and 24 months, and then they were monotonically tested up to failure. The code name given to each series follows the format “Xn” where “X” defines the environmental condition (LE – laboratory environment; TW – tap water immersion; CW – immersion in water with chlorides; WD – wet/dry cycles in water with chlorides; TCA – thermal cycles with temperatures ranged between −15 °C to +60 °C; TCB – thermal cycles with temperatures ranged between +20 °C to +80 °C; FT – freeze/thaw cycles; real environments: REA – airborne salt/Mediterranean environment; REB – temperate environment), and “n” indicates the number of days/cycles that the series was submitted to the environmental condition (120, 180, 240, 480, and 720 days). For the case of the series TCA, TCB, FT, REA and REB in addition to the aged series, corresponding reference (R) series were also tested at the same time. The DPT specimens (see Figure 1a) consisted on concrete cubic blocks with 200 mm of edge, where a CFRP laminate with a cross-sectional area of 10 × 1.4 mm² was installed in a pre-cut groove opened in the concrete cover. The depth and the width of the groove were, respectively, 15 and 5 mm. A constant bond length of 60 mm, filled with the epoxy adhesive was adopted. The monotonic DPT tests were undertaken under force control at a load rate of 0.013 kN/s up to 10 kN and then under displacement control by a LVDT in loaded end section, at a rate of 2 μm/s. Mechanical properties of the CFRP laminate and epoxy resin are determined by performing the tensile tests (TT), while the mechanical characterization of the concrete was assessed by means of compression tests. Detailed information about the configuration of the DPT test, tensile tests on CFRP and epoxy adhesive and compressive tests on concrete, specimen preparation and ageing test procedures can be found elsewhere (Fernandes 2016).

**Results and Discussion**

The results obtained in the compressive tests on concrete specimens indicated an average compressive strength in cylinders, $f_{cm}$ of 36.0 MPa, with a coefficient of variation (CoV) of 3.9%, and an average Young’s modulus of 28.4 GPa (CoV = 5.8%), at 28-days of concrete age. However, due to the inclusion of fly ash (40% of the total binder content) in the concrete composition, the $f_{cm}$ continues to evolve up to one year of age; and, a maximum compressive strength of about 52 MPa (CoV = 2.5%) was achieved. Table 1 summarises the main results obtained in durability tests on the used CFRP and epoxy adhesive and the NSM CFRP-concrete system. In this table the meaning of each entity is the following: $f_{t_{FRP}}$ is the tensile strength of the CFRP laminate; $f_{t_{ad}}$ is the tensile strength of the epoxy adhesive; $F_{l_{max}}$ is the maximum pullout force of the bond system; $s_{l_{max}}$ is the slip at the loaded end at $F_{l_{max}}$. Table 1 also provides information about the failure mode (FM) of the bond tested specimens. Based on the obtained results, the following major observations can be drawn: (i) in general, all the environmental conditions investigated did not cause remarkable changes on the concrete compressive strength, except for the thermal cycles TCB which lead to a maximum reduction of 15%; (ii) CFRP samples presented negligible losses on their tensile properties when exposed to different environmental conditions; (iii) on the epoxy adhesive an increase up to 58% and 33% on the mechanical properties (tensile strength and elastic modulus, respectively) was observed, when the specimens were exposed to thermal cycles, due to a post-curing phase which occurs when temperatures higher than the ones experienced at the first curing are achieved. Contrarily, a significant reduction on its mechanical properties (up to 38% and 47% for the tensile strength and elastic modulus, respectively) was verified when the epoxy samples were submitted to wet environments due to water absorption (water uptake – plasticization phenomenon); (iv) the maximum reduction of about 12% on bond strength of the system was verified for the real environmental conditions (REA and REB); (v) thermal cycles between −15 °C and +60 °C improved the bond behaviour, with a maximum increase of 8% on bond strength; (vi) the effect of the exposure time also played an important factor on the degradation of bond properties, being greater on the specimens that aged for longer periods. It is important to note that the strong reduction on mechanical properties of the epoxy resin verified due to effect of some environmental actions did not have the correspondence on the global bond response of the NSM CFRP-concrete system, as can be seen in Figure 1b. One of the reasons that can be justified is associated to the obtained FM on bond specimens. As the maximum pullout force is limited by the type of FM and since the failure occurs mainly by debonding at adhesive/laminate interface, it means that the weakest component is the bond at

913
adhesive/laminate interface (adhesion strength). Thus, the tensile strength of the epoxy adhesive is not directly comparable with adhesion strength at the interface between adhesive and laminate.

Notes: the values between parentheses are the corresponding coefficients of variation; *the value between parentheses is the number of specimens with this type of failure mode; I-FA = debonding at the interface FRP/adhesive; I-AC = debonding at the interface adhesive/concrete; C-C = cohesive shear debonding in concrete; CS = concrete splitting; CC = concrete cracking; AC = adhesive cracking.

The failure modes were classified with the generic denomination “X-Y”, where X defines the type of failure mode (interfacial - I or cohesive - C) and Y identifies the location where it occurred (concrete - C, adhesive - A, interface FRP/adhesive - FA or interface adhesive/concrete - AC). Besides the three main failure modes above described (I-FA, I-AC and C-C), in some specimens the final appearance also included one (or more) of the following damages (see Table 1): CS, CC and AC. The predominant failure mode occurred by I-FA (see Figure 1c). In fact, the pure interfacial failure is critical for FRP bars with a smooth surface since the smooth surface of CFRP strips used in this work is insufficient to provide mechanical interlocking between the laminate and the adhesive, and the rougher surface of the concrete leads to better bonding with the adhesive, the bond resistance relies primarily on chemical adhesion between the strip and the epoxy.

Figure 1 Durability tests: (a) DPT configuration; (b) Comparison between the variations of the $f_{f,adh}$ and $F_{lmax}$ due the distinct environmental conditions; (c) Main failure mode occurred in bond tests (I-FA).
QUALITY CONTROL OF NSM CFRP SYSTEMS

A new methodology for continuous monitoring of the evolution of elastic modulus of an epoxy adhesive used in FRP applications, based on adaptations of an existing technique originally devised for continuous monitoring of concrete elastic modulus since casting, called EMM-ARM (Elasticity Modulus Monitoring through Ambient Response Method) was proposed and validated (Granja et al. 2015). Afterwards, the influence of temperature on the curing process of the structural epoxy and its impact on the bond behaviour of NSM CFRP strengthening applications was investigated. For this purpose, an experimental program composed of three groups of tests, considering three different curing and testing temperatures (20 °C, 30 °C, and 40 °C) were developed:

(i) EMM-ARM tests (see Figure 2a) on adhesive samples to assess the evolution of the adhesive elastic modulus of the epoxy at different curing temperatures;

(ii) DPT tests on concrete cubic specimens strengthened with CFRP laminate strips, aimed at describing the development of the interface behaviour under variable curing conditions;

(iii) Tensile tests (TT) performed according to EN ISO 527-2:2012, to evaluate the elastic modulus value of the hardened epoxy.

The development of the epoxy elastic modulus obtained through EMM-ARM and the evolution of $F_{\text{limax}}$ obtained in bond NSM CFRP-concrete specimens along the curing time, at the three curing temperatures under test are presented in Figure 2b. The results of TT at 7-days of epoxy curing are also added to Figure 2b. The elastic modulus was calculated from TT results, according to the American Standard ASTM D638M-93. EMM-ARM applications on epoxy have demonstrated good repeatability of the experimental setup and procedures (Benedetti et al. 2016). The elastic modulus values estimated through the TT were lower than the values provided by EMM-ARM tests, with stiffness differences under 12.6% (~1.22 GPa for the 20 °C test). In addition, the results show that the reaction rates intensify with the increase of the curing temperature. For instance, the elastic modulus of 4 GPa is achieved at approximately 10.7 hours at 20 °C as opposed to the approximately 6.2 and 5.5 hours at 30 °C and 40 °C, respectively. These variations also occur in the duration of the dormant period, where adhesive stiffness is nearly null. With the increase in the curing temperature the duration of the dormant period becomes shorter, as can be observed in Figure 2b. At the reference temperature (20 °C) the setting time (herein defined as the time when the elastic modulus reached 0.25 GPa) is 4.5 ± 0.2 hours, as opposed to the shorter 2.6 hours observed in the test at 40 °C.

Figure 2b highlights that the peak pullout force and the epoxy elastic modulus obtained by EMM-ARM exhibit very similar evolution kinetics, thus indicating that the bond performance of NSM CFRP-concrete system strongly depends on the stiffness of the adhesive regardless of the curing temperature. The increase on bond stiffness is consistent with the stage at which the rate of thermosetting reactions is higher, although its development was slightly delayed compared to elastic modulus development. In general, $F_{\text{limax}}$ has a significant increase from 6 to 24 hours for the three analysed temperatures. For 20 °C, between 6 and 9 hours the peak pullout force increases by 3 kN and even by 10.56 kN in the subsequent 4 hours.

The slight difference on the kinetics of the two properties seems to be similar for all temperatures and may be attributed to a delay in the development of the molecular bond quality, which usually has less influence on the stiffness of the epoxy resin than on its strength (Moussa et al. 2012). Based on this kind of relationship, EMM-ARM can be employed for estimating the $F_{\text{limax}}$ and the minimum curing time to reach a threshold value of pullout force. In this manner it is possible to know the time required to put the strengthened structure in service, taking into account the influence of different environmental curing conditions.

DESIGN OF BOND OF NSM CFRP SYSTEMS

In Coelho et al. (2015), the existing guidelines for the design and use of NSM FRP systems in concrete were analysed. At least four guidelines were identified: firstly, the CAN/CSA S6-06:2006 does not propose a closed-form formulation for evaluating the bond strength of NSM FRP systems. Alternatively, it refers that the bond strength should be obtained either by testing the NSM FRP system to be used, or it should be provided by the manufacturer; secondly the new annex of EN 1992-1-1:2013 is only applicable to FRP bars with rectangular cross-section (strips). In addition, its formulation requires some adhesive properties, such as tensile and compressive strengths, which are not often provided by the adhesives’ manufacturers. Furthermore, the formulation proposed by this guideline to estimate the bond strength depends on some coefficients which shall be provided by the manufacturer for each NSM FRP system, or adjusted by testing; the last two guidelines are the ACI 440.2R-08 (ACI 2008) and HB 305-2008 (SA 2008). These do not present the aforementioned drawbacks. In fact, they provide a set of closed-form expressions which are straightforward to apply since they depend on geometrical and mechanical parameters simple to obtain.

Hence, the ACI 440.2R-08 and HB 305-2008 guidelines were further analysed. Firstly, their accuracy was assessed based on a database with 363 and 68 direct and beam pullout tests, respectively (Coelho et al. 2015). The obtained results showed average errors of about 30% and 40% when ACI 440.2R-08 is applied to DPT and BPT, respectively; and 30% when HB 305-2008 is used for both DPT and BPT. These errors were computed by applying Eq. 1 to the total tests (N) in each database where, \( F_{f \text{max,Exp}} \) and \( F_{f \text{max,Num}} \) are the maximum pullout force values obtained in the experimental tests and by applying the corresponding guideline formulation, respectively.

\[
\sum_{i=1}^{N} \frac{|F_{f \text{max,Exp}} - F_{f \text{max,Num}}|}{F_{f \text{max,Exp}}} / N
\]

Then, a reliability analysis was conducted in order to allow using these guidelines under the framework of the Eurocodes design philosophy (Coelho et al. 2016). Since the amount of tests using CFRP strips was larger than the other types of FRP fibres/cross-sections, it was decided to conduct this task only for these types of tests. Table 2 presents the final formu eagles of each guideline (including the corresponding partial safety factors) that can be applied to estimate the bond strength of NSM CFRP strips. As can be seen, both formulations are based on the assumption that a certain length is required to develop the entire strength of the NSM FRP system (development length, \( L_d \)). If the bonded length, \( L_b \), is lower than \( L_d \), the maximum pullout force, \( F_{f \text{max}} \), will be linearly reduced according to \( L_b/L_d \). In Table 2 the following parameters are involved: \( A_t \), \( p_t \), \( E_p \), \( f_{k,c} \) and \( \gamma_t = 1.4 \) (FRP area, perimeter, elasticity modulus, characteristic tensile strength and partial safety factor), \( b_d \) and \( d_g \) (groove width and depth), \( f_{k,c} \) and \( \gamma_e = 1.5 \) (concrete characteristic compressive strength and partial safety factor), \( \tau_e \) and \( \delta_e \) (design bond strength and slip), \( L_{per} \) and \( \phi_{per} \) (failure perimeter length and ratio), \( \eta_p \) and \( \eta_b \) (safety factors). Detailed description and values of all parameters can be obtained in (Coelho et al. 2016).

CONCLUSIONS

This paper has presented a summary of the research conducted at the Department of Civil Engineering of the University of Minho in the context of bond of FRP NSM systems in concrete. Important contributions were made namely in the topics of durability, quality control and design. The environmental conditions investigated, which were considered to be quite severe, did not lead to significant changes on global bond performance of the NSM CFRP-concrete strengthening system, with a maximum reduction of about 12% on bond strength occurred under real environmental actions. EMM-ARM has potential to be employed for in-situ monitoring of the hardening of an epoxy adhesive curing in un-controlled conditions used in FRP applications. The bond behaviour of NSM CFRP-concrete systems is totally governed by the state of hardening of the adhesive. The peak pullout force and the epoxy elastic modulus obtained by EMM-ARM exhibit very similar evolution kinetics, thus indicating that the bond performance of NSM CFRP system strongly depends on the stiffness of the adhesive regardless of the curing temperature. Regarding the bond design, the major contribution consisted of adapting two existing guidelines’ formulas (American and Australian) to the partial safety factors framework (European philosophy). However, these formulas are not yet sufficiently accurate, thus further work should be carried out in this aspect and a newer and more accurate formulas should be developed.

ABSTRACT

In this study, a series of reinforced concrete beams strengthened with near-surface mounted (NSM) carbon fiber reinforced polymer (CFRP) rods and strips were tested under four-point bending fatigue loading. Monotonic loading was applied to their corresponding control specimens to obtain the static monotonic flexural strength. Fatigue loading with a range of 10% of the corresponding static strength to various upper limits was applied to determine the empirical relationship for each type of specimen. It was found that the dominating failure mode under fatigue was rebar rupture. Mixed failure modes of rebar rupture and unstable cracks in concrete were also observed in specimens with longer fatigue life. As the specimens underwent more fatigue cycles, increase was observed in their tensile strains of CFRP and deflections due to accumulated damage and loss of stiffness.

KEYWORDS

Fatigue, Reinforced concrete (RC), Fiber-reinforced polymer (FRP), Near-surface mounted (NSM).

INTRODUCTION

The durability of many existing concrete structures is being compromised by corrosion, overload and material deterioration, and the structures are therefore in urgent need of rehabilitation (ASCE 2013). Compared to the conventional rehabilitation techniques and materials, fiber reinforced polymer (FRP) composites using near-surface mounted (NSM) reinforcements have appeared to be an attractive solution due to their ease of installation, high load-carrying capacity and flexural stiffness, and improved structural ductility (Hassan and Rizkalla 2003; Barros et al. 2006). For the overall flexural fatigue behavior of NSM-strengthened RC beams, several experimental studies exist in the literature. In general, NSM technique is reported to deliver great performance in aspects including longer fatigue life (Wahab et al. 2011), fewer signs of debonding (Quattlebaum et al. 2005), and lower stress ratio in prestressing strand (Rosenboom and Rizkalla 2006). Specimens were reported to fail by various modes, such as concrete crushing (Rosenboom and Rizkalla 2006), FRP debonding (Wahab et al. 2011) and rebar rupture (Badawi and Soudki 2009). Yost et al. (2007) concluded in their study that the addition of CFRP rod and strip also slightly increased the yielding load, while the ultimate static strength remained unchanged. Oadah and El-Hacha (2012) found the damage level of the strengthened structure was independent of the prestressing level of the NSM CFRP strip. Fernandes et al. (2015) concluded that the smooth NSM FRP strip did not affect either the ultimate load-carrying capacity or the failure mode of NSM-strengthened concrete slabs.

However, the recorded results are primarily driven by targeted performance comparison or improvement, in which case important fatigue-specific behavior, such as strain redistribution among steel, FRP and concrete, the deflection and crack progression throughout the fatigue life, and how those affect and lead to the final failure modes, oftentimes is either overlooked or lacking of detailed explanation. Moreover, these existing test data are still far from sufficient to develop accurate analytical models that are capable of predicting the physical fatigue behaviour and fatigue life of NSM-strengthened RC beams. In consideration of these research insufficiencies, this paper discusses a comprehensive experimental study of NSM CFRP rod- and strip-strengthened RC beams subject to both monotonic and fatigue loading under various load ranges. It includes important static behavior, fatigue life up to failure, and detailed fatigue flexural behavior between the uses of two different types of NSM reinforcement (e.g., strain redistribution, deflection, crack progression and stiffness degradation).
EXPERIMENTAL PROGRAM

Materials

The average 28-day and day-of-test compressive strength of concrete was experimentally obtained as 32.2 and 35.0 MPa, respectively, per ASTM C39/39M (ASTM 2005). Two types of CFRP reinforcement were used: CFRP round sand-coated spirally wound rod (R) and CFRP rectangular roughened strip (S), as listed in Table 1. Following ACI 440.3R-12 (ACI 2012), 3 standard material coupons for each type were prepared and tested to obtain the average mechanical properties of these reinforcements. All coupons failed due to rupture of CFRP reinforcement during the tests. Table 1 summarizes these experimentally obtained average material properties in comparison with the manufacturer’s data. Epoxy-based adhesive (S32 Hi-Mod) was used based on the results from a previous study that examined different types of adhesives (Lee et al. 2013). The bond strength, tensile and shear strength of the epoxy adhesive is 15.17, 48.26 and 42.95 MPa, respectively.

Specimens

Twenty RC beams strengthened with NSM CFRP were cast in 2 batches, with a total length of 3,861 m and a rectangular cross-section of 203 mm wide and 305 mm deep (Figure 1). Each beam had two No. 6 rebars with a diameter of 19.05 mm as the tensile steel reinforcement at the bottom of the section, and two No. 3 rebars with a diameter of 9.53 mm as the compressive steel reinforcement at the top. Additionally, No. 3 U-shape shear stirrups were used at a space of 76.2 mm for the shear reinforcement. The concrete cover for the tensile and compressive steel reinforcement was 40 and 30 mm, respectively. Among the 20 beams, half was strengthened with NSM CFRP rods and the other half with NSM CFRP strips. Groove dimensions of 15 mm (width) and 25 mm (depth) were selected for both the CFRP rod and strip. The grooves were first cleaned by pressure washer and dried out by pressured air. The bottom half of the groove was then filled with epoxy resin followed by the embedment of the NSM reinforcements in the center and finished with filling up the top half of the groove. The grooves were allowed to cure for at least 14 days to develop the full strength in epoxy prior to any testing.

Each set of the specimens consisted of two identical specimens. The labeling scheme for the specimens (Table 2) was based on three parameters: the shape of the NSM reinforcement, the upper limit of the applied fatigue load, and the specimen number in the set. For instance, R-S-1 represents the first specimen in the set using NSM CFRP rod and subject to monotonic loading (static); S-75-2 represents the second specimen in the set with NSM CFRP strip and subject to a fatigue load ranging from 10% to 75% of its corresponding monotonic beam strength (Pu).
adaptation, during which load was applied in steel rebar slowed down [Figure 2(a)].

The compressive strain in the concrete [Figure 2(d)] existed but was less substantial.

Instrumentation and test setup

Each beam was instrumented with strain gauges and linear potentiometers, as shown in Figure 1. All beams were simply supported, and tested in four-point bending flexural condition. To better track and measure the crack length and crack opening width throughout the fatigue life, a small notch (10 mm deep) was pre-cut on the bottom surface of concrete at the mid-span to initiate the major flexural crack. This small notch was intended to facilitate the quantitative measurement of crack propagation throughout the test and did not affect the flexural behavior of the beams. Static monotonic tests were first conducted on control specimens and the other specimens in the same category were then tested under fatigue to a defined upper limit of the fatigue loading.

TEST RESULTS AND DISCUSSIONS

Monotonic test

Under the monotonic loading, the average monotonic beam strength ($P_m$) was recorded to be 158.06 and 145.45 kN (Table 2) for NSM rod and strip specimens, respectively. The two rod specimens and one strip specimen all failed by concrete crushing after steel rebar yielded (CC), and the other strip specimen (S-S-2) failed by interfacial debonding (D) between epoxy and CFRP reinforcement. Concrete started to crack at 13 kN and the yielding of steel rebar occurred when the load reached 110 kN. This can be confirmed from the sudden change of the slope in the load vs. strain and deflection curves as shown in Figure 2 for rod (R-S-2) and strip specimens (S-S-1). After yielding, the steel rebar experienced substantial increase in its tensile strain [Figure 2(a)] while load increased slowly. After the load reached approximately 130 kN, the tensile strain in steel rebar slowed down [Figure 2(a)] while the strain in FRP kept increasing steadily [Figure 2(c)]. This indicates a redistribution of load resistance beyond the 130 kN level between the NSM reinforcement and steel rebar, where strain hardening in the steel rebar only accounted for a very small stress increase. At the ultimate load level during the final stage (approximately 160 kN), most specimens failed by concrete crushing, and no failure was observed in the NSM reinforcements such as rupture or slip. Moreover, at the ultimate load level, the tensile strain of the steel rebar and FRP as well as the mid-span deflection were much greater in the rod specimen R-S-2 than those in the strip specimen S-S-1, implying a more ductile behavior in the specimens strengthened with NSM rods. The difference of the compressive strain in the concrete [Figure 2(d)] existed but was less substantial.

</table>

$^a$Percentage of monotonic strength of the respective group; $^b$Not applicable; $^c$Monotonic strength from static monotonic test or the number of cycles to failure from fatigue test (fatigue life); $^d$Not available since the specimen failed after the first cycle by insufficient curing of epoxy resin; $^e$Stress range of steel rebar after 1000 cycles of fatigue loading were applied; and $^f$CC = concrete crushing, UC = unstable crack, RR = rebar rupture, D = debonding.
Fatigue Test

**General Behavior** – Table 2 summarizes the main test results of the 16 strengthened beam specimens under fatigue loading varying from a fixed lower limit (i.e., 10% of the corresponding ultimate strength under monotonic loading, $P_u$) to a selected range of upper limit (i.e., 45%, 55%, 65% and 75% of $P_u$). The observed dominating failure mode was rebar rupture (RR) although a small group of specimens experienced some level of debonding in NSM that mostly affected their fatigue behavior. In some cases especially the beams subject to lower fatigue loading (with longer fatigue life), steel rebar rupture was occasionally accompanied with concrete crushing (UC+RR), which was resulted from excessive and unstable crack propagation in concrete. Only 1 out of 16 specimens failed due to premature debonding.

**Fatigue Damage** – Figure 3 displays the load vs. mid-span deflection response under different number of fatigue cycles for both types of specimen. It can be seen that the deflection is fairly linear during the loading and unloading throughout the fatigue life. A significant increase of the deflection was not observed until the final stage of the fatigue life was reached. The relation between the peak deflection at the mid-span and the normalized number of cycles with respect to its failure cycles is displayed in Figure 4. It can be seen that the progression of the peak deflection during the fatigue life is similar to the crack propagation behavior where three distinct stages existed. Such stage-wise response of peak deflection was mainly due to the progression of the fatigue cracks, the concrete fatigue creep, and the bond degradation of the NSM reinforcements. As can be seen from Figure 4, the deflections for beams under the 75%$P_u$ fatigue load (i.e., R-75 and S-75 series) are much larger than the others throughout the normalized fatigue life, while their corresponding number of fatigue cycle up to failure is the smallest among all. This could be due to the accumulation of large plastic deformation experienced in those specimens under high level of fatigue loading.

The stiffness degradation of both the rod and strip specimens throughout the fatigue life is illustrated in Figure 5. For both types of specimens, the stiffness degradation trends are similar among specimens under different levels of fatigue loading. It can also be seen that most of the degradation occurred during the first 5% of the fatigue life, Stage (1), after which the stiffness tended to stabilize showing slight degradation with constant rate within Stage (2). As the specimen approached its ultimate failure, Stage (3), the degradation became rapid again due to the large crack opening and propagation, and the shrinkage of effective area of the steel rebar. Similar trend was also reported elsewhere (e.g., Barnes and Mays 1999; Oudah and El-Hacha 2012).
**Figure 4** Progression of peak deflection at mid-span for: (a) rod specimens; and (b) strip specimens

**Figure 5** Stiffness degradation during the fatigue life for: (a) rod specimens; and (b) strip specimens

**Tensile Behavior of Steel Rebar and CFRP** – The response of load vs. tensile strain in steel rebar and NSM reinforcement under different number of fatigue cycles is shown in Figures 6(a) and 6(b) for rod specimens, and in Figures 6(d) and 6(e) for strip specimens. It can be seen that, as the number of fatigue cycles increased from 1000 (rod specimens) or 7000 (strip specimens) up to the prior-to-failure stage, the tensile strain curves for different number of cycles are close to each other, indicating a slow increase in the tensile strain in both steel rebar and NSM CFRP. At the prior-to-failure stage, the strengthened beams behaved differently as compared to during their earlier stages before the final fatigue life was reached. The tensile strain in steel rebar decreased considerably [Figures 6(a) and 6(d)], while the tensile strain in NSM reinforcement increased substantially [Figures 6(b) and 6(e)]. The compressive strain in concrete at mid-span [Figures 6(c) and 6(f)] generally had a small increase within the first two or three thousand cycles (e.g., from 857 to 1000 με in R-55-2 within the first 2000 cycles), which then remained constant throughout the rest of the fatigue life.

**Figure 6** Fatigue strains of reinforcements and concrete in specimens R-55-2 and S-55-1

**Fatigue Life** – Table 2 summarizes the number of cycles to failure (fatigue life) of each beam specimen. The fatigue load range (L) versus the number of cycles to failure curves is plotted in Figure 7. Based on the test results, two empirical equations are proposed to estimate the fatigue life of the strengthened concrete beams:

922
\[ L = -25.47 \log(N) + 181.28 \quad \text{for rod specimens} \]  
\[ L = -25.44 \log(N) + 189.67 \quad \text{for strip specimens} \]

where \( L \) = fatigue load range and \( N \) = fatigue life. The R-squared value was 0.9760 and 0.9822 for the rod and strip cases, respectively. It can be seen that the NSM strip specimens generally have longer fatigue life than the rod specimens under the same load range (%\( P_u \)).

**CONCLUSIONS**

A total of twenty NSM CFRP strengthened reinforced concrete beams were tested to investigate their fatigue behavior. The main conclusions include: (1) A typical elastic-plastic behavior was observed for the strengthened specimens under monotonic loading with the “yielding” occurred when the tensile strain of steel reached 0.2%; (2) Most specimens under fatigue failed due to rebar rupture, while debonding and unstable crack was observed in specimens with lower fatigue load and longer fatigue life; (3) Deflection progression generally showed three distinct stages with the second stage counting for the majority of the fatigue life; (4) The internal bending moment contributed by steel and NSM generally remained unchanged, but the tensile strain drastically redistributed from steel to NSM during Stage (3); and (5) Empirical equations are proposed, where the NSM strip specimens showed longer fatigue life than the rod specimens under the same fatigue load range.

ABSTRACT

Reinforced concrete bridge deck slabs receive traffic loads directly. Structural damage can occur, such as residual deformation and numerous cracks, which eventually decreases the life of the deck as well as its load carrying capacity. The use of near surface mounted (NSM) fibre reinforced polymer (FRP) is a promising strengthening technology for increasing the ultimate strength of reinforced concrete structures. However, the study of the behaviour of FRP NSM strengthening concrete bridge deck slabs is rather limited. This paper deals with strengthening reinforced concrete bridge deck slabs with NSM FRP bars. A series of one third scale BFRP retrofitted concrete deck slabs were conducted and tested. In the test, the supporting beam sizes and strengthening configuration were varied to investigate the behaviour of the FRP NSM strengthening test deck slabs. The test results show that FRP NSM technique improves the loading-bearing capacity of reinforced concrete deck slabs. The test on the deck system also presents that NSM BFRP retrofitting together with arching action had a cumulative beneficial effect on the loading-carrying capacity. Subsequently, a theoretical study was carried out and a model for prediction in loading-carrying capacities of NSM FRP strengthened concrete deck slabs was proposed. The ultimate strengths predicted by this theoretical method show good agreement with the test results.

Concrete bridge deck slab, NSM strengthening, FRP bars, Arching Action.

INTRODUCTION

Due to increasing the traffic load, structural damage can occur in reinforced concrete deck slabs, which eventually decreases the life of deck slabs (Takeshi 1994). For this reason, it appears to be significantly critical to strengthen the deteriorated concrete deck slabs. Nowadays, many different types of materials are used to strengthen deteriorated concrete members (Kumar et al. 1990). Due to high strength, stiffness-to-weight ratio and corrosion resistance, FRP laminates and strips have been widely used to retrofit or strengthen existing bridge structures using externally bonded (EB) technique (Teng et al. 2002). In the externally bonded FRP strengthened concrete deck slabs, FRP reinforcement could be highly susceptible to damage from collision, fire and temperature, ultraviolet rays and moisture absorption (De Lorenzis and Teng 2007). In some strengthened bridge cases, insufficient protection may reduce the service life of the structures. To overcome this disadvantage of externally bonded strengthening method and improve the utilization of the FRP materials, near surface mounted (NSM) FRP method was introduced as a promising technique (Zhang et al. 2013). Although there has been some research on NSM FRP strengthened concrete structures, the study of concrete slabs strengthened with NSM FRP reinforcement is rather limited, especially for strengthened concrete bridge deck slabs. Additionally, bridge deck slabs in the typical beam-and-slab type bridge have inherent strength due to in-plane forces set-up as a result of the restraint provided by the slab panel boundary conditions (Zheng et al. 2015). This is known as arching action (Zheng et al. 2010). This arching effect has a significant influence on the behaviour of concrete bridge deck slabs (Zheng et al. 2010, 2015). However, the effect of arching action on the behaviour of deck slabs strengthened with FRP has not been explored fully. Hence, this paper aims at investigating the combined effect of NSM FRP bars and arching action on the enhancement of the loading-carrying behaviour of strengthened concrete bridge deck slabs. In this study, a series of one-third scale concrete deck slabs strengthened by NSM FRP bars was conducted and tested in the laboratory. Thereafter, an understanding of the nature of behaviour of NSM FRP strengthened concrete bridge
deck slabs can be extended. Subsequently, the ultimate strengths of test specimens were predicted by the standard
design method (ACI Committee 440.2R-08, 2008) and the reported punching-strength theoretical method for FRP
strengthened concrete deck slabs (Hongseob and Sim 2004). The results indicated that those methods yielded
inaccurate predictions due to the neglected arching action. Based on the method of arching theory (Zheng et al.
2010), a modified model was proposed. The proposed approach was validated by the good correlation obtained
between the predicted results and the test results.

EXPERIMENTAL PROGRAMME

As shown in Figure 1, a one-third scale deck panel with dimension of 2000mm by 800mm was adopted to simulate
the behaviour of a real bridge deck supported by two steel I-section beams, which is determined based on the
previous study by authors (Zheng et al. 2014). The composite effect between the steel beam and concrete bridge
deck was achieved by the steel stud weld on the top flange of the steel beam. In this test, Basalt Fibre Reinforced
Polymer (BFRP) bars with a diameter of 6mm were used as NSM strengthening material. The mean tensile strength
and the modulus of elasticity of the tested BFRP bars were 1300 N/mm² and 68000 N/mm² respectively. Figure
2a illustrates the size and the location of the grooves, which were cut in the transverse direction at the bottom of
concrete deck slabs and cut to be 1.5 times of the diameter of NSM bars (De Lorenzis and Teng 2007). In the
strengthening procedure, the Sika (Sikadur-30) adhesive for bonding reinforcement was used as epoxy adhesive
with an average tensile strength of 46.8N/mm² and an elasticity modulus of 12000N/mm². In all the tests specimens,
the steel reinforcing bars with a diameter of 6mm were used as internal reinforcement. The spacing of steel bar
was configured to be 100mm.

**.-Concrete strength is tested based on 100mm×100mm×100mm cube test.

As shown in Table 1, the structural variables were external restraint stiffness and strengthening configurations. To
achieve a noticeable arching effect in this test, the influence of external restraint stiffness was studied by varying
the major and minor axis I value—\( I_{xx} \) and \( I_{yy} \) value of edge beams. To study the effect of NSM strengthening
configurations, the spacing of NSM FRP bars were varied from 100mm to 200mm, as shown in Table 1. In addition,
to avoid the debonding failure between NSM FRP and concrete, a combined strengthening method of NSM FRP
bars in transverse direction and externally bonded (EB) FRP plate in longitude direction was used in this test, see Figure 2b.

EXPERIMENTAL RESULTS

The cracking pattern at the bottom face of the six test deck models at failure was shown in Figure 3. All tested slabs had almost similar cracking patterns. The first cracks appeared directly under the loaded area and were oriented in the longitudinal direction parallel to the supporting beams. As the applied load increased, subsequent cracks propagated in the radial direction away from the loaded area. Compared to the unstrengthened deck specimen, fewer cracks with narrower widths were observed on the underside of the strengthened deck slabs. This indicates that the propagation of the cracking at bottom face was limited by NSM FRP bars. In addition, by using the externally bonded (EB) strengthening method in the longitudinal direction, less cracking was observed in the deck slab coded as DS-MB1EB.

The responses of load vs. vertical deflection at midspan of deck specimens are illustrated at Figure 4. It can be seen that, for all the test specimens, the load vs. deflection responses were very similar, which was almost linear up to failure, before the applied load reached the cracking load (around 25-30kN). After this loading level, the structural stiffness of strengthened deck panels was improved and a delay in the stiffness degradation was evident by using the NSM strengthening materials. As shown in Figure 4, the structural behaviour of NSM FRP strengthened concrete deck slabs were enhanced by increasing the supporting beam sizes. This could be due to the enhancement of aching effect (Zheng et al. 2010). Interestingly, the spacing of NSM FRP bars could not affect the load-deflection response significantly as shown in Figure 4, which could be due to the contribution of arching action to structural behaviour. Figure 4 illustrated that the stiffness of the concrete deck slabs strengthened by the
combination of NSM and EB methods (the specimen coded as DS-MB1EB) was slightly higher than that strengthened by NSM methods (the specimen coded as DS-MB1), and the strength were increased by around 10% over that of specimen. This indicates that two-directional strengthening with NSM FRP bars and EB FRP plates is more effective than the transverse NSM strengthening scheme. This finding is similar to that reported in the previous study (Sim et al. 2006).

![Figure 4 Load vs. deflection response in concrete deck slabs](image4)

The load-strain relationship for transverse steel reinforcement is shown in Figure 5. It was found that the applied load corresponding to yielding strain was significantly enhanced by using the NSM strengthening method. Additionally, it can be found that the steel reinforcement yielded prior to the punching failure in all the test specimens except the model with strong lateral restraint stiffness (model coded as DS1-BB1), see Figure 5. It is could be summarised that the contribution of steel reinforcement was reduced by increasing the aching action. Figure 5 illustrates that the relationship of load vs. reinforcement strain before the load reached the yielding load was not affected by the variation of supporting beam sizes. Conversely, reducing the spacing of NSM FRP bars resulted in larger yielding load due to the improved flexural stiffness. By using the combination of NSM and EB strengthening, a delay of yielding in transverse reinforcement was expected by the increased strengthening efficiency. With the further applied load, the contribution of steel reinforcement to loading-carrying capacity was reduced by increasing the supporting beam sizes and strengthening percentages.

![Figure 5 Strain values of steel reinforcement in concrete deck slab vs. applied load](image5)

Figure 6 shows the response of strain in NSM FRP bars and the applied load. It was found that this structural response is similar in all the strengthened test deck slabs before the applied load reached the cracking load. As the load increased, a delay in the stiffness degeneration was evident in the response of strain in FRP bars and the applied load in all the strengthened deck slabs. This indicated that the contribution of NSM FRP bars to loading-carrying mechanism significantly after the occurrence of cracking. As expected, the strain value of NSM FRP bars in the deck slab with small supporting beam (specimen coded as DS-SB1) and small strengthening ratio (specimen coded as DS-MB2) are larger than those from other strengthened deck slabs. Additionally, increasing the lateral restraint stiffness resulted in the smaller strain of NSM FRP bars at failure load. After the test, it was found that the rupture of FRP bars occurred in the deck slabs with small supporting beams (coded as DS-SB1). This suggests that the strengthening percentage is insufficient for this deck specimen. Therefore, it can be summarised that the effect of strengthening percentage and arching action should be both considered in the structural design.
In order to investigate the efficiency of the strengthening method, the comparison of loading-carrying capacity in all the test deck slabs was shown in Table 1. It can be seen that the ultimate load of deck slabs was increased by 25% by using NSM FRP bars in transverse direction with comparison of the results from the specimens coded as D-MBCon and DS-MB1. Increasing the supporting beam sizes resulted in larger ultimate loads, which is the same as that is reported in the works of concrete deck slabs by authors (Zheng et al. 2010). This indicates that the arching action has similar effect on loading-carrying capacity of NSM strengthened concrete deck slabs. In addition, the variation of spacing of NSM FRP bars (strengthening percentage) could not affect the ultimate loads significantly, which could be caused by the increased contribution from arching action (Zheng and Xia 2015). The test results showed that NSM FRP strengthening method, together with in-plane restraint providing arching action, had a cumulative beneficial effect on the ultimate capacity.

In this study, the flexural strength of strengthened test slabs was predicted by a design code named as ACI 440.2R-08(2008). On the hand, a prediction method by Hongseob and Sim (2004) for externally bonded strengthened concrete deck slabs was adopted to predict the punching shear strength of test specimens. The predicted strengths by the current theoretical models of ACI 440.2R-08(2008) and Hongseob and Sim (2004) were shown in Table 2. It was evident that those two theoretical models yielded highly conservative predicted ultimate strengths for strengthened concrete deck slabs and the reliability of those two predictions was not good. To accurately determine the ultimate capacity of strengthened concrete bridge deck slabs, a proposed theoretical method based on arching theory in the authors’ previous study (Zheng et al. 2010) was used. In this proposed method, the bending capacity and was modified to be predicted by ACI 440.2R-08(2008). In addition, the influence of NSM FRP bars was assumed to be a contribution to "virtual reinforcement percentage" (Zheng et al. 2010) in the prediction of shear punching capacity. The test to predict ultimate capacities using the proposed theoretical method are listed in Table 2. It can be noted that this method yielded accurate and reliable punching strengths of the tested NSM FRP strengthened concrete deck slabs. The ratio of \( P_t/P_p \) is 1.0 with a coefficient of variation of 6%.
CONCLUSIONS

To investigate the behaviour of concrete deck slabs strengthened by NSM FRP bars, a series of one third scale concrete deck specimens were conducted and tested up to failure in the laboratory. The test results indicate that the NSM strengthening scheme effectively increased the concrete deck slabs punching capacities and stiffness. Debonding of NSM FRP reinforcement did not occur in the test process until the failure. By using the combination of NSM and EB FRP strengthening schemes, debonding of NSM FRP reinforcement was avoided, and then the capacity and stiffness was increased. The study of this combined strengthening method should be carried out in the further research. The tests on the deck specimens showed that NSM FRP strengthening, together with in-plane restraint providing arching action, had a cumulative beneficial effect on the ultimate capacity. In addition, it was shown that the contribution of steel reinforcement to the loading carrying capacity was reduced by increasing the lateral restraint and using the NSM strengthening method. The contribution of NSM FRP reinforcement was varied by the lateral restraint stiffness after the applied load reached the 80% of failure load. The NSM FRP strengthening showed a relatively greater increase in capacity for slabs with a lower external in-plane restraint. Therefore, this suggests that the effect of arching action should be considered in the calculation of NSM strengthening percentage for laterally restrained concrete deck slabs. In the comparison between the predicted strengths from the theoretical from literatures (ACI 440.2R-08, 2008; Hongseob and Sim 2004), it was shown that those methods yielded conservative prediction predictions. Because the influence of arching action was not considered, increasing the supporting beam sizes resulted in higher underestimation of ultimate strengths. The proposed prediction method was modified based on the arching theory and combined with the modified bending capacity prediction method and an “equivalent” area of arching reinforcement percentage. This punching strength prediction model predicted the loading-carrying capacities of the test slabs with reasonable accuracy.

ABSTRACT

Near Surface Mounted (NSM) strengthening technique has been used in a sustainable way for retrofitting existing structures. This technique, which utilizes CFRP laminates inserted in the concrete cover, has been used due to the several advantages when compared with the technique based on the application of these reinforcing materials on the concrete surface (EBR technique). Although several studies have been developed on this topic in the recent past, open issues still deserve research, such as the influence of the adhesive type on the performance of the NSM-CFRP system. The present work details an experimental program carried out in order to assess the effect of using three adhesives with distinct mechanical properties on the bond behavior of the NSM-CFRP system, through direct pullout tests (DPT). Thus, the following variables were considered in the present study: (i) the type of adhesive; (ii) the cross-section of the laminate; and, (iii) the bond length. The experimental pullout force-slip responses were obtained and digital image correlation (DIC) was used for obtaining additional information about the bond mechanisms developed. In general, two of the three adhesives, with similar mechanical characteristics, provided essentially similar bond behavior, with high level of effectiveness, whereas the third adhesive, which had a much lower elastic modulus than the other two, provided the lowest effectiveness in terms of the investigated parameters.

INTRODUCTION

Fibre reinforced polymers (FRP) have been extensively investigated for repairing and/or strengthening existing structures. These materials can be introduced in the concrete cover of the element to be strengthened through the near surface mounted (NSM) technique. An epoxy adhesive is commonly used to fix the CFRP laminate to concrete. This bonding agent plays a critical role on the composite performance of the system. Extensive research has been developed to assess the bond behaviour of this strengthening system using carbon fibre reinforced polymers (NSM CFRP system). According to Coelho et al. (2015) the performance of the NSM CFRP system depends mainly on the: (i) geometry of the groove and of the FRP; (ii) mechanical properties of the concrete; (iii) mechanical properties of the adhesive; (iv) FRP cross-section and its external surface; and, (v) surface roughness in the groove. Digital Image Correlation (DIC) is a method that allows to evaluate the displacement fields at the surface of a structural element, as well as to compute the deformation fields during the test. Essentially the method is based on comparing two consecutive images of the element surface, before and after its deformation, through the application of an appropriate correlation technique (Chu et al. 1985). More information about this technique can be found elsewhere (e.g., Pereira et al. 2012; Carloni and Subramaniam 2013). In the literature few investigations can be found dedicated to analyzing the influence of adhesive and cross-section geometry of the laminate on the bond behavior of NSM CFRP system, e.g. Macedo et al. (2008).

In this research the effect of three adhesives for fixing CFRP laminates to concrete substrate according to the NSM technique is analyzed, by means of direct pullout tests. The main motivation for testing two stiff adhesives and one of much lower stiffness lies on the reported advantage of using highly deformable (flexible) adhesives in external bonding (EB) of CFRP laminates to RC beams as strengthening (Derkowski et al. 2013). In this research the type geometry of the CFRP cross-section as well as the bond length were also analyzed and as study variables. The experimental program is detailed and the main results are presented and analyzed in the subsequent sections.
EXPERIMENTAL PROGRAM

Test program, specimens and test configuration

The experimental program was composed of 51 direct pullout tests (DPT) where the influence of adhesive type, cross-section geometry and bond length of the bond NSM CFRP system were analysed. Table 1 presents the experimental program which includes: (i) three adhesive types - Adhesive 1 (ADH1), 2 (ADH2) and 3 (ADH3); (ii) two cross-sections of CFRP laminate - 10×1.4 mm² (L10) and 20×1.4 mm² (L20); and, (iii) six bond lengths (Lb) - 50, 60, 80, 100, 200 and 300 mm. Concrete cubic specimens were adopted with Lb values up to 100 mm, while concrete prismatic specimens were adopted with Lb values of 200 and 300 mm. Each series was composed of 3 specimens, being its generic denomination ADHX_LYY_LbZZ, where X represents the adhesive type (1, 2 or 3), YY is the width of CFRP in millimeters and ZZ indicates the bond length also in millimeters.

The geometry of the pullout specimens and test configuration adopted for both types of geometries is presented in Figure 1. In the cubic specimen, which consisted on concrete cube blocks with 200 mm of edge, grooves were performed on their lateral faces with a cross-section geometry of 5×15 mm² in general, or 5×25 mm² for insertion of CFRP laminates L10 and L20, respectively. In order to avoid the premature specimen failure by the formation of a concrete fracture cone between the load end and the top of the block, 100 mm of unbounded zone was guaranteed between these two points (in the case of ADH3 series the distance adopted was 50 mm). A steel plate of 20 mm of thickness was used to fix the upper part of the concrete block to the stiff base through four M10 steel threaded rods, ensuring negligible vertical displacements. In the prismatic specimens, which consisted of concrete prisms of 150×150×600 mm³, only grooves with a cross-section of 5×25 mm² for insertion of laminates L20 were performed. The distance between the loaded end and the top of the prism was also equal 100 mm. The specimen was supported on a steel frame through a steel plate, threaded rods, horizontal bars and a hydraulic jack. The tests were performed under displacement control at the loaded end adopting two displacement rates: for stiff adhesives ADH1 and ADH2, 2 µm/s, and for flexible adhesive ADH3, 5 µm/s. A load cell, placed between the grip and the actuator, was used to measure the applied force, \( F \), and a linear variable displacement transducer - LVDT1 - was used to measure the loaded end slip (relative displacement between the concrete and the CFRP laminate at the loaded end).

In order to help with interpreting the evolution of the degradation mechanisms of the anchorage zone during testing, the surface of the specimens at which the laminates were inserted was analysed using a Digital Image Correlation procedure (Blaber et al., 2015). The evolution of the crack pattern was documented during the monotonic loading by processing a sequence of images with a constant time step. The lens used had an aperture of f11 and the focal length was 100 mm. Led lights were used to illuminate the surface of the specimen. The camera sensor was a full frame size, with 36 Mpix. Considering that the priority was to trace the initiation and propagation of the cracks during testing, the principal tensile strain fields were mapped considering a very fine facet mesh. This mapping was particularly important to identify the location of the first cracks with respect to the CFRP laminate load end and to document the process of initiation and propagation of new cracks during the entire loading sequence.
Materials characterization

The compressive strength of the concrete was assessed using cylinders with 150 mm of diameter and 300 mm of height, at 28 and 110 days after casting. The modulus of elasticity and the compressive strength were assessed according to LNEC E-397:1993:1993 and NP EN 12390-3:2009 recommendations, respectively. An average modulus of elasticity \( (E_{cm}) \) of 27.0 GPa, with a coefficient of variation, CoV, of 0.5% and an average compressive strength \( (f_{cm}) \) of 35.4 MPa (CoV = 4.8 %) were obtained at 28 days. At 110 days, \( E_{cm} = 28.3 \) GPa (CoV = 2.5%) and \( f_{cm} = 38.5 \) MPa (CoV = 2.1%) were obtained. The mechanical properties of the adhesives were assessed according to ISO 527-2:2012. The following average values were obtained for the elastic modulus \( (E_a) \) and tensile strength \( (f_a) \):

- ADH1 - \( E_a = 11.67 \) GPa (CoV = 0.51%) and \( f_a = 25.59 \) MPa (CoV = 7.40%);
- ADH2 - \( E_a = 7.57 \) GPa (CoV = 6.15%) and \( f_a = 17.19 \) MPa (CoV = 5.43%);
- ADH3 - \( E_a = 0.012 \) GPa (CoV = 9.09%) and \( f_a = 2.67 \) MPa (CoV = 12.49%).

The mechanical properties of CFRP laminates can be found in (Fernandes et al. 2015) for L10 and in (Sena-Cruz et al. 2013) for L20.

RESULTS AND DISCUSSIONS

Main results

Table 2 presents the main results obtained from the pullout tests, including the average results for each series, as well as the observed failure modes, including: \( F_{\text{max}} \) is the maximum pullout force reached during the test; \( \tau_{\text{max,avg}} \) is the average shear bond strength at laminate-adhesive interface, which was computed by dividing \( F_{\text{max}} \) by the contact area between the CFRP laminate and the adhesive, \( 2(w_f + t_f)L_b \); \( s_{\text{max}} \) is the slip at \( F_{\text{max}} \); \( \tau_{\text{max,avg}} \) is the average shear bond strength at laminate-adhesive interface, which was computed by dividing \( F_{\text{max}} \) by the contact area between the CFRP laminate and the adhesive, \( 2(w_f + t_f)L_b \); \( s_{\text{max}} \) is the slip at \( F_{\text{max}} \). The responses are similar to those obtained by e.g. Fernandes et al. (2015). They are mostly non-linear, probably as a result of the non-linear behaviour of the adhesive, as well as due to the debonding process. For the series ADH1 and ADH2, short post-peak branches are observed, related to the failure mode in the form of debonding at the laminate-stiff adhesive interface. On the other hand, the responses obtained for series ADH3 are characterized by the long post-peak branches, related to cohesive failure in the flexible adhesive. Comparing the response of series ADH1 and ADH2 with the response of ADH3, significantly higher ultimate loads \( F_{\text{max}} \) are obtained for the stiff adhesives and significantly higher slip \( s_{\text{max}} \) for the flexible adhesive. Simultaneously, ADH3 provides lower stiffness on the NSM CFRP system than ADH1 and ADH2, but higher ductility.

Failure modes

Failure modes obtained in ADH1 and ADH2 series include the debonding at the laminate-adhesive interface (see Figure 3(a) – microscope photography) and laminate failure (see Figure 3(b)). In series ADH3 the failure mode observed was a mixed failure mode, i.e., specimens failed due to debonding at laminate-adhesive interface in some parts of the bond length, as well as due to the cohesive failure of the adhesive close to laminate-adhesive interface on the other parts (see Figure 3(c)).
Influence of study variables on the bond behaviour

The influence of adhesive type and cross-section geometry of the CFRP laminate were assessed for different bond lengths, and the summary of the results is presented in Figure 4. As expected, and in accordance to the literature (e.g. Sena-Cruz 2005; Coelho et al. 2015; Peng et al. 2015), $F_{\text{max}}$ tends to increase with the increase of $L_b$, coinciding the upper limit of $F_{\text{max}}$ with the tensile strength of the CFRP laminate (e.g. ADH2_L10 series with $L_b$ of 80 and 100 mm). $F_{\text{max}}$ is higher for L20 series than L10 series, which probably is related to the higher contact area at both interfaces and the consequent superior capacity of stress transfer from the laminate to concrete. Notes: the values between parentheses are the corresponding coefficients of variation (CoV); FM (Failure Modes): I-FA = Debonding failure at laminate-adhesive interface; C-A = Cohesive failure of adhesive close to laminate-adhesive interface; F = CFRP failure; the values between parentheses are the number of specimens where this failure occurred. ¹Results collected from publication Sena-Cruz et al. (2015).

Figure 2 Typical average pullout force vs. load end slip relationship, obtained in the experimental program for the same bond length of $L_b= 100$ mm and two CFRP width: (a) ADH1; (b) ADH2; (c) ADH3.

Figure 3 Failure modes observed in the experimental program: (a) and (b) ADH1 and ADH2; (c) ADH3.
general according to $F_{\text{max}}$, less stiff ADH2 is more efficient than stiffer ADH1, while ADH3 provides $F_{\text{max}}$ values significantly lower than the previous ones. For instance, in series L20 for Lb80 the $F_{\text{max}}$ obtained with ADH3 is only 12% of the average value obtained when ADH1 and ADH2 are used. However, the performance of ADH3 tends to be closer to series ADH1 and ADH2 with the increase of $L_b$ (see series L20 with Lb300).

$t_{\text{max,avg}}$ tends to decrease with the increase of $L_b$ for ADH1 and ADH2 (stiffer adhesives) due to the higher contact area between the CFRP and adhesive and the non-uniform distribution of bond stresses along the bond length, as referred and justified in (Coelho et al. 2015). Using ADH3 (flexible adhesive), it can be noted that $t_{\text{max,avg}}$ tends to be similar for all tested bond lengths, which can be justified by a better and more uniform distribution of bond stresses along $L_b$ due to the lower stiffness of the adhesive ADH3, which has an elasticity modulus three orders of magnitude lower than the ones of ADH1 and ADH2. The cross-section geometry of the laminate did not significantly influence $t_{\text{max,avg}}$, in the present work: $t_{\text{max,avg}}$ was fond to be similar for L10 and L20, for the tested bond lengths (except ADH2 series). This finding probably demonstrates that the bond stress development at laminate-adhesive interface is independent of the cross-section of the laminate. Finally, it can be noted that the adhesive type has a significant influence on $t_{\text{max,avg}}$. Series ADH2_L10 reached higher $t_{\text{max,avg}}$ values than series ADH1_L10, while on ADH1_L20 and ADH2_L20 the values obtained were similar in both cases. $t_{\text{max,avg}}$ on series ADH3 was significantly lower than in the case of both ADH1 and ADH2 series.

$s_{\text{max}}$ also tends to increase with the increase of $L_b$ (except between series ADH2_L10_Lb80 and ADH2_L10_Lb100, probably due to the laminate failure that took place for $L_b$ equal or higher than 80 mm). $s_{\text{max}}$ is also influenced by the cross-section geometry of the laminate. For instance, for $L_b$ of 80 and 100 mm with ADH1 and ADH2, $s_{\text{max}}$ tends to be higher for series L10, on contrary to ADH3 where it was higher for laminate L20, namely for $L_b$ of 100 mm. Finally, $s_{\text{max}}$ is higher for ADH3_L20_Lb300 series than for ADH1_L20_Lb300 and ADH2_L20_Lb300 series.

Figure 4 Influence of study variables on the (a) peak pullout force, (b) maximum average bond strength and (c) loaded end slip at maximum pullout force.

Digital Image Correlation Analysis

Figure 5 presents two typical cases where DIC method was applied in order to compare the field strains of stiff and flexible adhesives. Figure 5(a) and Figure 5(b) present the results obtained for specimen ADH1_L20_Lb100_1 (“_1” means the first on specimen of the series) and ADH3_L20_Lb100_1, respectively at peak pullout force. In the first case, diagonal concrete cracks appear, which are caused by the stress transfer from the laminate to the concrete and produces the typical “fish spine” crack pattern due to the resistant mechanisms developed by the system (Sena-Cruz 2005). The use of stiff adhesives tends to lead to the concentration of damage on the concrete surrounding the reinforcing region and at the adhesive-concrete interface, remaining the adhesive almost intact. In contrast, the use of flexible adhesives leads to the significant damage concentration at the adhesive only, remaining the other materials almost intact.

CONCLUSIONS

This paper presents an experimental research on the bond behaviour of NSM CFRP system and on the evaluation the influence of the following parameters: (i) bonding agents (adhesives) with different mechanical properties; (ii) CFRP cross-section geometry; and, (iii) bond length. This assessment was performed through direct pullout tests (DPT). Specimens failed either by debonding at laminate-adhesive interface or by laminate failure with stiff adhesives depending on the bond length. In specimens strengthened adopting the flexible adhesive, the failure occurred by debonding at laminate-adhesive interface at some parts of the bond length, together with the cohesive failure of adhesive close to the surface of laminate on the remaining parts. In general an increase of the maximum pullout force with the increase of the bond length observed, as well as the greater system efficiency on transferring
stress between the laminate and the concrete substrate when the stiff adhesives were used. As expected, the pullout force was higher when the larger cross-section geometry was adopted for the laminate. Moreover, the deformations reached at the same load levels when flexible adhesives were used were significantly higher than the ones obtained when using the stiff adhesives. In general the average bond strength tended to decrease with the increase of bond length when utilising stiff adhesives, remaining approximately constant when the flexible adhesive was used. The cross-section geometry did not significantly influence the average bond strength. Stiff adhesives provided higher values of the average bond strength than flexible adhesives. DIC method allowed to document the development of the bond mechanisms for both types of adhesives during the entire loading sequence. The use of stiff adhesives led to a failure/damage concentration mostly at the concrete substrate and at the laminate-adhesive interface. In contrast, when the softer adhesive was used the damage/failure was found to be in the adhesive.

ABSTRACT

The application of carbon fibre-reinforced polymers (CFRP) according to the near-surface mounted (NSM) technique has proved to be one of the most effective systems to strengthen existing reinforced concrete (RC) members in flexure. In spite of that, there are many open issues that deserve investigation such as the effects of exposure to elevated temperatures on the flexural behaviour of RC slabs strengthened with NSM-CFRP systems. The present work aims to experimentally evaluate the mechanical performance of RC slabs strengthened with NSM-CFRP systems under elevated temperatures by using steady-state and transient heating situations combined with applied loads. The temperatures studied were: 20, 40, 50, 70 and 80 °C for the steady-state tests, and 20 and 80 °C for the case of transient tests. Deflections, strains, temperatures and loads were registered in all phases of the tests, in order to thoroughly analyse the response of the system in terms of the load-deflection curves, evolution of the strains of concrete, CFRP and bond stresses between epoxy adhesive and CFRP. The experimental results have shown that the RC slabs strengthened with NSM CFRP systems presented a slight decrease in the ultimate strength and a change on failure mode at the temperature of 80 °C only.

KEYWORDS

Concrete, NSM CFRP, RC slab, strengthening, elevated temperatures.

INTRODUCTION

In the last few decades, the application of near-surface mounted (NSM) technique by using carbon fibre reinforced polymers (CFRP) has been increasingly used in the strengthening of reinforced concrete (RC) structures. One of the key aspects in the structural strengthening performance of a system is its response to the environmental conditions. In the case of structures strengthened with epoxy adhesives, the environmental temperature plays an important role, limiting the application range of such adhesives due to the glass transition temperature ($T_g$). The $T_g$ indicates the transition of an epoxy from solid to a viscous state taking place over a certain temperature range (of about 10-20 °C) (Silva et al., 2016; Michels et al., 2015). Since the bridges can easily reach high temperatures (close to 80 °C) due to sealing layer and asphalt application for example (Silveira, 1996), the performance of structures strengthened with FRP materials bonded with epoxy adhesives should be evaluated.

Several authors have been studying the behaviour of NSM technique under elevated temperatures, such as the work developed by Burke et al. (2013). The beams, strengthened with NSM CFRP systems, were initially loaded up to sustained load (40% of CFRP ultimate tensile strain) at ambient temperature and then heated up to 100 °C and 200 °C, concluding the strengthening system was capable of withstanding over 40 and 30 minutes at 100 °C and 200 °C, respectively. The failure mode observed was debonding at the epoxy adhesive-concrete interface whilst the beams tested at ambient temperature failed by splitting bond of the NSM CFRP system in the concrete adjacent to the epoxy-concrete interface. Apparently, NSM CFRP strengthening systems at the conditions previously specified, are able to maintain their structural capacity for short term periods of exposure to temperatures higher than the $T_g$ of the epoxy adhesives used ($T_g$=69 °C).

Firmo et al. (2014a) performed an experimental program comprising double-lap shear tests with CFRP strips installed according to the NSM technique for temperatures in interface varying between 20 °C and 150 °C. The $T_g$ of the epoxy adhesive used was about 55 °C. In the experimental procedure adopted, the specimens were firstly heated up to a predefined temperature (20, 40, 55, 90, 120, and 150 °C), and then loaded up to failure. From the bond-slip curves obtained, a reduction on the stiffness and maximum bond strength of about 16% at 55 °C was observed. Also, when compared with the control specimen (at 20 °C), a significant bond strength loss was achieved.
for the test with temperatures much higher than the $T_g$ of the epoxy adhesive, (84%, 40% and 33%, respectively, at 55, 90, and 120 °C) (Firmo et al., 2014a; Firmo et al., 2014b).

The present study aims to evaluate the behaviour of the RC slabs strengthened with NSM CFRP system when submitted to elevated temperatures in order to better understand the behaviour of the reinforced system during the glass transition process of the epoxy adhesive. An experimental program was developed including a total of 9 slabs, in which two different types of tests were performed: (i) steady-state tests, and (ii) transient tests. In the steady-state tests, the slabs were heated up to a predefined temperature, and then they were monotonically tested up to failure. In the case of the transient tests, firstly the slabs were preloaded up to 2/3 of ultimate load, and then submitted to an increase of temperature. When the slabs reached the target temperature, the slabs were unloaded and then, monotonically tested up to the failure. The temperatures tested were above and below the $T_g$ of the epoxy adhesive used the present study.

**EXPERIMENTAL PROGRAM**

Protocols adopted for the tests at elevated temperatures

The experimental program is divided in two main groups: (i) the steady state tests (SS) and, (ii) the transient tests (TR). In the first group six slabs (SL) strengthened by the NSM CFRP technique were tested at different target temperatures, namely, 20, 40, 50, 70 and 80 °C. In the second group, one slab was tested at the target temperature 20 °C and the other two at target temperatures of 80 °C. As shown in Figure 1, in the steady state tests, the slabs were firstly heated up to the target temperature without any load application, and then, after reaching this pre-set temperature, they were monotonically tested up to failure. In the case of the transient tests, the two slabs were initially submitted to a constant load of 2/3 of ultimate load (applied in a quasi-static manner) and, then, keeping the load constant, they were submitted to an increasing the temperature up to the predefined value (see Figure 1). One of the slabs was exposed to the temperature at about 80 °C over a period that last 4h, another one a period of 12h, approximately. After this phase the slabs were unloaded and subsequently loaded until failure. Moreover, one control specimen (reference slab) was monotonically tested up to the failure under at temperature of 20 °C.

**Specimen’s geometry and test set up**

The tested slabs used in the present program are 2000 mm long, 300 mm wide and 80 mm thick. Figure 2a depicts the geometry of the cross-section, including the longitudinal reinforcement (4 bars of 6 mm of diameter - 4 Ø6), corresponding to a longitudinal reinforcement ratio of 0.47%. The slabs were strengthened with three CFRP laminate strips, which corresponds an equivalent longitudinal reinforcement ratio of 0.68%. Figure 2b details the geometry of the groove and corresponding reinforcement.

Figure 1 Protocol of the test steady-state and transient tests

Figure 2 Slab’s geometry: (a) cross-section (b) details of the strengthening. [Note: all units are in millimetres]
A four-point bending test configuration was used, with 600 mm of shear spans. The deflections were measured through 5 LVDTs (see Figure 3a). A total of 7 strain gauges (TML BFLA-5-3-3L) were used to measure the strains developed on the CFRP laminates and steel bars, 5 strain gauges in sections S2, S3, S4, S5 and S6 (see Figure 3a) and 2 placed in S6, respectively. One strain gauge (TML PFL-30-11-3L) was used to measure the strain at the top layer of concrete at mid-span section. Finally, the applied load (F) was registered by a load cell placed between the grip and the actuator, with a static load carrying capacity of 200 kN (linearity error < ±0.05% F.S.).

The monotonic tests up to failure were performed by displacement control of 0.02 mm/s. For the case of the TR tests, the load of 2/3 of slab’s ultimate capacity carrying capacity, was applied under force control with a speed of 14 N/s. The unloading phase of unloaded at a velocity of 0.1 mm/s.

Figure 3b shows the general view of the prefabricated chamber and heating system where the SS and TR tests were performed, under controlled environmental temperature. The chamber was developed with extruded polystyrene foam and it was prepared to work up to 100 °C. Two industrial hot-air blowers heated the environment inside the chamber, controlled by an Arduino UNO (Arduino) using an MAX31855 thermocouple amplifier ADC, with cold-junction compensation. Also, a total of 25 thermocouples type-K were installed in order to register the temperature inside the chamber and, at different points of interest inside the slab, as shown in Figure 2a. Some holes were made to place thermocouples in the centre of the slab and at the depth of the strengthening (see Figure 2a). The number of thermocouples positioned in the mid-span cross-section were replicated in another cross-section at about 5 cm from the support and before the extremity of CFRP laminate strip (S1 in Figure 3a). Note the heating velocity of the materials, mainly concrete, was only dependent by the heating power of 6 kW of the hot-air blowers and by the target temperature fixed in the thermostat.

Material Characterization
The tested specimens had approximately 3 years of age and the compressive strength of cylinders (150 mm × 300 mm) was assessed by means of compression tests, following NP EN 12390-3:2011. The Young’s modulus was determined according to LNEC E397-1993:1993. The average concrete compressive strength was 51.9 MPa (CoV=3.9%) and Young’s modulus was 28.8 GPa (CoV=1.5%). The tensile properties of the CFRP laminate strips were assessed according to ISO 527-5:1997, presenting a tensile strength of 2648.3 MPa (CoV=1.8%) and a Young’s modulus of 169.5 GPa (CoV=2.5%). The uniaxial tensile properties of hardened epoxy adhesive were evaluated according to ISO 527-2:1993, and the following average values were obtained: 22 MPa (CoV=4.5%) for tensile strength, 7.2 GPa (CoV=3.7%) for Young’s modulus and 0.36% (CoV=15.2%) for the strain at the peak stress. The glass transition temperature (T_g) of the epoxy adhesive used is 55 °C (Silva et al., 2016). The steel longitudinal reinforcement was evaluated according to NP EN 10002-1:1990, and the obtained average values of E-modulus, hardening modulus and ultimate strength were, respectively, 212.2 GPa (CoV=6.3%), 0.7 GPa (CoV=6.6%) and 733.0 MPa (CoV=1.0%).
RESULTS AND DISCUSSION

Steady-state tests

Figure 4a illustrates the evolution of the air temperature inside the chamber and the average temperature measured at top of slab (concrete surface) – TC1, in the epoxy (inside of groove) – TC4/TC8 – and in the concrete core – TC3 – for the slab SL2_SS_80 (see also Figure 2a). The average temperature was calculated considering the temperature measured by two thermocouples positioned at the two different cross-sections. Although the temperature target was distinct for each experimental test, all slabs tested presented similar temperature development: in which the temperature evolution in first phase was linear during approximately one hour, attaining of about 60% the target temperature. Regarding to the CFRP and concrete strain measured during the heating phase in the slab SL1_SS_80, Figure 4a shows the strain evolution caused by the effect of temperature increase in the slab: (i) in the first 2 hours, up to of about 60 °C of temperature, both strains at the CFRP and concrete increase to the expansion of the slab; (ii) then, the CFRP strain continues to increase and the concrete strain starts to decrease. This behavior it may be explained by the fact of during this phase the slab is submitted to the self-weight in addition to the steel devices used for the application of the load which causes deflection and the balance between the loss of stiffness of the epoxy and the axial stiffness of the concrete and CFRP reinforcement. However, this statement requires scientific support based on further works to be developed, mainly numerical modeling.

Figure 4b plots all the load-deflection curves \( F \)-\( \delta \) obtained in the monotonic tests up to the failure (see also Figure 1). Table 2 includes the values of notable points of total load-deflection curves, such as: midspan deflection and applied load for crack initiation \( (\delta_{cr}, F_{cr}) \), yield initiation of the longitudinal reinforcements \( (\delta_{y}, F_{y}) \), maximum load \( (\delta_{max}, F_{cr}) \), and CFRP and concrete ultimate strains \( (\varepsilon_{CFRP} \text{ and } \varepsilon_{conc}) \). The values of \( F_{cr} \), \( F_{y} \) and \( F_{cr} \), the variation of slabs submitted to the temperature and the reference one (SL1_SS-20) are also represented in Figure 5b. The slab SL1_SS_40 presented the highest ultimate carrying capacity, even comparing with the reference slab (SL1_SS-20). The third branch of the \( F \)-\( \delta \) curve of this slab had a higher slope than the remaining slabs. Although, the air temperature has been constant during the heating phase and in the monotonic test up to the failure, the better performance of slab SL1_SS_40 may be related with a post-curing phase occurred during heating phase since the epoxy adhesive had been submitted to a temperature higher than the ones during the first its cure (Moussa et al., 2012). The post-curing can increase the mechanical properties of the material due to an increase in chain branching and molecular strength. Additionally, the adhesion mechanisms between concrete and the epoxy as well as the epoxy and the CFRP may be also improved. Also, slab SL1_SS_50 was found to have a higher stiffness of the third branch, even though the ultimate capacity has been lower than the reference slab. In this case the slab was submitted to temperatures close to this trigger point \( T_{c} \) justifying this weaker behavior. The slabs submitted to a temperature of 70 °C or higher, presented a stiffness reduction in the first and third branches when comparing with the remaining ones. This behavior is related to the temperature effect on the epoxy adhesive since the temperatures studied in the present work marginally affect the response of concrete itself (Neville, 1995; Anderberg et al., 1976). Moreover, the ultimate load started to be affected comparing to the reference one. The decrease was approximately 9.0%, 11.5% and 12.8% for slab SL1_SS_70, SL1_SS_80 and SL2_SS_80, respectively.

Regarding to the strains, the slabs SL1_SS_20 and SL1_SS_50 attained the maximum concrete strains of about 0.4%, while the maximum CFRP strains were registered in slabs SL1_SS_20 and SL1_SS_40 (at about 1.4%). The slabs tested between 20 °C and 70 °C failed by concrete crushing, while the slabs tested at 80 °C failed by
Transient tests

Figure 5a plots the evolution of deformations for the predefined temperatures. The deformation of the reference slab (SL1_TR_20) was at about 4.3 mm after 9 hours, while for the case of slabs SL1_TR_80 and SL2_TR_80 the deflection reached 11 mm and 14 mm after 4 and 12.5 hours, respectively. The high deformation in the slabs submitted to the 80 °C can be related with the simultaneous effects of creep of concrete and the decrease of the stiffness of epoxy adhesive. It is difficult to quantify the contribution of each effect individually since the creep deformation is greatly influenced by the temperature and the stiffness of the epoxy decrease significantly with the increase of temperature (Silva et al., 2016). According to literature, the creep in the concrete at mean temperature of 40 °C is 25% higher than that at 20 °C (1992-1-1, 2004).

Notes: (a) values reached at the pre-loading phase; (b) strains measured at point-load section; (c) yielding of the reinforcement after the submitted a sustained loading.

Figure 5 Experimental tests (a) loading and heating phase of TR tests; (b) variation of the notable points.

Thereafter, the slabs were unloaded before being submitted to the monotonic tests up to the failure. Figure 4b depicts the total load – mid-span deflection curves in which, as expected, a linear response up to the deformation reached in the heating phase was observed. Table 2 includes the values of notable points of these curves. The stiffness in the first linear branch of the slabs tested at higher temperatures was not affected when compared with the reference slab. The behavior in the branch after the yielding of the longitudinal reinforcements was also similar between the slabs submitted at the same conditions, but marginally stiffer than the reference one (SL1_TR_20). Regarding to the ultimate load, the slabs SL1_TR_80 and SL2_TR_80 only present a decrease of -1.3% and -3.2% when compared with the reference (SL1_TR_20). The slight difference between the ultimate load of the slabs SL1_TR_80 and SL2_TR_80 can be related with the period of time that slabs were submitted to the load conditions, that was of 4 and 12 hours, respectively. Regarding to the strains, the maximum CFRP strain attained by the slab SL1_TR_20 was 1.4% and the concrete one was at about 0.4% and, therefore, the failure mode occurred by concrete crushing. Since the remaining two slabs (SL1_TR_80 and SL2_TR_80) failed by cohesive failure at the epoxy, the CFRP strain only reached about 1.27% and 1.23% in the slab SL1_TR_80 and SL2_TR_80, respectively, approximately 12% less than the reference.

Figure 5b presents the evolution of cracking, yielding and ultimate load of all slabs tested. As can be observed, the slabs submitted at 80 °C under steady-state tests presented a higher decreased of ultimate load than the slabs...
submitted to the same temperature in the transient tests. Regarding to the yielding load, the TR tests presented higher values due to the cracking caused in the loading and heating phase. Moreover, the behavior of the slabs of TR tests presented a higher stiffness up to the yielding load than the remaining slabs, as can be seen in Figure 4b. In these tests, after the yielding of reinforcement, the laminate does not reach strains as high as the remaining slabs, perhaps associated to the residual deflection after the unloading and the damaged caused by the period of time that slabs were submitted to the loading and heating.

CONCLUSIONS

The main goal of the present work was to study the behaviour of reinforced concrete slabs strengthened with CFRP laminate according NSM technique when subjected to the elevated temperatures. For this purpose, two different types of experimental tests were performed, namely: (i) steady-state (SS) tests, and (ii) transient (TR) tests. In the case of SS tests, the slab submitted to 40 °C presented the highest ultimate load comparing with the reference slab tested at 20 °C, that could be related with a post-curing occurred in the epoxy adhesive. The ultimate load of slabs submitted to 80 °C were the most affected by the temperature, and when compared with the reference one, a decrease of approximately 12% was observed. Regarding to the TR tests, the slabs submitted at high temperatures suffer 3 times more deformation than slab tested at 20 °C during the heating phase, that may be related with the decrease of the stiffness of epoxy and the increase of creep effect of concrete at higher temperatures. However, in the monotonic test up to the failure a maximum decrease of about 3% was observed in comparison to the reference. In both types of tests, the slabs submitted at 80 °C of temperature failed by cohesive failure at the epoxy, while in remaining slabs the failure mode was concrete crushing. From the test results, it can be seen that the elevated temperatures up to 80 °C only have marginal effect of the the behaviour of RC slabs strengthened with NSM CFRP systems. However, further works (e.g. numerical modelling of the tests carried out) are necessary for a better and more in-depth understanding of the test results.

ACKNOWLEDGMENTS

This work was supported by FEDER funds through the Operational Program for Competitiveness Factors – COMPETE and National Funds through FCT (Portuguese Foundation for Science and Technology) under the project FRLongDur POCI-01-0145-FEDER-016900 (FCT PTDC/ECM-EST/1282/2014) and partly financed by the project POCI-01-0145-FEDER-007633. The authors also like to thank the S&P Clever Reinforcement Ibérica Lda. company for providing the material tested in ambit of the present work. ASSESSMENT OF CURRENT GUIDELINE FORMULATIONS FOR FLEXURAL STRENGTHENING OF REINFORCED CONCRETE BEAMS USING NSM REINFORCEMENT

ABSTRACT

Near surface mounted (NSM) fiber reinforced polymer (FRP) reinforcement represents a valid alternative to externally bonded (EB) FRP reinforcement for strengthening existing reinforced concrete (RC) elements. When the NSM technique is employed for flexural strengthening, FRP composites are embedded into grooves cut into the concrete cover and filled with an inorganic or organic binding agent. Although many studies on the bond behavior of NSM FRP composites can be found in the literature, limited work is available regarding analytical models for designing NSM strengthening of RC members. In this paper, a database of experimental tests of 155 RC beams strengthened in flexure using NSM reinforcement is collected from the literature. The experimental results are employed to assess the accuracy of the analytical provisions obtained following the American, English, Canadian, and Italian guidelines.

KEYWORDS

NSM, RC beams, strengthening, analytical formulation, assessment.

INTRODUCTION

In the last decades, fiber reinforced composite materials have gained increasing popularity in the civil engineering industry. Among them, fiber reinforced polymer (FRP) composites have been employed to strengthen existing reinforced concrete (RC) and masonry elements. FRP composite strips are largely applied to existing elements as externally bonded (EB) reinforcement (see e.g. CNR DT-200 R1/2013). A valid alternative to EB FRP systems is represented by near surface mounted (NSM) FRP systems, which consists in FRP bars (i.e. circular cross-section) or plates (i.e. prismatic cross-section) installed into grooves cut onto the element surface and put in place using an adhesive (ACI 440.2R-08). NSM reinforcement are usually comprised of glass, carbon, or aramid fibers and are put in place through inorganic (e.g. cement grout) or organic (e.g. epoxy resin) binding agents. Although NSM reinforcement cannot be used in concrete elements for which the depth of cover is low, it is indicated for application where the concrete surface is exposed to potential damage, is undulating, or a thin layer of poor concrete is present near the surface (TR 55 2012). Extensive research has been carried out to investigate the NSM-concrete bond behavior. However, limited work is available regarding analytical models for designing NSM strengthening of RC members.

In this paper, three analytical models for the estimation of the bending capacity of RC beams strengthened with NSM FRP composites (i.e. American ACI 440.2R-08, English TR 55 (2012), and Canadian CSA S806-12 guidelines) are analyzed. Furthermore, the procedure for EB reinforcement proposed by the Italian CNR DT-200 R1/2013 is extended to the case of NSM reinforcement. An experimental database comprised of 155 RC beams strengthened in flexure with NSM reinforcement was collected from the literature. Comparisons between the maximum bending moment computed by the analytical models and the corresponding experimentally measured value allow to assess the accuracy of each model. Although conservative, the analytical models considered are generally poorly accurate and further studies are needed to provide reliable and accurate procedures for designing flexural strengthening with NSM reinforcement.

NSM FLEXURAL STRENGTHENING ANALYTICAL MODELS

The analytical procedures proposed by the American, English, Canadian, and Italian guidelines are herein briefly recalled. For each procedure, failure of the FRP reinforcement is assumed to occur when the strain in the FRP is

943
According to the American guideline ACI 440.2R-08 the maximum strain of the FRP reinforcement $\varepsilon_{fd}$ is:

$$\varepsilon_{fd} = 0.7\varepsilon_f^*$$  \hspace{1cm} (1)

where the design rupture strain of the FRP reinforcement $\varepsilon_f^*$ is:

$$\varepsilon_f^* = C_e \cdot \varepsilon_f$$  \hspace{1cm} (2)

where $\varepsilon_f^*$ is the ultimate rupture strain of the FRP reinforcement and $C_e$ is an environmental reduction factor, which was assumed equal to 1.0 in this study. Reliability of the FRP contribution to flexural strength should be addressed by applying an additional strength reduction factor $\Psi_f$. Since $\Psi_f$ reflects uncertainties inherent in FRP systems that are prevented in laboratory tests, it was assumed equal to 1.0 in this study.

According to the English guideline TR 55 (2012), NSM strengthening of RC beams should be designed against different failure modes. To avoid concrete cover separation, the strain in the FRP should be limited to:

$$\varepsilon_{fd} = \varepsilon_{lim} = 38 \frac{b}{n} \frac{f_{ck}}{E_f A_f} \leq \frac{\varepsilon_{fu}}{E_f A_f}$$  \hspace{1cm} (3)

where $b$ is the width of the concrete cross-section, $n$ is the number of NSM profiles provided, $f_{ck}$ is the concrete characteristic tensile strength, $E_f$ is the FRP modulus of elasticity, and $A_f$ is the area of a single NSM profile. Furthermore, to avoid concrete splitting failure the strain in the FRP reinforcement in the cross-section where the FRP is needed, i.e. where yielding of the steel reinforcement starts to occur, should be limited to the maximum ultimate anchorage strain $\varepsilon_{max}$:

$$\varepsilon_{fd} = \varepsilon_{max} = \begin{cases} 
10b_{notchperim} \frac{f_{ck}}{E_f A_f} & \text{for } l \geq l_{max} \\
10b_{notchperim} \frac{f_{ck}}{E_f A_f} \left[ \frac{l}{l_{max}} - \frac{2}{l_{max}} \right] & \text{for } l < l_{max} 
\end{cases}$$  \hspace{1cm} (4)

where $b_{notchperim}$ is the perimeter of notch, $l$ is the FRP anchorage length, and $l_{max}$ is the maximum anchorage length:

$$l_{max} = 0.135b_{notchperim} \frac{E_f A_f}{f_{ck}}$$  \hspace{1cm} (5)

To prevent failure in the adhesive layer, the strain in the FRP should be limited to:

$$\varepsilon_{fd} = \varepsilon_{ad} = \frac{0.3f_{at} \cdot b_{haperim} \cdot l}{E_f A_f}$$  \hspace{1cm} (6)

where $f_{at}$ is the adhesive tensile strength and $b_{haperim}$ is the perimeter of NSM profile. For the sake of simplicity, the NSM reinforcement was assumed to be designed against NSM-concrete and NSM-adhesive separation failure (TR 55 2012).

The Canadian standard CSA S806-12 does not provide specific formulations to prevent FRP debonding failure but simply limit the strain in the FRP reinforcement to $\varepsilon_{fd}=0.007$. Therefore, when employing the Canadian formulation, failure is assumed either when the strain in the compressed concrete is equal to 0.0035 or when the FRP strain is equal to 0.007.

The Italian guideline CNR-DT 200 R1/2013 does not provide a specific procedure for designing RC beams strengthened with NSM reinforcement. However, in this paper the procedure provided by CNR-DT 200 R1/2013 for EB reinforcement was extended to the case of NSM reinforcement to investigate the possibility of using the same approach for both EB and NSM reinforcements. As a first attempt, the thickness $t_f$ and width $b_f$ of an EB FRP strip were related to the geometrical properties of the NSM reinforcement as follows:

$$b_f = \begin{cases} 
\frac{\pi \cdot d}{2n} & \text{for NSM bars} \\
\left( b_n + 2h_n \right) \cdot n & \text{for NSM plates}
\end{cases}$$  \hspace{1cm} (7)
where $d_n$ is the diameter of the $n$-th NSM bar, and $b_n$ and $h_n$ are the width and thickness of the $n$-th NSM plates, respectively.

According to the Italian guideline, the strain in the FRP reinforcement should be limited to $\varepsilon_{\text{FRP}}$.

$$\varepsilon_{\text{FRP}} = \min \left\{ \frac{\eta_{\text{FRP}} \cdot \varepsilon_{\text{p}, \text{FRP}}}{\gamma_{\text{FRP}}}, \varepsilon_{\text{IC}} \right\}$$

where $\eta_{\text{FRP}}$ and $\gamma_{\text{FRP}}$ are safety factors assumed equal to 1.0 in this study, $\eta_{\text{FRP}}$ is the FRP characteristic failure strain, and $\varepsilon_{\text{IC}}$ is the FRP intermediate crack-induced (IC) debonding strain:

$$\varepsilon_{\text{IC}} = \frac{k_b}{\gamma_{\text{IC}}} \left( \frac{2 \cdot k_b \cdot k_G \cdot f_{cm} \cdot f_{cm}}{f_{dd} \cdot f_{dd} \cdot k_{cm} \cdot (s_n/a_{cm})} \right)$$

where $k_b=1.25$ for distributed loads and $k_b=1.00$ otherwise, $\gamma_{\text{IC}}$ and $FC$ are a safety factor and a confidence factor, respectively, assumed equal to 1.0 in this study, $k_G$ is a corrective factor whose mean value is 0.32 mm, $f_{cm}$ and $f_{dd}$ are the concrete mean compressive and tensile strength, respectively, and $k_b$ is a geometrical corrective factor:

$$k_b = \sqrt{\frac{2 \cdot b_f}{b_f + b_f}} \geq 1$$

To prevent end-plate (EP) debonding failure, the FRP reinforcement strain in the cross-section where yielding of the steel reinforcement starts to occur should be limited to:

$$\varepsilon_{\text{steel}} = \min \left\{ \frac{1}{\gamma_{\text{steel}}} \left( \sqrt{\frac{2 \cdot k_b \cdot k_G \cdot f_{cm} \cdot f_{cm}}{f_{dd} \cdot f_{dd} \cdot k_{cm} \cdot (s_n/a_{cm})}} \right), \varepsilon_{\text{FC}} \right\}$$

where the maximum anchorage length $l_{\text{max}}$ is:

$$l_{\text{max}} = \min \left\{ \frac{1}{\gamma_{\text{steel}}} \left( \sqrt{\frac{2 \cdot k_b \cdot k_G \cdot f_{cm} \cdot f_{cm}}{f_{dd} \cdot f_{dd} \cdot k_{cm} \cdot (s_n/a_{cm})}} \right), 200 \text{ mm} \right\}$$

where $k_G$ is a geometrical corrective factor whose mean value is 0.063 mm, and $s_n$ is the FRP-concrete interfacial debonding slip.

**EXPERIMENTAL DATABASE**

**ASSESSMENT OF THE ANALYTICAL MODELS CONSIDERED**

The accuracy of each analytical model considered was evaluated by comparing the maximum bending moment measured experimentally, $M_{exp}$, with the corresponding analytical maximum bending moment $M_a$. The analytical maximum bending moment was obtained by enforcing the equilibrium of the cross-section assuming elasto-plastic behavior of concrete and steel and linear-elastic behavior up to $\varepsilon_{\text{FRP}}$ of the FRP reinforcement. As indicated by the specific guideline, the concrete stress-strain behavior was described by the elasto-plastic model proposed by Hognestad (1951) when assessing the American and Canadian guidelines, and by the parabola-rectangle model proposed by EN 1992-1-1 (2004) when assessing the English and Italian guidelines. It should be noted that all
safety factors and partial coefficients provided by the models were assumed equal to 1.0. Furthermore, when values of the adhesive tensile strength $f_{ad}$ were not reported, Eq. (6) was not considered in assessing the TR 55 (2012) model.

The discrepancy between analytical results and experimental evidence was assessed by computing the average Avg and coefficient of variation CoV of the ratios between the $i$-th analytical and experimental maximum bending moment, $r_i = M_{th,i}/M_{exp,i}$. Furthermore, the accuracy of each analytical model was assessed by computing the coefficient of variation $CoV_{ref}$ with respect to the perfect match average ratio $Avg_{ref} = 1.0$:

$$CoV_{ref} = \sqrt{\frac{\sum_{i=1}^{N} (r_i - Avg_{ref})^2}{N}}$$

(14)

where $N$ is the number of tests considered, equal to 155 in this study.

RESULTS AND DISCUSSION

Figure 1 shows the comparison between analytical and experimental values of the maximum bending moment for the 155 beams included in the database. Values below the line $M_{th}/M_{exp} = 1.0$ are conservative since the estimated bending moment is lower than the corresponding experimentally measured value, whereas values above the line $M_{th}/M_{exp} = 1.0$ are non-conservative.

Figure 1 Comparison between analytical and experimental maximum bending moment values of the 155 beams included in the database.

Values of the average Avg, coefficient of variation CoV, and perfect match coefficient of variation $CoV_{ref}$ obtained are reported in Table 1 for each model considered. The results obtained show that the American ACI 440.2R-08 and Canadian CSA S806-12 models provided the most accurate results, whereas the less accurate estimations were obtained by extending the Italian CNR DT-200 R1/2013 EB reinforcement model to the case of NSM reinforcement. Although a specific formulation to prevent NSM reinforcement debonding failure is not provided, the Canadian CSA design procedure seems particularly attractive because provides accurate results with a simple procedure. Similarly, the American approach provided accurate results with a simple procedure, which appears more reliable than the Canadian approach because the maximum strain in the composite is related to the NSM reinforcement failure strain and it is not a fixed value. However, ACI 440.2R-08 does not directly take into account the effect of the FRP reinforcement anchorage length, which can lead to premature failure along the anchorage
length. The Italian approach generally provided conservative results, which are attributed to the fact that the procedure adopted was originally developed for EB reinforcement that usually fails due to debonding at strain values lower than those observed for NSM reinforcement (see e.g. ACI 440.2R-08). The English TR 55 (2012) approach, which was developed specifically for NSM reinforcement and imposes several different analyses, generally provided conservative results with limited accuracy.

**CONCLUSIONS**

This paper presents the assessment of four analytical models for the estimation of the bending capacity of RC beams strengthened with NSM reinforcement. The NSM reinforcement design formulations proposed by the American ACI 440.2R-08, English TR 55 (2012), and Canadian CSA S806-12 guidelines were considered. Furthermore, the procedure for EB reinforcement proposed by the Italian CNR DT-200 R1/2013 was extended to the case of NSM reinforcement. An experimental database comprised of 155 RC beams tested in flexure by 28 working groups was collected from the literature. The accuracy of each analytical model was assessed by comparing values of the maximum bending moment obtained from the analytical formulations with corresponding values measured experimentally. The results obtained showed that the Canadian approach seems particularly attractive because provides accurate results with a simple procedure. Similarly, the American formulation provided accurate results with a simple procedure that appears to more reliable than the Canadian approach because relates the maximum strain in the composite reinforcement to the NSM reinforcement failure strain. The English procedure, which was developed specifically for NSM reinforcement, generally provided conservative results with limited accuracy. The Italian approach generally provided conservative results, which are attributed to the fact that the procedure adopted was originally developed for EB reinforcement that usually fails due to debonding at strain values lower than those observed for NSM reinforcement. Based on the results obtained, further studies seem to be necessary to provide reliable and accurate procedures for designing flexural strengthening with NSM reinforcement.

ABSTRACT

The near-surface-mounted (NSM) fiber-reinforced polymer (FRP) technique has many obvious advantages including good bonding efficiency, the effectiveness of strengthening and especially the fire resistance. These performances can be highly affected by filling materials in the groove (refer to as the groove-filling materials or GFMs). In this paper, the performance of FRP bars under different working conditions in the fire and the impact of different GFMs on the fire resistance of reinforced concrete (RC) beams strengthened with NSM FRP bars are investigated. Through experimental and numerical studies, it was found that the fire resistance of RC beams filled with fiber polymer mortar (FPM) was improved significantly, while was inferior to the control beams when the filling material was modified acrylic emulsion mortar (MAEM). At the late stage of the fire test, strengthened members with longer adhesive anchorage length could delay the stiffness degradation and have relatively higher fire resistance. These preliminary test results indicated that the fire resistance of RC members strengthened with NSM FRP bars was highly dependent on the types of the GFMs.

INTRODUCTION

There are many coupling factors affecting the performance of FRP materials under high temperatures (Bisby et al. 2005; Wang et al. 2007). But in-depth studies on the performance of FRP materials under high temperatures are very lacking. Therefore, systematical researches on properties of FRP under different high temperatures, fire conditions and the analysis of its performance decline rules are necessary.

In recent years, near-surface-mounted (NSM) FRP reinforcing technique has attracted increasing attentions as a promising alternative to externally bonded (EB) FRP reinforcing technique. NSM method has many obvious advantages over EB method (Hassan et al. 2003; De Lorenzis et al. 2007; Rein et al. 2007; Wu et al. 2007; Ceroni et al. 2012; Burke et al. 2013; Seo et al. 2013; Bianco et al. 2014), such as higher anchoring capacity, better bond characteristics and even higher fire resistance. But its effectiveness of strengthening is greatly affected by filling materials in the groove (refer to as the groove-filling materials or GFMs). Fire resistance of RC beams strengthened with NSM FRP bars using different GFMs under different working conditions was tested in this paper. Two kinds of GFMs (fiber polymer mortar and modified acrylic emulsion mortar) and different adhesive anchorage lengths (300 mm and 400 mm) were considered respectively.

Because few studies have been conducted on the influence of cracks on the temperature transfer in the inner concrete, there are no clear conclusions about this. Vejmelková et al. (2008) had conducted a research about the influence of micro-cracks. It was concluded that the generated inner micro-cracks aggravated the porosity under high temperatures, and thus led to the reduction in thermal conductivity. However, there are no studies on the influence of macro-cracks on fire resistance of structures. In order to study the influence of the macro-cracks on the temperature field, the distribution and development of the temperature of some specimens with pre-fabricated cracks were monitored and the mechanism is analysed.
**EXPERIMENTAL PROGRAM**

Five cement-mortar specimens with pre-fabricated cracks were made, and the crack widths are 0.3mm, 0.5mm, 1.0mm, 1.5mm and 2.0mm, respectively. FRP bars were installed in the mould before cement-mortar pouring. The high temperature furnace used in the experiment is shown in Figure 1. As shown in Figure 2, the size of the mortar specimens was 75mm x 75mm x 300mm. The cracks were made by placing steel sheet with different thickness at the middle of the mortar blocks.

The specimens are numbered as S-0.3, S-0.5, S-1.0, S-1.5 and S-2.0. Three thermocouples were arranged on every FRP bar for measuring temperature at different points, the distance between the measuring points is 70mm. As shown in Figure 3, the upper and lower measuring points are located at the interior mortar, and the middle point is located at the pre-fabricated crack. The internal temperatures of mortar specimens are measured by TDS-303. The heating rate was set to be 5 °C/min to avoid spalling of the mortar blocks, referred to the previous experience by the authors and other researchers. When the target temperature (400 °C) was reached, the furnace temperature was maintained for a heating period of 1 hour. The furnace temperature and the temperatures at FRP bar at the three points (two inside mortar and one at the crack) were monitored.

For NSM FRP bars, three sides of FRP are protected by concrete and only one side is exposed to fire temperature filed. The GFM have significant effects on the bond property of concrete-FRP and on the fire resistance of strengthened beams. Previous tests (Vejmelková et al. 2008; Zhang 2014) have been conducted on NSM FRP bars strengthened RC beams using organic binder with/without fire protection. From those tests, for the two types of GFMs—organic binder and inorganic polymer composites, the former properties are superior to the latter under the normal temperature but inferior to the latter under the high temperatures. So it is of a great significance to combine the advantages of organic binder and inorganic polymer composite. Based on the previous research results, this paper focuses on the fire resistance of RC beams strengthened by NSM technique using organic glue at the end of the members and inorganic polymer composite materials at the middle grooves of the members.

A total of seven beams, with a span of 3.6m and a cross section of 0.2m x 0.45m, were tested. Details on the configuration of these beams are listed in Table 1 and Figure 4. Two specimens were tested at room temperature to acquire the ultimate bearing capacity, and the other five specimens were heated according to ISO-834 heating curve under 50% of the acquired ultimate load at room temperature. Beam L1 and L3 are the ordinary RC beams, L2, L4, L5, L6 and L7 are NSM strengthened beams with CFRP bars. K-type thermocouples in L3 to L7 were embedded at the different locations pointed out via sign “×” and serial numbers.

As shown in Figure 5, steel wire meshes-reinforced mortar was selected to guarantee the end anchorage property of NSM FRP bars in the fire, inorganic materials were used to fill the grooves in the middle part. The measured
average cylinder compressive strength of the C30 concrete, fiber polymer mortar (FPM) and modified acrylic emulsion mortar (MAEM) were 33.0MPa, 52.4MPa and 41.9MPa, respectively. The tensile strength and elastic modulus of CFRP bars with nominal diameter of 11 mm were 2285MPa and 177GPa, respectively. The yield strength and elastic modulus of the steel bar were 438.3MPa and 210GPa, respectively.

**TEST RESULTS AND DISCUSSION**

*The effect of cracks on temperature transferring*

The average temperatures of the two measuring points at the internal mortar of cement-mortar specimens are compared with that of the measuring point at the crack. The temperature-time curves are shown in Figure 6. Only the results of S-0.3, S-1.0 and S-2.0 are showed because of the same variation regularity of S-0.5 and S-0.3, and the nearly same regularity between S-1.0 and S-1.5.

As shown in figure 6, all the temperatures at crack and internal point showed rising trends with the increasing of furnace temperature, and each of the two temperature-time curves emerged an inflection point at around 80 minutes when the furnace temperature reached the constant temperature stage. It can also be found that the temperature curves at internal point and crack point are nearly consistent before the target temperature (400℃) was reached. However, after the target temperature 400℃ was reached inside the furnace and kept constant, the increasing speeds of temperature at the crack point were higher than the internal points. At the end of the test, the temperatures at the crack point of S-0.3, S-1.0 and S-2.0 were 7℃, 13℃ and 22℃ higher than the internal point, respectively.

The above phenomena indicate that the presence of crack does not accelerate the transfer of temperature from external to the internal at the initial heating process. In addition, it can also be concluded that although a wider crack will lead to a slightly higher temperature transfer speed at the constant temperature stage, 2.0 mm crack...
width was still not serious for temperature transferring when the environment temperature was below 400 ℃.

After exposure to the high temperature, the FRP bars were taken out, as shown in Figure 7. The softness and decomposition of the resin and the combustion of fiber of S-2.0 were more serious; FRP bars of S-1.5 was slightly loose and bulged locally; the fiber and resin of S-0.3~S-1.0 had no obvious damage at the crack site. This indicated that although the FRP bars at the crack site directly were exposed to the high temperature, the decomposition of the resin was limited under the function of oxygen insulation. As a consequence, it is reasonable to infer that the FRP bars could still have certain residual mechanical property if only fine and dense cracks appeared in FRP bars strengthened RC members.

![Figure 7 Surface configuration of FRP bars after high-temperature](image)

**Analysis of beam deflection**

the deflection curves of L3 to L7 at different times under fire recorded by LVDT's located along the beam are shown in Figure 8. For example, the L3-30 curve in the Figure 8a represents the deflection curve of L3 after 30 minutes. Compared with L3 to L5, within 30 minutes, the deflection values of L6 and L7 were very small because of the non-negligible expansion of concrete during the early heating stage. For L3 to L5 within 90 minutes of fire exposure, the deflection curves were nearly similar and stable, while the deflection of L6 and L7 were much larger. The reason was that the MAEM suffered serious degradation of mechanical performance in high temperatures. It was peeled off from the beam bottom, and then the exposed NSM FRP bars directly contacted with the fire, which leaded to the degradation of stiffness and strength of the strengthened RC beams.

![Figure 8 The deflection curves of L3 to L7 under different times](image)

**Fire resistance of NSM beams**

The failure modes of L3 to L7 exposed to fire were concrete crushing in compression zone as well. The fire resistance, mid-span deflection and temperatures of rebars at mid-span are listed in Table 2. From Table 2, L4 and L5 with FPM have better fire resistance than L3 and L6 to L7 with MAEM, which means that the fire resistance of beams can be significantly improved when appropriate inorganic materials were used as groove filler. When comparing L4 with L5 and L6 with L7, respectively, it can be inferred that a longer end anchorage length with steel wire meshes reinforced mortar can increase the fire resistance.

**The effect of crack-width control**

Fine and dense cracks were observed on the grooves as shown in Figure 9a, and the number of cracks in the FPM was more than that in the bottom and side concrete. The mortar was not significantly peeled off after being cooled...
for 120 minutes. Only the bottom surface of exposed CFRP bar became loose due to the high temperature carbonization while the other part was still dense due to the oxygen barrier protection of mortar, and it could still bear loads.

(a) L4

![Surface condition of L4 after fire exposure](image1)

(b) L6

![Surface condition of L6 after fire exposure](image2)

The surface condition of L6 after fire exposure is shown in Figure 9b, several cracks went through to the top of the beam in the pure bending section, the mortar spalling was serious in the groove of beam bottom, there was a 400 mm bar bare section at the left side of beam and a 200 mm bar bare section in the beading-shearing section at the right side of beam. The CFRP bar in the bare section was seriously carbonized and its resin was basically volatilized. In the other groove, mortar has swelled with a larger gap, and it basically lost thermal-insulation protection effect. The MAEM after fire exposure has become loose and can be even squeezed into granular substances. The crack-widths of L4 and L6 were tested.

The largest crack width of L4 and L6 measured after fire exposure was about 1 mm in the groove. Considering the crack closure after unloading and referring to the relationship between the deflections before and after unloading, it was estimated that the crack width when nearly reaching the fire resistance generally exceeded 2 mm.

It can be seen that the fire resistance of a strengthened beam would be sufficiently improved if there are only fine and dense cracks at the beam bottom. For further study, the relationship of FRP residual mechanical performance and heating period as well as how to use the relationship to analyze fire resistance of beams are worth examining.

### CONCLUSIONS

In this paper, the influence of cracks on the temperature transfer was tested first, and then the performance of NSM CFRP bars-strengthened RC beams with two types of GFMs and different lengths of end anchorage under fire exposure were experimentally studied. The main conclusions based on the results are as following:

1. As the crack width is limit, it will hinder heat transfer into the internal specimen, so the temperature of air at the crack is much lower than that in the high temperature field and is consistent with internal temperature. Meanwhile, while FRP material at the narrow crack site is in direct contact with air, its resin volatilization is less, so it can still maintain good mechanical properties. With the increase of the crack width, the hinder function gradually decreases and resin volatilization is more serious.

2. The adhesive anchorage length has little effect on the deflection in the early stage of the fire, but in the late stage of fire function, longer length of anchorage glue and protection can delay the decline of the stiffness of strengthened beam and its fire resistance is relatively high.

3. The performance of GFMs at high temperatures has great effect on the fire resistance of strengthened beam. The generated large crack width or spalling of the filled material can lead to direct exposure of FRP bars to
fire, which will cause a significant reduction of the fire resistance of the overall member.

(4) In the groove of the strengthened RC beam, the FPM produces fine and dense cracks under fire condition and is hard to peel off. By contrast, the MAEM is easy to burst, so it is important to select proper inorganic polymer mortar for meeting good fire resistance of NSM strengthening.

INTERACTION FORCES IN RC BEAMS STRENGTHENED WITH NSM FRP ROUND BARS

S.S. Zhang and T. Yu
School of Civil, Mining and Environmental Engineering, University of Wollongong, Australia
(shishun@uow.edu.au)

ABSTRACT
The near-surface mounted (NSM) strengthening method has attracted an increasing worldwide attention in the last decade. Although the bond efficiency between FRP and concrete in the NSM method is much improved compared with the externally bonded (EB) FRP strengthening method, debonding failures have also been often observed in reinforced concrete (RC) beams strengthened with NSM FRP bars. In such FRP-strengthened RC beams, debonding may initiate at either of the two ends of the NSM bar (i.e. end debonding), due to the existence of large localized interaction forces between the NSM bar and concrete near the bar ends. This paper presents an analytical solution to the interaction forces in RC beams strengthened with NSM FRP round bars, which are one of the most popular types of FRP bars used for NSM strengthening. The key elements of the proposed analytical solution are the two interfacial stiffness parameters (i.e. tangential interfacial stiffness and normal interfacial stiffness) and the eccentricity of the tangential interaction force to the centroid of the NSM bar. The accuracy of the analytical solution is verified with predictions from a sophisticated 3D finite-element (FE) model of a RC beam strengthened with a NSM round bar.

KEYWORDS
FRP, finite element (FE) analysis, interaction forces, interfacial stiffness, near-surface mounted (NSM), RC beams

INTRODUCTION
The use of near-surface mounted (NSM) FRP composites for strengthening RC beams in flexure has become increasingly popular in the last decade (Hassan and Rizkalla 2004; Sena Cruz et al. 2006; De Lorenzis and Teng 2007; Oehlers et al. 2008). In the NSM FRP method, grooves are cut into the concrete cover of a concrete member for the embedding of FRP bars using an adhesive. A typical schematic of NSM FRP for flexural strengthening of RC beams is shown in Figure 1. Compared to the externally bonded FRP method, the NSM FRP method has a number of advantages including a reduced risk of debonding failure and better protection of the FRP reinforcement (De Lorenzis and Teng 2007). However, the improved bond effectiveness cannot eliminate the possibility of debonding failure in RC beams strengthened with NSM FRP bars (Zhang et al. 2013; 2014). The debonding failure in an NSM FRP-strengthened beam may initiate from a major intermediate crack (i.e. IC debonding), or from either of the two ends of an NSM bar (i.e. end debonding) (Teng et al. 2006). For the latter case which has been more often observed, the failure are closely related to the existence of large localized interaction forces between the NSM bar and concrete near the ends of the bar in such strengthened RC beams.

Figure 1. Schematic of NSM FRP strengthening systems
Recently, Zhang and Teng (2013) proposed a closed-form solution to the interfacial interaction forces in RC beams strengthened with NSM rectangular FRP bars. Zhang and Teng's (2013) solution includes the establishment of approximate equations for the interfacial stiffness parameters, and its accuracy has been demonstrated by a 3D linear elastic finite element (FE) model. Following Zhang and Teng's (2013) work, this paper develops a closed-form analytical solution to the interaction forces in RC beams strengthened with NSM round FRP bars, with the key issue being on the establishment of interfacial stiffness parameters (Figure 2) and the eccentricity of tangential interaction force to the centroid of the NSM bar. In this paper, the governing equations and solutions proposed by Zhang and Teng (2013) are first presented, followed by determination of the two interfacial stiffness parameters and the eccentricity of tangential interaction force particularly for round NSM FRP bars. The proposed analytical solution is then verified by a sophisticated 3D FE model of RC beam strengthened with an NSM round bar.

GOVERNING EQUATIONS AND SOLUTION

The governing equations of interaction forces between NSM FRP and concrete (\( F_t \) and \( F_n \), i.e., the interaction forces in the tangential direction and the normal direction respectively) for RC beams strengthened with NSM bars subjected to a uniformly distributed load (UDL) \( q \) can be expressed as (Zhang and Teng 2013):

\[
\frac{d^2 F_t(x)}{dx^2} - k_T \left( \frac{d_s}{E_s I_s + E_f I_f} + \frac{1}{E_s A_b} \right) F_t(x) - k_F \left( \frac{d_s}{E_s I_b + E_f I_f} \right) V_r(x) = 0 \tag{1}
\]

\[
\frac{d^2 F_n(x)}{dx^2} + k_T \left( \frac{1}{E_s I_b} + \frac{1}{E_f I_f} \right) F_n(x) + k_f \left( \frac{y_b}{E_s I_b} - \frac{y_f}{E_f I_f} \right) \frac{dF_n(x)}{dx} + k_t \frac{1}{E_s I_b} q = 0 \tag{2}
\]

where \( x \) is the distance from the NSM bar end in the longitudinal direction; \( E_t \), \( A_b \) and \( I_f \) are the elastic modulus, cross-sectional area and second moment of area of the NSM FRP bar respectively; \( E_s \), \( A_b \) and \( I_b \) are the elastic modulus, cross-sectional area and second moment of area of the original beam respectively; \( E_n \).

\( G_n \), and \( t_n \) are the elastic modulus, shear modulus and thickness of the adhesive layer respectively; \( d_o \) is the distance between the centroids of the original beam and the NSM bar; \( y_b \) and \( y_f \) are the eccentricities of the tangential interaction forces to the centroid of the beam and that of the NSM bar respectively; and \( V_r \) is the shear force in the beam. \( k_T \) and \( k_f \) are the tangential interaction stiffness and the normal interaction stiffness respectively, which can be defined as the interfacial interaction forces between the NSM bar and concrete per unit length corresponding to a unit relative displacement between the NSM bar and concrete in the designated direction (as shown in Figure 2).

The solutions to Eqs. 1 and 2 are in the following form:

\[
F_t(x) = B_1 \cosh(\lambda x) + B_2 \sinh(\lambda x) + mV_r(x) \tag{3}
\]

\[
F_n(x) = e^{-\lambda x} \left[ C_1 \cos(\beta x) + C_2 \sin(\beta x) \right] - n_1 \frac{dF_t(x)}{dx} - n_2 q \tag{4}
\]

The constants in Eqs. (3) and (4) are as follows:

\[
B_1 = \frac{k_T y_b q a}{E_s I_b 2 \lambda} (L-a) - \frac{k_f}{\lambda^2} \left( \frac{d_s}{E_s I_b + E_f I_f} \right) q \tag{5}
\]

\[
B_2 = -B_1 = \frac{k_T y_b q a}{E_s I_b 2 \lambda} (L-a) + \frac{k_f}{\lambda^2} \left( \frac{d_s}{E_s I_b + E_f I_f} \right) q \tag{6}
\]

\[
C_1 = \frac{k_T}{2 \beta^2 E_s I_b} \left[ V_r(0) + \beta M_r(0) \right] - \frac{k_f}{2 \beta^2} \left( \frac{y_b}{E_s I_b} - \frac{y_f}{E_f I_f} \right) F_t(0) + \frac{k_T q \lambda^2}{2 \beta^2} \left( \frac{y_b E_f I_f - y_f E_s I_s}{E_s I_b + E_f I_f} \right) \left( \frac{y_b a}{E_s I_b} (L-a) - \frac{1}{\lambda^2} \left( \frac{d_s}{E_s I_b + E_f I_f} \right) \right) \cos(\lambda x) \tag{7}
\]

\[
C_2 = -\frac{k_n}{2 \beta^2 E_s I_b} \left[ M_r(0) \right] + \frac{k_T q \lambda^2}{2 \beta^2} \left( \frac{y_b E_f I_f - y_f E_s I_s}{E_s I_b + E_f I_f} \right) \left( \frac{y_b a}{E_s I_b} (L-a) - \frac{1}{\lambda^2} \left( \frac{d_s}{E_s I_b + E_f I_f} \right) \right) \cos(\lambda x) \tag{8}
\]
\[ \lambda^2 = k\left( \frac{d^2}{E_I b^2 + E_h A_f} + \frac{1}{E_h A_h} + \frac{1}{E_f A_f} \right) \]  
(9) 
\[ m = \frac{k}{\lambda^2} \left( \frac{d_o}{E_I I_b + E_h I_f} \right) \]  
(10) 
\[ \beta = \frac{k}{4} \left( \frac{1}{E_I b} + \frac{1}{E_f I_f} \right) \]  
(11) 
\[ n_1 = \frac{y_h E_I I_f}{E_o I_b + E_f I_f} \]  
(12) 
\[ n_2 = \left( \frac{E_f I_f}{E_o I_b + E_f I_f} \right) \]  
(13) 

where \( M_r(0) = \frac{qa}{2}(L-a) \) and \( V_r(0) = q\left( \frac{L}{2} - a \right) \) are the total bending moment and the total shear force in the strengthened beam at \( x=0 \) (i.e. at the NSM bar end) respectively, \( L \) and \( a \) are the span of the beam and the distance from the bar end to the nearest support respectively.

As can be seen from Eqs. 3 to 13, most parameters are directly associated with either the material properties of FRP/concrete or the geometric properties and can thus be easily obtained, except for (1) the two interfacial stiffness parameters (i.e., \( k_t \) and \( k_n \)), and (2) the eccentricity of tangential interaction force (i.e., \( y_f \)) to the centroid of the NSM bar. Zhang and Teng (2013) proposed equations of the above-mentioned parameters for RC beams strengthened with NSM rectangular bars and this paper provides the equations for RC beams strengthened with NSM round bars.

**INTERFACIAL STIFFNESS PARAMETERS**

In the present study, the interfacial stiffness parameters were obtained directly based on their definitions by making use of FE models developed in ABAQUS (2012). According to the definitions of interfacial stiffness parameters, the interaction force between the NSM bar and concrete per unit length needs to be found out for a unit relative displacement between the two in the designated direction. Therefore, the FE models consisted of an NSM round bar, the surrounding adhesive layer and the groove surface which was set to be a fixed boundary of the adhesive layer. With such FE models, the interfacial stiffness was just equal to the total reaction force of the boundary (i.e. the groove surface) when a unit displacement (i.e. 1 mm) was applied to the NSM bar in the designated direction. The schematic of the FE models used to obtain the interfacial stiffness parameters is shown in Figure 2.

(a) Unit-length segment          (b) Tangential interfacial stiffness \( k_t \)          (c) Normal interfacial stiffness \( k_n \)

![Diagram](image)

Figure 2. Schematic of the FE models used for the determination of interfacial stiffness parameters

In determining the interfacial tangential stiffness (Figure 2b), 8-node solid elements with a full Gauss integration were used and the adhesive layer is restrained against displacements in the two transverse detections (i.e. only displacements in the longitudinal direction were allowed). To save the computation time, the length of the models was set to be 0.1 mm instead of the unit length of 1 mm; the reaction force obtained from these FE models was then multiplied by 10 to obtain the reaction force corresponding to a unit length. As the adhesive layer was under pure shear, such treatment does not affect the accuracy of the results. In evaluating the normal interfacial stiffness (Figure 2c), the problem was simplified as a plain strain problem in the transverse direction and 4-node quadrangle
plane strain elements with a full Gauss integration were used, considering that the length of the FRP bar is usually much larger than the cross-sectional dimensions of the groove. Regression analyses of the FE results obtained from the numerical parametric studies using the above-mentioned FE models were conducted and the best-fit equations for the interfacial stiffness and eccentricity are as follows:

\[ k_t = AG_a = 7.1G_a(R - 1)^{0.61} = 7.1G_a \left(\frac{1}{R - 1}\right)^{0.61} \]  
\[ (14) \]

\[ k_n = BE_a = 4E_a(R - 1)^{0.66} = 4E_a \left(\frac{1}{R - 1}\right)^{0.66} \]  
\[ (15) \]

\[ y_f = \frac{0.165}{W^{0.72}D^{0.72}} \]  
\[ (16) \]

Where \( D \) is the diameter of the FRP bar, \( W \) is the side length of the square groove, and \( R \) is the ratio of \( W/D \).

VERIFICATION OF THE ANALYTICAL SOLUTIONS

To verify the proposed analytical solutions (Eqs. 3 to 13), 3D FE analysis of a RC beam strengthened with an NSM round bar under a UDL were conducted using ABAQUS (2012) and the results are compared with analytical predictions. The modelled RC beam had a span of 2400mm, a height of 300mm and a width of 150mm. The diameter of the NSM round bar was 8 mm and the groove side length was 12 mm, leading to a length-to-diameter ratio of 1.5. The NSM round bar was symmetrically placed with respect to the mid-span of the beam, with a length of 1800mm; the distance from the NSM bar end to the nearest support was thus 300mm. A UDL of 30 N/mm was applied on the top surface of the beam. By taking advantage of symmetry, only a quarter of the beam was modelled, with symmetric boundary conditions applied (Figure 3). All of the materials were modelled using 8-node solid elements with a full Gauss integration.

The interaction forces were obtained by integrating the relevant stresses along a prescribed path in the adhesive layer. The interaction forces obtained from the FE model are compared with the predictions from Eqs. 3 to 13 in Figure 4, from which it can be seen that the analytical predictions of both tangential interaction forces and normal interaction forces agree very well with the FE predictions, with gaps only existing in a very small region close to the NSM bar end. The errors of the analytical solution in that small region is due to the fact that the analytical solution does not take into account the boundary condition of zero shear stress at the bar end.
CONCLUSIONS

An analytical solution to interaction forces between the NSM bar and concrete in RC beams strengthened with NSM round bars are presented in this paper, following the work conducted by Zhang and Teng (2013) for RC beams strengthened with NSM rectangular bars. The key elements of the proposed analytical solution are the two interfacial stiffness parameters (i.e. tangential interfacial stiffness and normal interfacial stiffness) and the eccentricity of the tangential interaction force. FE models developed using ABAQUS (2012) were adopted to conduct numerical parametric studies, the results from which were used to determine the interfacial stiffness parameters and eccentricity of the tangential interaction force. The accuracy of the proposed analytical solutions has been verified with a sophisticated 3D FE model of a RC beam strengthened with a NSM round bar. Both analytical predictions and FE predictions identified high interaction forces near the NSM bar end, which to some extent explain why end debonding failures commonly happen in RC beams strengthened with NSM round bars.

ABSTRACT

Near surface mounted (NSM) fiber-reinforced polymer (FRP) technique has been proved to be a reliable rehabilitation and strengthening method for deficient concrete structures. In such strengthened structures, debonding between FRP and concrete substrate is a typical failure model. This paper presents the simulation results for the bond behavior under direct pullout condition throughout the debonding process using a comprehensive three-dimensional finite element model. The concrete is simulated using concrete damage plasticity model while the FRP and adhesive are treated as linear-elastic materials. Tie joints are used at the adhesive-FRP and adhesive-concrete interface. Debonding is assumed to be caused by the concrete damage occurring in the region near the interface of adhesive-concrete. Instead of common static analysis approach, dynamic approach is introduced to overcome convergence problem, which provides more stable and accurate results than the static approach. Numerical results obtained are in close agreement with the available test data. The modeling approach proposed in this paper is not only applicable to NSM FRP system, but also offers a reliable tool to investigate characteristics of other systems relate to FRP and concrete bond.

INTRODUCTION

Near surface mounted (NSM) fiber-reinforced polymer (FRP) is a reliable rehabilitation and strengthening technique for deficient concrete structures (e.g. De Lorenzis and Nanni 2002). Such strengthened concrete structures often fail by debonding between FRP and concrete substrate. Numerical simulation that can capture such a debonding mechanism is essential for predicting the capacity and investigating the bond characteristics of NSM FRP in concrete. Extensive studies for debonding simulation have been conducted on the externally bonded (EB) technique. These simulations typically employ two-dimensional finite element (FE) models (e.g. Chen et al. 2011; Kotynia et al. 2008; Lu et al. 2005) because the stresses in the EB application occur approximately within the plane along the direction of the bonding interface and its vertical component. However, for NSM technique, the strengthened member experiences the hoop and radial stresses in addition to the stress along the bonding interface. The stresses of NSM FRP occur in the three-dimensional space, which are more complex than EB FRP. As a result, these two-dimensional modelling approaches for the EB FRP cannot be employed to simulate the NSM FRP debonding without modification. Several existing studies use three-dimensional FE models (Cruz et al. 2006; De Lorenzis et al. 2004; Echeverria and Perera 2013; Hawileh 2012; Sasmal et al. 2013). Interfacial element and spring element are deployed between the FRP and concrete substrate for modelling the adhesive layer. Both of these elements are specified by using a constitutive law of bond-slip relationship from physical debonding tests. However, the results show that, by using this approach, the FE models could only simulate the debonding process but were unable to predict the capacity and investigate the bond characteristics. Teng et al. (2013) employed a more practical FE model in which concrete, FRP, and adhesive layer are modelled with solid elements. Teng’s model described a more realistic mechanical state of debonding than the other existing models, and is not limited to simple debonding simulation only. However, certain deficiencies such as failure model of adhesive and size reduction could reduce its accuracy and restrict the general applicability of the model itself.

This paper proposes an improved finite element modelling approach for the bond behaviour of NSM FRP under direct pull-out condition throughout the debonding process. Simulation results, which compare well with the available test data, are presented to prove the capability and accuracy of the proposed approach.
PROPOSED FE MODEL FOR NSM FRP-CONCRETE BOND JOINT

General

The FE model in this study is constructed using FE software ABAQUS (Dassault Systems Corp. 2014). Only half of the specimen along the width is modelled due to the symmetric configuration of the typical direct pull-out test, where appropriate boundary conditions are applied on the plan of symmetry. Size simplification, which was used in several other studies (e.g., Echeverria and Perera 2013; Teng et al. 2013), is not considered herein because it was reported to lead to inaccurate stress state (Yao et al. 2005).

The first-order hexahedral stress element in ABAQUS is used to model the FRP, concrete and adhesive layer materials. These three parts are connected to each other through the tie contact function in ABAQUS. Although debonding could be caused by either adhesive failure or concrete failure near the adhesive–concrete interface, the latter is found to be more common in physical testing and therefore is considered in the current modeling. The FRP and adhesive materials are assumed to behave linear-elastically and the concrete is modeled using the concrete damage plasticity model in ABAQUS to simulate its nonlinear behavior.

Modelling of Concrete

Constitutive law

For concrete under uniaxial compression, according to CEB-FIP (1990), the stress-strain relation shown in Figure 1 is composed of two branches described by the following set of equations:

\[
\sigma = \begin{cases} 
\frac{E_{ci} \varepsilon_c}{E_{ci}} - \left(\frac{\varepsilon_c}{\varepsilon_{c1}}\right)^2 & \text{for } |\varepsilon_c| < |\varepsilon_{c,lim}| \\
1 + \frac{E_{ci} - 2}{E_{ci}} \frac{\varepsilon_c}{\varepsilon_{c1}} - \frac{f_{cm} \varepsilon_c}{E_{ci}} & \text{for } |\varepsilon_c| > |\varepsilon_{c,lim}| 
\end{cases}
\]

(1a)

\[
\sigma_c = -\left(\frac{1}{\varepsilon_{c,lim}/\varepsilon_{c1}} - \frac{2}{\varepsilon_{c,lim}/\varepsilon_{c1}^2}\left(\frac{\varepsilon_c}{\varepsilon_{c1}}\right)^2 + \frac{4}{\varepsilon_{c,lim}/\varepsilon_{c1}} - \xi\right)\left(\frac{\varepsilon_c}{\varepsilon_{c1}}\right)^{-1} f_{cm} \varepsilon_c \quad \text{for } |\varepsilon_c| > |\varepsilon_{c,lim}|
\]

(1b)

where \(\sigma_c\) is the compression stress, \(\varepsilon_c\) is the compression strain, \(f_{cm}\) is the compressive strength, \(\varepsilon_{c1}\) is the correspond strain of \(f_{cm}\) (typically given as 0.0022), \(E_{ci}\) is the tangent modulus, and \(E_{c1}\) is the secant modulus from the origin to \(f_{cm}\).

\[\xi = \frac{4 \left(\frac{\varepsilon_{c,lim}}{\varepsilon_{c1}}\right)^2 \left(\frac{E_{ci}}{E_{c1}} - 2\right) + 2 \frac{\varepsilon_{c,lim}}{\varepsilon_{c1}} - \frac{E_{ci}}{E_{c1}}}{\left[\frac{\varepsilon_{c,lim}}{\varepsilon_{c1}} \left(\frac{E_{ci}}{E_{c1}} - 2\right) + 1\right]^2} \quad \text{(2a)}\]
In the equations above, $E_{ci}$ is typically estimated from the compressive strength of concrete $f_{cm}$, i.e., $E_{ci}=E_{00}[f_{cm}/f_{cm}]^{1/3}$, where $E_{c0}$ and $f_{cm0}$ are constants set to be equal to 2.15x10^4 MPa and 10 MPa per CEB-FIP (1990), respectively.

For the tension part of the concrete behavior under uniaxial tension, the ascending branch in the constitutive relation is assumed to be linear-elastic up to the stress equaling concrete’s tensile strength, and the softening branch employs the curve proposed by Nordijk (1991) as follows:

$$\frac{\sigma_c}{f_t} = \left[1 + \left(\frac{3w_c}{w_f}\right)^{1/3}\right] \exp\left(-6.93\frac{w_c}{w_f}\right) - 28\frac{w_c}{w_f}\exp(-6.93)$$

$$w_c = 5.14G_f/f_t$$

where $\sigma_c$ is the tensile stress, $f_t$ is the tensile strength, $w$ is the crack opening width, $w_c$ is the ultimate crack opening width, and $G_f$ is the fracture energy. $f_t$ and $G_f$ can be estimated based on CEB-FIP (1990) if no test data is available, i.e.,

$$f_t = 1.4\left(\frac{f_{cm0} - 8}{10}\right)^{2/3}$$

$$G_f = \left(46.875 \times 10^{-6} d_{max}^2 - 0.0005 d_{max} + 0.026\right)(f_{cm0}/10)^{0.7}$$

where $d_{max}$ is the maximum aggregate size. In the present model, $d_{max}$ is assumed to equal 20 mm.

**Damage model**

The concrete damage plasticity model in ABAQUS is adopted to simulate the nonlinear behaviour of concrete after cracking to avoid the phenomenon of “strain localization” due to the well-known drawback in the smear crack model in ABAQUS. The ratio of $r_t$ to $r_c$, defined by $K$, is assumed to equal 0.66, in which $r_t$ is the distance between the tension meridian line and the hydrostatic pressure axis, and $r_c$ is the distance between the compression meridian line and the hydrostatic pressure axis. The ratio of the initial yield stress under equibiaxial loading to the initial yield stress under uniaxial loading, $f_{s0}/f_{cm0}$, is set to be equal to 1.16 (Lubliner et al. 1989). These two ratios are used to define the yield field $F(\sigma, \dot{\varepsilon}^s)$ in the damage plasticity model. The other two coefficients, the dilation angle, $\Psi$, and the eccentricity, $\epsilon$, are assumed to be 30 and 0.1, respectively. These two coefficients are needed to define the flow potential $G$ in the damage plasticity model.

In addition to the yield field and the flow potential, the compressive damage variable, $d_c$, and the tensile damage variable, $d_t$, need to be defined although the model is only subject to monotonic loading (An 2015). The damage variables are estimated by the following:

$$d_c = 1 - \frac{\sigma_c/E_{ci}}{\varepsilon_c^u(1-b_c) + \sigma_c/E_{ci}}$$

$$d_t = 1 - \frac{\sigma_t/E_{ti}}{\varepsilon_t^u(1-b_t) + \sigma_t/E_{ti}}$$

where $\varepsilon_c^u = \varepsilon_c - \sigma_c/E_{ci}$ is the inelastic strain for concrete under uniaxial compression, and $\varepsilon_t^u = \varepsilon_t - \sigma_t/E_{ti}$ is the cracking strain for concrete under uniaxial tension. $b_c$ and $b_t$ are two variables related to strain, which are assumed to be constants equalling 0.7 and 0.1, respectively (Birtel and Mark 2006). Note that Eq. (7b) specifies $d_t$ using the stress-strain instead of the stress-displacement relationship. As a result, the crack bond model proposed by Bazant and Oh (1983) is applied to transform the stress-displacement curve defined by Eq. (3) into a stress-strain curve. The crack bond model assumes that the tensile fracture of concrete occurs in the form of a blunt smeared crack band in which the concrete undergoes progressive microcracking characterized by a stress-strain relation that exhibits strain softening. Hence, the relation of the crack opening width, $w$, the crack band width, $h_c$, and the crack strain, $\varepsilon_c^s$, can be expressed using the following equation based on the crack band model:

$$w = \int_0 h_c \varepsilon_c^s dh$$

The crack bandwidth $h_c$ in Eq. (8) can be estimated using $\sqrt{2e}$, in which $e$ is the element length (Rots and Blauuwendraad 1989).
Modelling of FRP and Adhesive Layer

As previously mentioned, debonding is assumed to occur in the concrete adjacent to the adhesive-concrete interface. Therefore, the FRP and adhesive are treated as linear-elastic material. Their material properties, such as tensile strength and Poisson’s ratio, are obtained from the material coupon tests in the lab (to be discussed in the next section).

Solution Method

For conventional static solution techniques, there is a challenge that lies in the convergence issue of the FE model during later stages of loading. These techniques such as the Newton-Raphson method are insufficient to handle the strain softening phenomena described by the material constitutive law. Solution process is often interrupted when concrete starts to experience damage. Some experimental observations, such as intermittent crack noises during debonding process and quick energy release at debonding failure, have suggested that the debonding failure should be treated as a dynamic problem instead of a static problem. Chen et al. (2015) proved this hypothesis and proposed a dynamic solution approach to overcome the convergence challenge when simulating the strain softening behaviour of concrete. In their study, both the implicit HHT-α method and the explicit central difference method were investigated based on a FE modelling for a FRP-strengthened reinforcement concrete (RC) beam. The former method was found to provide a better performance than the latter on accuracy and stability. However, the implicit HHT-α method does not exhibit its potential in the present study as claimed in their study (Chen et al. 2015). It even failed due to a severe convergence issue similar to the conventional static solution technique. Therefore, the central difference method is employed herein as a viable solution technique.

For a dynamic approach, two key elements exist, the damping scheme and the loading time. The Rayleigh damping is adopted in the present model to define the damping scheme, where the damping matrix $C$ can be estimated by the following:

$$C = \alpha_0 M + \alpha_1 K$$

(9)

where $M$ and $K$ are, respectively, the mass matrix and the stiffness matrix. $\alpha_0$ and $\alpha_1$ are the proportionality constants for mass component of the damping and stiffness component of the damping, respectively. These two constants can be determined by the damping ratios of any two modes as follows:

$$\alpha_0 = \frac{2\omega_i\omega_j (\zeta_i\omega_i - \zeta_j\omega_j)}{\omega_i^2 - \omega_j^2}$$

(10a)

$$\alpha_1 = \frac{2(\zeta_j\omega_j - \zeta_i\omega_i)}{\omega_j^2 - \omega_i^2}$$

(10b)

where $\omega$ and $\zeta$ are the damping ratio and the circular frequency, respectively. Their subscripts represent the order of the mode. In the present study, the first and second modes are used to determinate $\alpha_0$ and $\alpha_1$ by assuming the same damping ratio for all modes. Although the values of the damping ratio, $\zeta$, and the loading time, $t$, are typically obtained based on a trial-and-error process, it is known that the loading time, $t$, should increase proportionally with the damping ratio, $\zeta$, in order to obtain an accurate solution (Chen et al. 2015). Therefore, a small value of $\zeta$ is recommended in order to reduce the computational effort.

Numerical Results

The direct pull-out debonding behavior reported by Li et al. (2005) is simulated using the proposed FE approach in this study for verification purpose. In this direct pull-out experiment, five NSM FRP strip-concrete bonded joints were tested. The concrete component consisted of a rectangular block with a square section of 150x150 mm and a length of 350 mm, as shown in Figure 2(a). The groove size had a width of 9 mm and a length of 22 mm. The bond lengths involved were 30 mm, 100 mm, 150 mm, 200 mm and 500 mm. The groove-filling material was a two-component epoxy adhesive. More details are provided in Table 1 (Li et al. 2005). The major results for specimen CS-150 with a bond length of 150 mm are selected herein for detailed discussion and the complete set of results is reported in separate publications.

Figure 2(b) below compares the load-displacement response at the loaded end of the specimen. Note that Li et al. (2005) only reported the ultimate pull-out load from the test (no load-displacement curve was available). It can be seen that the predicted ultimate pull-out load is in close agreement with the test results.

Figure 2 Details of: (a) geometry and boundary conditions; and (b) comparison of load-displacement response

Figure 3(a) displays the distribution of the local bond stress for various loading cases including 20%\(P_u\), 45%\(P_u\), 70%\(P_u\), 95%\(P_u\), and 100%\(P_u\) in the loading branch (where \(P_u\) is the ultimate load). The distribution of the corresponding tensile strain in the FRP strip in the loading direction is shown in Figure 3(b). Typical distributions of the local bond stress and FRP tensile strain can be seen in this figure. The local bond stress in Figure 3(a) exhibits a parabolic-shaped distribution in the loading direction, and its peak value progressively increases and moves away from the free end (i.e., towards the loaded end) as the load increases. Correspondingly, the tensile strain in the FRP strip increases nonlinearly towards the loaded end, but its gradient decreases in the region near the loaded end as the load increases. Although the predicted bond stress distribution is slightly different from the distribution measured in the test reported by Li et al. (2005), the predicted peak values for all the cases are in close agreement with the test data. The predicted tensile strain distribution represents a similar pattern to the test result (comparison is not included herein).

Figure 3 Distribution of: (a) local bond stress; and (b) FRP tensile strain

The predicted debonding failure pattern is illustrated in Figure 4, which shows a distinct spine-shaped concrete damage contour. This spine-shaped concrete damage contour is not only found in Li et al.’s tests (2005), but also observed in other existing pull-out experiments (e.g., Lee et al. 2013). Figures 5(a) and 5(b) illustrates the observed failure modes of two representative specimens by Li et al. (2005) and Lee et al. (2013), respectively.
CONCLUSIONS

This paper proposes an improved three-dimensional FE modelling approach for bond behaviour of NSM FRP under direct pull-out condition throughout the debonding process. Concrete damage is simulated using the concrete damage plasticity model while the FRP and adhesive are treated as linear-elastic materials. An explicit dynamic solution method is introduced to overcome the convergence issue often encountered in static method and implicit dynamic method. Numerical results showed that the proposed FE modelling approach could simulate the debonding failure of NSM FRP to a good accuracy.

ABSTRACT

The near surface mounted (NSM) strengthening technique possesses many advantages over externally bonded (EB) when it comes to strengthening of reinforced concrete (RC) beams using fiber reinforced polymer (FRP) composites. However, the majority of the research on NSM FRP has been confined to flexural and shear strengthening applications and no considerations for torsional strengthening have been made. The present study aims to present an experimental program that focuses on the torsional strengthening of RC beams using the NSM technique. Alternative torsional strengthening configurations were tested with full wrapping using FRP rope. Four RC beams have been tested where the results from two RC beams are presented and compared with unstrengthened control specimens. The beams were tested using a specialised torsional actuator and the results expressed in terms of the maximum torsional capacity with respect to the peak angle of twist. The results demonstrated that the NSM technique with FRP rope was an effective method to increase the torsional strength of RC members.

Torsion, RFP rope, grooves, NSM, concrete beam, epoxy, strengthening.

INTRODUCTION

In order of the reinforcement concrete beams to be generally strengthened, sheets of carbon fiber reinforced polymers (CFRP) are applied on the faces of the concrete using an externally bonded reinforcing (EBR) technique to increase the torsional resistance of beams (Fib Bulletin 14 2001, Hii 2006). The increase of the torsional resistance of concrete beams by adopting the EBR technique has been verified by many researchers (Hii and Al-Mahaidi 2006; Mohammadizadeh et al. 2009; Deifalla and Ghobarah 2010). On other hand, the maximum strain measured by using this technique is below the ultimate strain due to premature debonding. In an attempt to solve this problem, near surface mounted technique has been proposed where CFRP laminates are installed into thin pre-cut grooves (Nanni et al. 2004). This strengthening technique has already proven to be effective for the shear strengthening of reinforced concrete beams (Barros and Dias 2006; El-Hacha and Wagner 2009; Lim 2010). In the experimental program carried out by Barros and Dias (2006), the efficiency of the NSM technique by testing four series of beams has been investigated. Each group comprised five beams. One beam was strengthened with CFRP sheet strips applied according to the EBR technique to compare the efficacy of the EBR and NSM techniques. The researchers demonstrated that the NSM shear strengthening technique was the easiest to apply and the most effective of the CFRP techniques for both beam load-carrying capacity and deformation capacity. In another experimental program, seven reinforced concrete beams with a rectangular cross-section were cast and tested by El-Hacha and Wagner (2009) to investigate the effectiveness of vertical NSM CFRP strips. The NSM CFRP strips were applied for shear strengthening at different spacings on RC beams weak in shear. It was reasoned that the effective depth of the beams should be greater than the spacing between the strips to avoid brittle failure in shear before yielding of the longitudinal steel. Then, Lim (2010) examined the shear strengthening effectiveness of nine beams strengthened with NSM CFRP strips and EBR CFRP strips. One beam was not strengthened and tested as a control, and five beams were tested as beams strengthened with EBR FRP strips with different spacings. Three beams were strengthened using NSM FRP strips. One was strengthened with 25 mm NSM with a spacing of 150 mm, whereas the rest were strengthened with the combined use of NSM and EBR CFRP strips. It was concluded that shear stiffness and strength were considerably developed for the beams strengthened by combined NSM and EBR compared with the control beam. The first and the only study conducted by Al-Bayati et al. 2016 to evaluate the effectiveness of using NSM technique with torsion according to the authors’ knowledge. Ten beams have been tested, two control beams and eight beams strengthened with CFRP laminates applied to all four faces of the beams. Epoxy adhesive was used in four strengthened beams and modified cement-based adhesive was used as a substitute
for epoxy in the remaining four beams. Two different spacings between the grooves (0.75D and 0.375D where D is the depth of the beam) were examined for each type of adhesive. According to their results, the torsional behaviour of the beams was improved in the strengthened beams by almost 28.22% and 35.93% when using the epoxy for 0.75D and 0.375D spacings of CFRP NSM laminates respectively. On the other hand, the NSM technique with the cement-based adhesive was also an effective method in increasing the torsional strength by by 23.4% and 26.5% for 0.75D and 0.375D spacings respectively.

In the present paper, a similar technique of the torsion strengthening was used with the difference that, instead of CFRP laminates at four faces, FRP rope around the cross section of the beam with the equivalent carbon fiber percentage was used. Four beams have been prepared and tested comprising of two matching control beams and an additional two beams strengthened in torsion using FRP rope and epoxy. Similar strengthening technique was used for the two strengthened beams in order to confirm the consistency of the results.

**EXPERIMENTAL PROGRAM**

**Beam prototype and strengthening configuration**

Four rectangular reinforced concrete beams with 260 mm by 140 mm in cross section and 2000 mm long were poured; two comparable control beams and two were identically strengthened using the NSM technique with epoxy resin. The design of the beams was performed in order to fail in torsion in the middle 1.2 m section of each beam which allowed more than one torsional spiral crack to form at 45° angles with respect to the beam longitudinal axis. Figure 1 presents the dimensions of the beams’ cross section and the steel reinforcement details. The beams were under-reinforced according to the Australian design code AS3600-2009 (SAI 2009) to simulate beams that were torsionally deficient under some future loading condition. In addition, it was decided to intentionally exceed the minimum spacing of the hoop reinforcement specified by the design code in order to minimize the stirrups ability to restrict the torsional cracks, thus facilitating the observation of torsional failure. FRP ropes were embedded into grooves cut around the beam cross section within the 20 mm cover zone of the concrete beams. The groove dimensions are 5 mm wide and 18 mm deep respectively. In order to make a comparison with the results of the beam strengthened using externally FRP strips (Hii and Al-Mahaidi 2004), it was decided that the spacing between the grooves will be 195mm (0.75D where D is the beam depth) as shown in Figure 2, which is the same strips’ spacings used by Hii and Al-Mahaidi 2004. In addition, the cross section of the FRP rope used in each groove was selected to provide the same FRP area of the 50 mm width FRP wraps used by Hii and Al-Mahaidi 2004.

Material properties and beams preparation

The compressive strength of the supplied concrete by a local supplier was evaluated at 28 days and at the age of the beam tests, executing direct compression tests with cylinders of 100 mm diameter and 200 mm height, according to ASTM C873/C873M-15. In the tested beams, steel reinforcement bars of 6 mm diameter were used. Three bars of each diameter were selected and uniaxial tensile tests were carried out to obtain the Elastic modulus (Es), yield and ultimate strength (fy, fu) according to the recommendations of ASTM A370-10 2010. The mechanical properties of CFRP rope were characterised through uniaxial tensile tests using a 250 kN MTS machine carried out according to the ASTM D3039/D3039M (2008) and BS EN ISO 527-5 (2009) recommendations. Strain gauges were used to obtain the CFRP strains during the test. The Sikadur-330 epoxy was used as adhesive to fill the grooves, while The Sikadur-300 epoxy were used as impregnating resin. The Sikadur-330 is a 2 parts light grey epoxy, the Sikadur-300 is however a 2 parts epoxy clear and liquid when mixed.

Table 1 includes the mechanical properties of all materials, which summarises the average compressive strength, tensile strength and modulus of elasticity of the concrete. The tensile strength of the epoxy was also tested and the modulus of elasticity was based only on specifications supplied by the manufacturer. Three reinforcement bars for each diameter and the five samples of CFRP rope were tested and the average values measured from these experimental programs were presented in this table.
In all beams, electrical resistance strain gauges (length 5 mm) were used to monitor the strain and verify whether yielding in the selected steel stirrups had occurred. Four strain gauges were used for each beam and placed on north legs of the stirrups (tension legs), which were titled S1-S4 as shown in Figure 3 (a).

To apply the pre-cured CFRP rope using the NSM technique After 28 curing days of the beams, the following procedures were carried out: (1) grooves were opened on the concrete cover of the all faces of the beam using a diamond chaser; (2) the grooves were cleaned by brush and vacuum cleaner to remove dust and any loose materials; (3) the ropes were measured and cut with the desirable length to surround the cross section of the beam with enough overlap; (4) The Sikadur-330 and Sikadur-300 epoxy was produced according to the supplier recommendations; (5) the FRP rope was impregnated with Sikadur-300 epoxy resin until completely saturated then the air and the excess resin was squeezed out of the rope; (6) The groove around the cross section was filled with Sikadur-330 adhesive using a plastic blade; (7) The FRP rope was carefully inserted into the groove around the cross section to the bottom, the lateral faces and the top of the beam consecutively with the use of the plastic blade until reaching the bottom of the groove and the plastic blade was carefully removed without pulling the rope back out; (8) The surface was levelled and excess adhesive that has been squeezed out of the groove was removed. To guarantee a proper curing of the epoxy, already enough time (90 days) passed between the beam strengthening operations and the test. Figure 3 (b) presents photos for the preparation of the strengthened beams.

To apply the loading arm was used to apply torsion on the one end of the beam where another end was fixed to the support as illustrated in Figure 4. As the focus was just on the pure torque, the loading arm was ensured to be in line with the end spherical support to prevent flexure from being applied on the beam. At the fixed end, a steel frame was used consisting of two half I crossbeams bolted to two steel columns. Each column was fixed to the 1 m thick reinforced concrete strong floor using anchor bolts as shown in Figure 4 (a). Flanges and collar were used to anchor the beam to the fixed frame as no longitudinal, vertical, transverse and rotational movements were allowed. At the loading end, a roller seat on a linear bearing with a spherical ball was used to support the beam where the load was applied which also permitted axial movement. This allowed twisting the beam freely while allowing elongation or shortening as presented in Figure 4 (b). A single 250kN capacity hydraulic actuator fixed to the loading frame was adopted to apply the torque through the loading arm. The roller seat and the loading arm were aligned to produce pure torsion and ensure that no other bending or shear forces were introduced into the system. Another spherical ball was located over the cantilever arm and under the hydraulic actuator to ensure that the load remained vertical during the test. To facilitate effective use of lab instruments, the beams were tested with the shorter sides facing
up and down. The orientation of the cross-section was unimportant as a pure torsion was applied. To avoid stress concentrations from developing between the steel flange and the top flange of the beam, minor grinding was provided to smooth out any imperfections between the interfaces. A photo of the test setup is shown in Figure 4. (c). Instrumentations were used to record the torque, angle of twist, and cracks. A load cell was located under the hydraulic actuator to determine the applied torque. The exact amount of twist was measured using inclinometers were placed at both ends of the beam as in reality, there is always a small compliance at the fixed end.

RESULTS AND DISCUSSION

Figure 5 shows the relationship between the applied torque and the angle of twist for all four beams. All beams experience a linear elastic response until the crack torque was reached then it was followed by a large increase in the angle of twist with gradual increase in torque until failure. The strengthened specimens exhibited higher peak torques and more ductile behaviours after peak torques than the control specimens. For beams C2-1, E2-195R-1, and E2-195R-2, the first cracks appeared at the south faces which and propagated to the other three faces. However, the first crack developed at the north face of the beam C2-2 then was observed at the south face. The strengthening of beams developed stiffer pre and post-cracking responses than the control beams. Photos taken after testing for the beams’ depicting failure zones are presented in Figure 6. All beams failed in torsion as the applied torque was constant along the length of the beams between the gripping systems. The location of failure showed no specific trend, however the exact location of first crack initiation and failure could be related to factors such as: reinforcement spacing, non-homogeneity of concrete properties and other factors immanent to imperfections in beam fabrication. The failure modes of the all beams were by yielding of the steel closed ties followed by local concrete cover spalling and concrete crushing. A few large cracks have been observed for the control beams and the largest cracks were located in the vicinity of concrete spalling zone. For the strengthened beams, the FRP ropes seemed to be well bonded to the concrete. The concrete cover delamination was observed with separation of the concrete that includes the FRP rope. A lot of relatively small uniformly distributed cracks occurred in the space between grooves. The larger cracks developing between the first and the third grooves and between the second and the fourth grooves for beams E2-195R-1 and E2-195R-2 at the east side of the beam passed through the second and the third grooves respectively. More cracks were developed in the space between the grooves. The main results of the crack load, ultimate torsional loads and corresponding angle of twists are included in Table 2. The average loads and twists for each beam type are presented and the increase in torsional strength with respect to the control beam is presented in between the brackets. The average crack torque of the strengthened beams has an increase in torsional strength of 21.4% than the control beams while the increase percentage of ultimate torque was 23.3%. However, the increase percentages of ultimate torques of the beams using the EBR technique was 25.2% (Hi and Al-Mahaidi 2004).
Table 3 shows the strain values of stirrups measured at the peak load level where S1 was the nearest strain gauge to the load arm. The results of S2 strain gauge in beams E2-195R-1 was removed as they were damaged during beam manufacture. The yield strain is 0.002254 for the stirrups. In all beams, at least one strain gauge shown that the strain of the bar was exceeded the yield strain before reaching the peak torque. In Figure 7, torque versus stain curves are presented for all beams. After spiral cracks started to form in the beams, the reinforcement strain values increased rapidly. The stiffness of the beams was reduced with increasing crack opening as more force was transferred to the stirrups. From the strain gauges results, it was observed that the load carried by the stirrups of the strengthened beams was generally small compared with the reference beams. At control beams torque levels, the strain levels measured were generally lower than in beams C2-1 and C2-2.

CONCLUSIONS

Based on the experimental work results, the use of Near Surface Mounted (NSM) technique with FRP rope is viable for torsional strengthening of reinforced concrete beams. Using an epoxy adhesive, the results for the strengthened beams were evaluated and compared with the reference beams. The crack and ultimate torques of the beams have been significantly improved by an average of 21.4% and 23.3% respectively. It was also observed that the strain at the same level of torque for the strengthened beams was generally small compared with the control beams. More ductile behavior was observed for the strengthened beams. At failure, the critical torsional cracks of the strengthened beams developed through the middle of the groove where the delamination of the concrete cover with the FRP rope. Further investigation is warranted to study other parameters for beams strengthened using the NSM technique to increase the FRP contribution in strengthening.

ABSTRACT

This paper presents experimental and numerical investigations about the fire behaviour of reinforced concrete (RC) beams flexurally strengthened with carbon fibre reinforced polymer (CFRP) strips applied according to the near surface mounted (NSM) technique. The experimental programme included fire resistance tests on NSM-CFRP strengthened RC beams protected with calcium silicate boards with varying thickness along their length. The numerical study comprised the development of three-dimensional (3D) finite element (FE) models in order to simulate the fire resistance tests. The models considered the variation with temperature of the thermal and mechanical properties of the constituent materials, and the CFRP-adhesive-concrete interaction was simulated by means of bi-linear bond-slip laws previously (and independently) calibrated by the authors for different temperatures. The numerical results were compared with experimental data in terms of temperatures, midspan deflections and time to CFRP debonding. The models provided accurate predictions of the thermo-mechanical fire response of the strengthened beams. Together with the experiments, it was shown that it is possible to exploit the CFRP mechanical contribution through a cable mechanism, provided that a thicker insulation is applied along the CFRP anchorage zones. In addition, the results obtained also confirmed (and allowed quantifying) the much better fire resistance performance of NSM compared to EBR. Indeed, with the former technique, it has been shown that it is possible to attain relatively long fire endurances using relatively modest fire insulation thicknesses.

KEYWORDS

Reinforced concrete beams, CFRP strengthening, NSM, fire resistance, experimental tests, numerical models, uncoupled thermal-mechanical analysis.

INTRODUCTION

Carbon fibre reinforced polymer (CFRP) materials have been successfully used to strengthen reinforced concrete (RC) structures through externally bonding strips or sheets to the surface of the members with epoxy-based adhesives (EBR - externally bonded reinforcement technique). During the last decade, the alternative near surface mounted (NSM) technique, in which CFRP strips/bars are inserted and bonded into slits cut inside the concrete cover, has been gaining increasing interest mainly due to its higher efficacy and better anchoring capacity when compared to EBR (e.g. Barros et al. 2007). However, regardless of the strengthening technique (EBR or NSM), the behaviour of CFRP systems at high temperature is a matter of concern due to the polymeric nature of the CFRP matrix, as well as of the epoxy adhesives used to bond it to the concrete substrate. In fact, the glass transition temperature ($T_g$) of CFRP and conventional epoxy adhesives (between 45 and 120°C) can be attained in outdoor applications and very easily and quickly exceeded in the event of a fire. A recent state-of-the-art review (Firmo et al. 2015b) showed that although considerable research has been undertaken to better understand the response of FRP-strengthened RC elements at high temperatures or in fire, there is a very limited number of studies on the fire behaviour of NSM-strengthened RC members (e.g. Burke et al. 2013, Palmieri et al. 2013). The available research indicated that considerable fire endurances can be attained by applying fire protection systems over the strengthening system; however, it was not yet possible to correlate the temperatures in the materials (namely in the adhesive) with the loss of structural effectiveness of the FRP system.

This paper presents experimental and numerical investigations about the fire behaviour of RC beams flexurally strengthened with NSM-CFRP strips. The objective is two-fold: (i) to evaluate the effectiveness of different fire protection schemes with thicker insulation layers applied in the anchorage zones of the strengthening system, and (ii) to improve the understanding about the fire performance of NSM-strengthening systems, more specifically regarding the maximum/critical temperatures attained in the adhesive when the mechanical contribution of the
CFRP system is lost. To this end, fire resistance tests were performed on NSM-strengthened RC beams protected with calcium silicate (CS) boards with varying thickness along their length. The numerical study included the simulation of the thermomechanical response of the tested beams by means of 3D finite element models.

EXPERIMENTAL INVESTIGATIONS

Test programme and description of the specimens

Four fire resistance tests were conducted in an intermediate scale furnace on RC beams flexurally strengthened with NSM CFRP strips and thermally insulated with CS boards. The beams were 150 cm long, 10 cm wide and 12 cm deep (cf. Figure 1) and were cast with ready-mixed concrete (average compressive strength in cylinders of 37 MPa at 279 days – age of testing). The internal steel reinforcement, with 1.5 cm of cover, consisted of four \( \phi 6 \) mm longitudinal rebars and \( \phi 6 \) mm transverse stirrups distanced of 6 cm. The strengthening system for flexure (supplied by S&P Clever Reinforcement) comprised two CFRP strips (cross section of 10 mm \( \times \) 1.4 mm, tensile strength of 2850 MPa, Young’s modulus of 168 GPa) and an epoxy-based adhesive (tensile modulus and tensile strength of 10 GPa and 14 MPa, respectively), providing a flexural strength increase of 111% (experimentally determined through 3-point bending tests at ambient temperature). The glass transition temperatures of the CFRP strips (\( T_g = 88 \) º C) and of the epoxy adhesive (\( T_g = 47 \) º C) were determined from dynamic mechanical analyses (based on the onset of the storage modulus curve decay).

The fire insulation systems consisted of CS boards, with thicknesses ranging from 25 mm to 50 mm, which were mechanically fixed to the bottom surface of the beams. As depicted in Figure 1, the fire protection exhibited variable thickness along the length, being typically thicker in the anchorage zones of the CFRP strips (thickness \( T \) in Figure 1) and thinner at the central zone (thickness \( t \) in Figure 1). The nomenclature adopted for the beams is related to the geometry of the insulation system: the first number corresponds to the dimension \( T \) and the second one to the dimension \( t \) (cf. Figure 1, both in millimetres). The following beams (insulation schemes) were tested: 0-0 (unprotected); 25-0; 25-25; and 50-25. A more detailed description of the fire protection system is provided in Firmo and Correia (2015a).

Figure 1 Geometry of the NSM-strengthened RC beams and position of the thermocouples: a) longitudinal view; b) midspan cross section (AA’).

The fire resistance tests were performed on a vertical furnace powered by propane gas and the tested beams were placed over its opened top (figure 2a). Concerning the thermal boundary conditions, the bottom face of the beams was exposed to the ISO 834 standard fire, whereas their top face was submitted to ambient temperature; the lateral faces of the beam specimens were thermally insulated. Consequently, only the bottom face was directly exposed to heat - the test conditions actually simulated the thermal exposure typically found on one-way slabs. Regarding the structural loading, all specimens were simply supported and subjected to a sustained load (comprising concrete blocks and steel plates) applied in a four point bending configuration (figure 2). The load level applied during the tests (70% of the design load at ambient temperature - according to the Eurocode 2) corresponded to 37% of the failure load of the strengthened beams and 78% of the load capacity of an unstrengthened member (ratios defined based on bending tests at ambient temperature).

The instrumentation consisted of an electrical displacement transducer for measuring the midspan displacement at the top (cold part) of the beams (\( \delta \), in figure 2b) and a set of 15 thermocouples type K, whose nomenclature and location are shown in figure 1. The fire resistance tests started with the application of the structural loading; after a period of about 30 min, set in order to guarantee the stabilization of the deflections, the bottom surface of the beams started to be thermally exposed to the ISO 834 standard fire. The burners of the furnace were turned off a few minutes after the CFRP strengthening system lost its structural effectiveness (which could be easily identified from the measurements of the midspan deflections).
Summary of results

**Temperatures along the bonded interface when the CFRP system debonded**

Figure 3a shows the temperatures along the bonded interface (measured by thermocouples T8 to T15, cf. Figure 1) when the strengthening system lost its structural effectiveness (instants detected on the midspan displacement vs. time curves - cf. Figure 4a). As expected, the beam with CS boards applied only in the anchorage zones of the NSM strengthening system (beam 25-0) exhibited very high temperatures at the central zone (left uninsulated) and considerably lower temperatures in the CFRP anchorage zones. The temperature distributions obtained in the uninsulated beam (beam 0-0) and those protected by a 25 mm thick CS board along the entire length of the CFRP system (beam 25-25) were roughly uniform, presenting lower temperatures at the CFRP ends due to the vicinity of the furnace walls. Although the above-mentioned distributions were expected, Figure 3a shows that the temperatures in the anchorage zones presented relatively high scatter. This scatter is clearly noticed in Figure 3b, where the average temperature along the hotter anchorage zone at the debonding instant is plotted. This figure highlights the complexity of the behaviour of NSM-strengthened systems under exposure to fire, which is related to (i) the thermal gradient existing along the depth of the slits, and also to (ii) the confinement effect on the strengthening system caused by the thermal expansion of the surrounding concrete. Albeit, the temperature distributions revealed that the debonding of the strengthening systems occurred when the temperature in the anchorage zones was considerably higher than the adhesive $T_g$: ranging from 111 °C ($2.4 \times T_g$) to 236 °C ($5.0 \times T_g$). Additionally, Figure 3b also shows that in beam 25-0 the CFRP system lost its structural effectiveness for considerably lower temperatures in the anchorage zones (compared to the remaining beams). This result might be related to the very high temperatures recorded along their central zone (unprotected length), where the CFRP-concrete bond was severely damaged, therefore increasing the bond stresses in the CFRP anchorage zones and thus explaining the occurrence of CFRP debonding for lower temperatures.

Figure 3 Temperatures in the adhesive when the CFRP strengthening system debonded: a) along the bonded interface (E – experimental, N – numerical); b) average along the anchorage length (20 cm, defined according to ACI 440.2R for 20 °C).
Figure 4a plots the midspan displacement increase of the beams as a function of the time of fire exposure. As expected, this displacement increased with time (and temperature) due to the stiffness (and strength) decrease of the materials. The loss of structural effectiveness of the CFRP strengthening system is marked in this figure (with a small circle), and can be clearly identified by an increase on the slope of the curves; in most cases a progressive slope increase was observed. The insulation systems applied along the strengthening system (beams 25-25 and 50-25) delayed the thermal induced degradation on the materials during the entire test, explaining their lower midspan displacement increase rate (before and after the CFRP loss). Figure 4b summarizes the time of fire exposure until the loss of the CFRP system and confirms the high susceptibility of the strengthening system when exposed to heat without any protection (beam 0-0) - the CFRP debonded after only 18 minutes. This figure confirms that the application of thicker layers of insulation material allowed extending the structural effectiveness of the strengthening system by exploiting the CFRP mechanical contribution through a cable mechanism (already observed in previous studies, namely in EBR systems cf. Firmo et al. 2015b).

The fire behaviour of EBR-CFRP strengthened beams was assessed in a parallel study conducted by the authors (Firmo and Correia 2015b), in which similar materials, fire insulation schemes and test conditions were adopted. The worse fire performance of the EBR technique is illustrated in Figure 5a, where it is shown that for all insulation schemes, the fire resistance of the EBR-strengthened beams is considerably lower than that of the NSM counterparts.

Figure 4 a) Midspan displacement increase vs. time of fire exposure (E – experimental, N – numerical); b) fire resistance of the NSM-CFRP strengthening system.

**NUMERICAL INVESTIGATIONS**

**Description of the models**

The numerical investigations comprised the simulation of the fire resistance tests described above. The objective was two-fold: (i) to improve the understanding about the fire behaviour of NSM-CFRP-strengthened beams, namely confirming the cable behaviour of the CFRP system during the fire resistance tests, and (ii) to further validate the concept of fire protection systems comprising thicker insulation layers in the CFRP anchorage zones.

To achieve the aforementioned goals, three-dimensional FE models of the four NSM-CFRP-strengthened RC beams (specimens 0-0, 25-0, 25-25 and 50-25) were developed using the commercial package ABAQUS. In order to reduce the computational costs, only half of the beams’ length was simulated. Figure 5b exemplifies the FE mesh (with a maximum dimension of 10 mm) in which 8 node isoparametric hexahedral elements (DC3D8 and C3D8 for the thermal and mechanical analyses, respectively) were used to model concrete, CFRP strips and CS boards. For the steel rebars, 2-node truss elements (DC1D2 and T2D2 for the thermal and mechanical analyses, respectively) were adopted. The bonding adhesive was not explicitly modelled but was considered as explained later. The mechanical contribution of the fire insulation system was not considered, since it was estimated to be negligible.

The temperature-dependency of the properties of all constituent materials was incorporated in the models due its significant influence on the thermal and structural responses of the beams when subjected to fire. For the concrete a classical damaged plasticity model was adopted; a perfect elasto-plastic model was adopted for the steel rebars; and the CFRP strips were considered as linear elastic isotropic. A detailed description of the variation with temperature of the mechanical and thermo-physical properties is available in Firmo et al. (2015a). The CFRP-concrete bond was simulated by bi-linear global laws (cf. Figure 6a), which were independently determined in a previous investigation.
(Arruda et al. 2016) based on an inverse analysis of CFRP-concrete bond tests for temperatures up to 150 °C; such laws were calibrated in order to minimize the relative differences between numerical and experimental results obtained from double-lap shear tests (the test specimens were manufactured using the same materials that constitute the beams simulated in the present study). For temperatures above 150 °C, no CFRP-concrete interaction was considered in the models. Regarding the steel-concrete interaction, a perfect bond was assumed.

The FE models simulated the fire behaviour of the tested beams by means of a sequentially uncoupled thermo-mechanical procedure: the heat transfer analysis (with a maximum time step of 10 seconds) was first performed to obtain the temperature distributions for a duration similar to that observed in the tests; it was followed by a mechanical analysis which considered the thermal data determined in the previous step. It is worth pointing out that the same FE mesh was used in both steps. The numerical procedure adopted in the present study has shown to be able to predict the fire behaviour of insulated EBR-CFRP-strengthened RC beams (e.g. Dai et al. 2015 and Firmo et al. 2015a).

Figure 5 a) Comparison between the fire performance of EBR and NSM strengthening systems (experimental results); b) FE mesh of the beam’s models (example of model 50-25).

Numerical results

Figure 3a shows the comparison between predicted and measured temperatures along the bonded interface when the CFRP strengthening system lost its structural effectiveness due to the debonding from the beams’ soffit, which was clearly detected in both experimental and numerical midspan displacement vs. time curves showed in Figure 4a. Overall, the numerical curves presented in Figure 3a exhibited a similar behaviour to those measured during the fire resistance tests, although the FE models overestimated the temperatures along the bonded interface at the instant of CFRP debonding in beams 0-0 and 50-25 (this is clearly seen in Figure 3b). Such differences are related to the fact that the temperature distributions in these two beams had been computed for slightly longer periods of fire exposure – as observed in Figure 4b the numerical models over-estimated the fire resistance of the strengthening system in these beams (18 min vs. 10 min in beam 0-0 and 90 min vs. 82 min in beam 50-25).

Regarding the midspan displacement increase, the numerical curves presented in Figure 4a exhibited slightly higher deflection increase rates than those measured during the tests, which may stem from (i) some horizontal friction in the pinned supports (not considered in the FE models), and (ii) differences between the actual temperature dependencies of the materials’ mechanical properties and those considered in the models. Nevertheless, as depicted in Figure 4b the FE models were able to predict the loss of the CFRP system with reasonable accuracy (namely, if considering the complexity of the fire behaviour of NSM-strengthened members).

Figure 6b shows the average bond stress at the CFRP-concrete interface (computed along the CFRP anchorage length and along the central length) as a function of the time of fire exposure. For time = 0 min, as expected, the numerical results showed (i) similar bond stresses in all beams (considering the same location), and (ii) higher average bond stresses along the anchorage length of the strengthening system (La, cf. Figure 1) compared to those along the central length (span). Moreover, this figure shows that the average bond stresses in the anchorage and central zones were approximately constant during the initial stages of fire (in some cases presenting slight increases), after which those along the central length decreased to zero, whereas those along the CFRP anchorage length increased at a high rate, then presented a less pronounced increase and finally decreased to zero, with such instant matching the loss of the CFRP system (cf. Figure 4). This behaviour is more pronounced in beams 25-0 and 50-25, confirming that the thicker insulation boards applied in the CFRP extremities promote bond stress transfer from the central part of the strengthening system to the anchorage zones, allowing the CFRP strip to retain its structural effectiveness through a cable mechanism. These numerical results, besides providing further data that simply were not possible to quantify experimentally, validate the fire protection methodology adopted in the fire resistance tests.
Figure 6 a) Shear stress vs. slip curves for different temperatures (Arruda et al. 2016); b) average bond stress at the CFRP-adhesive interface (along the CFRP anchorage length and central zone) vs. time of fire exposure.

CONCLUSIONS

This paper presents experimental and numerical investigations about the fire behaviour of RC beams flexurally strengthened with NSM-CFRP strips when subjected to a sustained load and the standard ISO 834 fire. The test results confirmed the susceptibility of NSM-CFRP strengthening systems when exposed to fire - the mechanical contribution of the CFRP strips in a non-insulated beam was lost after only 18 minutes of fire exposure. However, the structural effectiveness of the CFRP system was considerably extended (up to 114 min) by applying a thin insulation layer along its central length and a thicker one (up to 50 mm) at both anchorage zones. With these fire protection schemes, although the CFRP-concrete bond became highly damaged along the central zone (less insulated), the CFRP strips continued to carry tensile forces as suspended “cables” fixed in the cooler (more insulated) anchorages zones. For the beams tested and the insulation schemes adopted, the maximum/critical temperature in the adhesive at the anchorage zones when the CFRP debonded attained values considerably higher than its $T_c$ (ranging from $2.4 \times T_c$ to $5.0 \times T_c$), indicating the over-conservatism of adopting it as a threshold for fire design in this particular case. Additionally, the results obtained also confirmed the much better fire resistance performance of NSM compared to EBR. Regarding the numerical investigations, the results obtained provided further insights about the stress transfer mechanism in NSM-CFRP strengthening systems during fire, confirming that the application of a thicker insulation layer in the CFRP anchorage zones allows making use of the cable behaviour and therefore extend the fire resistance of the strengthening system.

ABSTRACT

The idea of wrapping concrete in Fiber-Reinforced Polymer (FRP) to enhance its compressive strength and deformation capacity first appeared in the technical literature and was demonstrated experimentally more than 35 years ago, but it took some time for the industry and the research community to recognize its potential. At present its most common practical application in the seismic regions of the world is in upgrading the ductility and flexural deformation capacity of deficient concrete columns. In the first European Standard for the seismic retrofitting of existing buildings, i.e., Part 3 of Eurocode 8, an effective mechanical ratio of FRP is added to the corresponding ratio of confining steel, to take into account the beneficial effect of confinement by FRP on the cyclic ultimate chord rotation of concrete members having their end regions wrapped in FRP; the effective elastic stiffness of the member and its moment resistance are presumed, though, to be unaffected by the FRP. If longitudinal bars are lap-spliced along a length which is less than certain limit values, these properties, as well as the cyclic ultimate chord rotation, are taken to depend on the FRP. In the light of recent tests all these rules, proposed about ten years ago by the author's team, have certain bias and lack of fit. So, in view of the upcoming revision of the European Standard, the team has updated them, to reflect our current experimental knowledge.

Confinement, deformation capacity, Eurocode 8, FRP, lap-splices, RC columns, stiffness, ultimate deformation.

INTRODUCTION: FROM THE FIRST IDEA TO THE PRESENT DAY SEISMIC DESIGN CODES

The first idea to enhance the strength and deformation capacity of columns through confinement by FRPs (Fardis and Khalili, 1981, 1982) went unnoticed by researchers, but was taken up few years later by the construction industry. The classic book Teng et al (2004) notes: "The compressive strength enhancement of concrete due to the external wrapping of FRP was first demonstrated by Fardis and Khalili (1981, 1982). This concept was first applied to the strengthening of real RC columns in Japan in the mid 1980s." According to "... a learned group of writers, recruited from the ranks of the editorial board of the ASCE Journal of Composites for Construction " in their ASCE 150th Anniversary paper Bakis et al (2002): "Historically, composites were first applied as flexural strengthening materials for RC bridges (Meier 1987; Rostasy 1987) and as confining reinforcement of RC columns (Fardis and Khalili 1981; Katsumata et al. 1987). Developments since the first research efforts in the mid-1980s have been tremendous. .... The number of applications involving composites as strengthening/repair or retrofit materials worldwide has grown from just a few 10 years ago to several thousand today.” Indeed, among the over hundred references of Bakis et al (2002) only Fardis and Khalili (1981) date before 1987. According to Akovali (2002), "In recent years the use of FRP composites for the strengthening of concrete columns has become increasingly popular among engineers and researchers. ... Enhancement in the compressive strength of concrete as the result of external wrapping by the FRP was first demonstrated by Fardis and Khalili (1981, 1982)." Zhu et al (2005) opens as follows: "Early attempts by Fardis and Khalili (1981) showed great potentials for concrete-filled fiber reinforced polymer (FRP) tube (CFFT) as structural members. The concept was revitalized in the 1990’s as a composite structure with superior performance in axial compression (Mirmiran and Shahawy 1995). Since then, significant research has been carried out towards better understanding of the behavior of CFFT stubs and confinement modeling for FRP (Lorenzis 2001; Teng et al. 2003)". Chen et al (2013) states: "FRP composites with unidirectional fibers are commonly used in column strengthening with the fibers oriented in the direction perpendicular to the longitudinal axis of the column. The first experiments on this technique were conducted in the early 1980s (e.g., Fardis and Khalili 1981, 1982), and the concept has been investigated extensively since then (e.g., Ahmad et al. 1991; Karbhari et al. 1997; Rochette and Labossiere 2000; Tamuzs et al. 2007; Xiao and Wu 2000; De Luca et al. 2011)."
Another concept first proposed and demonstrated by Fardis and Khalili (1981, 1982) and rediscovered about 15 years later is summarized by Li et al (2005) “Recently, attention has been paid to new construction using FRPs, directly. The main aim in this new type of composite structures is to replace the steel reinforcements in concrete columns by laminated FRP shells, or exoskeletons, in order to achieve superior strength, ductility, and durability that are essential for concrete columns subjected to static and dynamic loads. This results in FRP tube-encased concrete columns (FRP/ECCs). A number of studies have been conducted on FRP/ECCs. In the early 1980s, the concept of FRP/ECC was proposed by Fardis and Khalili (1981, 1982), who analyzed the behavior of a circular FRP/ECC and a rectangular FRP tube-encased concrete beam. These structures have shown several advantages over the traditional RC columns. They have demonstrated an increase in the compressive strength and maximum moment, and a reduction in structural weight. They have also shown that an FRP tube directly serves as formwork and hence reduces the cost, increases the speed of construction, and improves the durability and watertightness. However, owing to the high initial cost associated with FRP tubes, little attention has been paid to this new concept. With the reduced cost of FRP tubes and with the success of FRP-repaired concrete columns, attention has been paid to FRP/ECCs in recent years. A new FRP tube system was proposed by Mirmiran (1996), Seible et al (1997) and Mirmiran and Shahawy (1997). In their works, the tube was a multilayer composite shell that consisted of at least two plies: an inner ply of axial fibers, and an outer ply of hoop fibers. It possessed the same advantages as that of the FRP tube proposed by Fardis and Khalili. The structural behavior of FRP/ECCs has been a research focus for the past five to ten years”. On the same topic Fam and Mirmiran (2013) write in their review of "Hybrid FRP/Concrete Rectangular Beam Sections": "One of the earliest attempts to produce hybrid FRP/concrete beam elements was done by Fardis and Khalili (1981) as they proposed casting concrete into FRP boxes. They also pointed out the mechanical role of FRP and concrete as follows: (1) FRP carries the tensile forces in the tension zone; (2) It provides partial confinement of concrete in the compression zone, enhancing strength and ductility; (3) It carries part of the shear force in the beam through the two sides; and (4) The concrete core provides compressive strength and rigidity and prevents local buckling of the FRP casing. They also pointed out that adhesion between the concrete and FRP is not necessary provided that the FRP box is closed at the two ends and the unidirectional fibers at the bottom have adequate end anchorage, otherwise mechanical interlock can be introduced. .... The strength of all the beams tested was greater than that of typical conventional reinforced concrete beams of the same dimensions and ranging from over-reinforced to overly under-reinforced. This study proved that FRP-encased concrete beams are superior to reinforced concrete beams on a strength/material cost basis.”

On the basis of their own concentric compression tests of nine cylindrical concrete specimens wrapped in GFRP, Fardis and Khalili (1981, 1982) proposed a hyperbola for the full stress-strain law of FRP-confined concrete. Its three parameters were defined by the initial tangent Modulus of concrete (taken to be unaffected by confinement), the ultimate strength (for which the Newman and Newman (1971) triaxial strength model was adopted) and the strain at ultimate strength (taken to be increased by 0.0005Epdferc, where £t and p are the FRP Elastic Modulus and geometric ratio in the circumferential direction and f, the uniaxial concrete strength). This law was used then to construct moment-axial load interaction diagrams for concrete columns wrapped in FRP.

The other important contribution of the writer to the application of FRPs in concrete construction came with the first European Standard for seismic retrofitting of existing buildings (CEN 2005), which incorporated expressions by Biskinis and Fardis (2006, 2010a, 2010b) for the ultimate chord rotation under cyclic loading and the secant-to-yield-point stiffness of concrete members, before and after retrofitting with externally applied FRP. As shown in Figure 1, this stiffness is taken as effective elastic stiffness. The ultimate deformation (chord rotation, curvature, etc) is commonly defined as the deformation after ultimate strength where lateral force resistance drops to less than 80% of the ultimate strength.

![Figure 1 Idealized moment-chord rotation relationship of concrete members](image)

**CURRENT MODELS IN EUROCODE 8 FOR THE YIELD MOMENT, THE STIFFNESS AND THE CYCLIC CHORD ROTATION CAPACITY OF FRP WRAPPED CONCRETE COLUMNS**

As explained in Fardis (2006) and Biskinis and Fardis (2006, 2007), Part 3 of Eurocode 8 (CEN 2005) takes the
effective elastic stiffness to be unaffected by FRP wrapping. It takes the ultimate cyclic chord rotation after Biskinis and Fardis (2006, 2010b), i.e., to be proportional to 25 to a power equal to the mechanical ratio of confining reinforcement in the direction of loading to times a theoretical effectiveness factor (cf. Eq. 10); for FRP-wrapped columns the exponent is increased by the mechanical ratio of FRP in the direction of loading, \( \rho f_{\text{eff}} f_c \), times a theoretical effectiveness factor:

\[
a_t = 1 - \frac{(h-2R)^2 + (b-2R)^2}{3bh}
\]

where \( R \) is the radius of the (chamfered) corners of the section and \( b, h \) the sides of its circumscribed rectangle (equal to 2\( R \) in circular columns). Instead of its ultimate tensile strength, \( f_{u,t} \), an effective FRP strength is used:

\[
f_{t,e} = \min \left( f_{u,t} - \frac{\rho f_{\text{eff}} E_t}{E_t} \right) \min \left( 0.5, \left[ 1 - 0.7 \frac{\rho f_{\text{eff}} E_t}{f_c} \right] \right)
\]

The limit strain, \( \varepsilon_{u,t} \), is 1.5% for Carbon FRP (CFRP) or Aramid FRP (AFRP), and 2% for Glass FRP (GFRP). If longitudinal bars, of diameter \( d_b \), are lap-spliced under the FRP-wrapping with a lapping, \( l_o \), shorter than:

\[
l_{o,\text{ma}} = 0.2 d_b \sqrt{f_{y,c}} \left( f_{y,c} \text{ in MPa}\right)
\]

the tension bars have their yield stress multiplied by \( l_o / l_{o,y,\text{ma}} \) whereas both lapped compression bars count in the compression reinforcement. Moreover, the plastic part of the cyclic ultimate chord rotation of a member with \( n_{\text{tot}} \) pairs of lapped bars around the section, is multiplied by \( l_o / l_{o,y,\text{ma}} \), if \( l_o \) is less than:

\[
l_{o,\text{ma}} = \frac{d_b f_{y,c}}{1.05 + 14.5 f_{y,c} / f_{c}} \left( f_{y,c} \text{ in MPa}\right)
\]

As shown in Figure 2, in the light of more recent tests the rules in (CEN 2005) summarized above suffer from a certain lack of fit and bias and need revisiting and updating. As the revision of this European Standard is underway, this paper revisits the current expressions and rules and makes proposals that better reflect the S-o-A.

![Figure 2](image-url)

Figure 2 Tests on FRP-wrapped rectangular columns vs predictions per (CEN 2005): (a), (d) yield moment; (b), (e) chord rotation at yielding; (c), (f) ultimate chord rotation; (a)-(c) continuous bars; (d)-(e) lap-spliced bars.

[Note: coefficient of variation (CoV) of test-to-prediction ratio: (a) 19.4%; (b) for undamaged columns 37.4% (median 1.03); (c) 30.6%; (d) 10.5%; (e) 17.7%; (f) 36.3%; median and CoV for the effective elastic stiffness \( EI_{\text{eff}} = M_L / 3 \theta_0 \) of undamaged columns: 1.02 and 30%].

**RECENT MODELS FOR THE YIELD MOMENT, THE EFFECTIVE STIFFNESS AND THE CYCLIC ULTIMATE CHORD ROTATION OF FRP WRAPPED COLUMNS WITH CONTINUOUS BARS**
Part 3 of Eurocode 8 (CEN 2005) applies to buildings alone; so, it covers only rectangular columns. As it neglects the effect of concrete strength enhancement by the FRP wrapping on the yield moment, $M_y$, and the secant-to-yield-point stiffness, $E_{AM}=M_y/L_e/3\phi_y$, it underestimates these properties (Figure 2). Neglecting the effect of concrete strength enhancement by the FRP leads to similar underestimation of these properties in circular columns (Biskinis and Fardis 2013a). Figure 3 shows that section analysis gives an unbiased estimate of the yield moment both for rectangular and for circular columns, if strength enhancement due to the FRP is accounted for, e.g., per Lam and Teng (2003, 2009), Jiang and Teng (2007), Teng et al (2009). The same analysis gives the yield curvature, $\theta_y$, from which the chord rotation of the shear span, $\theta_c$, at yielding, $\theta_c$, is obtained as follows (Biskinis and Fardis 2013a, 2013b):

- For rectangular columns:

$$\theta_y = \phi_y \left( L_e + a_d z \right) + 0.0014 \left( 1 + 1.5 \frac{h}{L_e} \right) + a_d \frac{df}{8f_e} \left( f_y, f_c: \text{MPa} \right)$$  \hspace{1cm} (4a)

- For circular columns:

$$\theta_y = \phi_y \left( L_e + a_d z \right) + 0.0027 \left( 1 - \min \left( 1; \frac{L_e}{7.5D} \right) \right) + a_d \frac{df}{8f_e} \left( f_y, f_c: \text{MPa} \right)$$  \hspace{1cm} (4b)

In Eqs. 4 $h$ is the member depth and $D$ the diameter of circular sections. The internal lever arm, $z$, is included in the first term if diagonal cracks form before the end section yields; i.e., if $V_c=M/L_e$ exceeds the shear resistance without shear reinforcement, then $a_c=1$; if it doesn’t, $a_c=0$. The last term is the fixed end rotation due to slippage of the tension bars - with diameter $d_b$ and yield stress $f_y$(MPa) - from their anchorage zone beyond the member end; it is omitted if symmetry or physical constraints suppress it ($a_d=0$); normally they don’t and then $a_d=1$.

The ultimate chord rotation at a member end, $\Delta \theta_u$, is the sum of the chord rotation at apparent yielding, $\Delta \theta_u^p$, and of a plastic part $\Delta \theta_u^d$. In the reference model in (Biskinis and Fardis 2013a, 2013b) $\Delta \theta_u^d$ was set equal to the sum of the chord rotation produced by the plastic part of the ultimate curvature, $\phi_y-\phi_y$, within a plastic-hinge length, $L_{ph}$, and the post-elastic fixed-end-rotation due to slippage of longitudinal bars from their anchorage beyond the member end, $\Delta \theta_{u,\text{slip}}$:

$$\Delta \theta_u = \Delta \theta_u^p + \left( \phi_y - \phi_y \right) \left( 1 - 0.5L_{ph}/L_e \right) + a_d \Delta \theta_{u,\text{slip}}$$  \hspace{1cm} (5)

with $a_d$ defined as for Eq. 4. Biskinis and Fardis (2010b) presented a section analysis for the ultimate curvature, $\phi_y$, of RC members without FRP wrapping, with equations and ultimate strain criteria for all failure modes. They also fitted expressions for $\Delta \theta_{u,\text{slip}}$ to relative rotation measurements including fixed-end-rotation due to bar slippage from the anchorage zone under cyclic loading:

$$\Delta \theta_{u,\text{slip}} = 5.5d_f\phi_y$$, \hspace{1cm} or \hspace{1cm} $\Delta \theta_{u,\text{slip}} = 5d_f\left( \phi_y + \phi_y \right)$  \hspace{1cm} (6)

For elastic-perfectly plastic $\sigma$- strain law of steel, Biskinis and Fardis (2010b) found optimal agreement of the computed and the measured values of $\phi_y$ in about 225 tests of rectangular sections without FRP-wrapping which failed by steel rupture, if the limit strain, $\varepsilon_{u,\text{nom}}$, of the extreme tension bars is taken equal to $(3/8)\varepsilon_{u,\text{nom}}$, with $\varepsilon_{u,\text{nom}}$ denoting the uniform elongation of a steel bar at its ultimate strength. The $\sigma$- strain law of FRP-confined concrete is taken per Lam and Teng (2003): first parabolic, then linear up to $f_{cc}$, with $f_{cc}$ per Lam and Teng (2003). Recall that the model for $f_{cc}$ in Lam and Teng (2003) is accompanied by expressions for the ultimate strain of FRP-confined concrete, $\varepsilon_{u,\text{cc}}$, fitted to monotonic or cyclic tests in concentric compression. However, the ultimate curvatures of FRP-wrapped columns computed from these expressions do not agree with the test results of such columns in cyclic flexure. A much better fit was obtained in Biskinis and Fardis (2013a) by taking $\varepsilon_{u,\text{cc}}$ from the following modification of equations fitted in Biskinis and Fardis (2010b) to measured ultimate curvatures of rectangular columns without FRP-wraps which failed in cyclic flexure by concrete crushing:

$$\epsilon_{u,c} = 0.0035 + \left( \frac{10}{h(\text{mm})} \right)^2 + a f_c \min \left( 0.5 \frac{\rho_y (0.6 \varepsilon_{u,\text{f}}, E_t)}{f_{cc}}, \left( 1 - \min \left( 1; \frac{L_e}{7.5D} \right) \right) \frac{df}{8f_e} \left( f_y, f_c: \text{MPa} \right) \right)$$  \hspace{1cm} (7)

where $\alpha$ is given by Eq. 1 and $\rho_y, E_{cc}$ have been defined in Section 2; $\varepsilon_{u,\text{f}}$ is the failure strain of FRP. For CFRP, GFRP and polyacetal fiber (PAF) sheets $c_f$ is equal to 0.2 for rectangular sections (Biskinis and Fardis 2013a) and to 0.18 for circular ones (Biskinis and Fardis 2013b), dropping to 0.17 and 0.12 for AFRP. The original expressions by Biskinis and Fardis (2010b) have, instead of the FRP term (the last one at the right-hand-side of Eq. (7), its counterpart for confinement by steel ties with geometric ratio $\rho_y$ and yield stress $f_{yw}$, namely $0.4\rho_y f_{yw}/f_{cc}$, where $\alpha$ is the effectiveness factor for confinement by ties. If the FRP produces less confinement than the ties, the column may survive rupture of the FRP and reach an ultimate curvature controlled by the confined concrete core inside the ties. This curvature is computed from section analysis with a parabolic-rectangular $\sigma$- strain law for the steel-confined concrete core, with $f_{cc}$ and the associated strain taken from (fib 2012):

$$f_{cc} = f_y (1 + K), \text{ with } K = 3.5 \left( \frac{\rho_y f_{yw}}{f_y} \right)^{3/4}$$, $\epsilon_{u,\text{cc}} = \epsilon_{u,c} \left[ 1 + \frac{f_{cc}}{f_y} - 1 \right]  \hspace{1cm} (8)$

and the concrete strain at $f_{cc}, \epsilon_{u,cc}$, taken as 0.002. The limit value, $\epsilon_{u,\text{cc}}$, at the end of the horizontal $\sigma$-branch is given by the original form of Eq. (7), i.e., with the last term replaced by $0.4\rho_y f_{yw}/f_{cc}$.
For so-determined \( \phi_h \), \( \phi_l \) and \( \Delta \theta_{\text{clip}} \), the expressions adopted in Biskinis and Fardis (2013a, 2013b) for the plastic hinge length, \( L_p \), are those fitted in Biskinis and Fardis (2010b, 2013b) to over 1500 tests of flexure-controlled rectangular members without FRP-wrapping and adopted in (fib 2012). These expressions are:

- For non-circular sections: 
  \[
  L_{pl} = 0.2h \left[ 1 + \frac{1}{3} \min \left( 9; \frac{L_t}{h} \right) \right] 
  \]  

- For circular sections: 
  \[
  L_{pl} = 0.6D \left[ 1 + \frac{1}{6} \min \left( 9; \frac{L_t}{D} \right) \right] 
  \]

![Figure 3 Tests of FRP-wrapped columns v predictions of (Biskinis and Fardis 2013a, 2013b): (a)-(c) rectangular columns with continuous bars; (d)-(f) rectangular columns with lap-spliced bars; (g)-(i) circular columns; (a), (d), (g): yield moment; (b), (e), (h): chord rotation at yielding; (c), (f), (i) ultimate chord rotation.]

[Note: CoV of test-to-prediction ratio: (a) 19.3%; (b) 37.3% (median: 1.015); (c) 30.4%; (d) 10.5%; (e) 17.7%; (f) 23.2%; (g) for continuous bars 22.5%, for lap-spliced bars 13.8% (medians: 1.005 and 0.89); (h) for continuous bars 22.3%, for lap-spliced bars 32.8% (medians: 1.005 and 0.93); (i) for continuous bars 22.4%, for lap-spliced bars 39.1% (medians 1.005 and 0.975); median and CoV of effective elastic stiffness: \( E_{eff} = M/L/3\theta \) of rectangular columns: 0.985 and 30.4% for continuous bars, 1.025 and 19.8% for lap-spliced ones; ibid for circular columns: 1.21 and 23.2% for continuous bars, 0.975 and 20.7% for lap-spliced bars].

Eqs. 1 and 4-9, used with the Lam and Teng (2003) strength model, give predictions which compare to tests as shown in Figure 3(a), (b) and (g)-(i). Medians and coefficients of variation (CoV) of the corresponding test-to-prediction ratio are given in Figure 3 and its caption. Those of the ratio of the experimental ultimate chord rotations of FRP-wrapped members with rectangular section to the outcome of Eqs. 1 and 4-9 (omitted from Figure 3) are equal to 0.99 and 32.7%, respectively. The comparison in Figure 3(c) is for a second option for rectangular FRP-
wrapped columns: an extension of an empirical model fitted by Biskinis and Fardis (2010b) to 1400 flexure-controlled tests of members without FRP-wrapping - adopted in (CEN 2005) and (fib 2012):

$$\theta_u = \theta_y + \theta^\text{pl}_u = \theta_y + 0.0145(0.25)^{\left(\frac{\max(0.01, \omega)}{\max(0.01, \omega_{\text{col}} - \omega)}\right)^{0.3}} \left(f_c(MPa)\right)^{0.35} \frac{L_y}{h}$$

(10)

where:
- \(\nu=N/bhf_e\), with \(b\) the width of the compression zone and the axial force \(N\) positive for compression,
- \(\omega_{\text{col}}=\rho_{\text{col}}/f_c\) and \(\omega^d=\rho_{\text{f}}/f_c\) total and compression mechanical reinforcement ratio of the section,
- \((a\varphi/f_c)\); confinement term due to the FRP, given by Eq. 11 below (with \(f\) from Eq. 1 and \(c=1.8\) for CFRP or PAF sheets and \(c=0.8\) for GFRP or AFRP) instead of the current term in (CEN 2005) given by Eq. 3.

$$a_{\varphi}/f_c = a_f \beta_f \min\left[0.4; \frac{0.6\varepsilon_{f} E_f}{f_c}\right] + \frac{0.6\varepsilon_{f} E_f}{f_c} \left[1-0.5\min\left[0.5; \frac{0.6\varepsilon_{f} E_f}{f_c}\right]\right]$$

(11)

The test-to-prediction ratio of Eqs. 10 and 11 (cf Figure 3(c)) has slightly better statistics than that of Eqs. 4-9.

More recently Grammatikou et al (2016a, 2016b, 2017) used a large databank of curvature measurements in tests that led to flexure-controlled ultimate conditions to fit more elaborate ultimate strain criteria for circular sections and sections with rectangular or triangular compression zone. They proposed the following ultimate strains for unconfined and FRP-confined concrete, respectively, in members subjected to cyclic flexure:

$$0.0035 \leq \varepsilon_{\text{cu}} = \left(18.51/h(\text{mm})\right)^2 \leq 0.01$$

(12)

$$\varepsilon_{\text{cu},\text{c}} = \varepsilon_{\text{cu}} + a_f \beta_f \min(0.5; \rho_f(0.6\varepsilon_{f} E_f)/f_c) \left[1 - \min(0.5; \rho_f(0.6\varepsilon_{f} E_f)/f_c)\right]$$

(13)

Coefficient \(a_f\) is given by Eq. 1; \(\beta_f\) is equal to 0.115 for CFRP, GFRP or PAF sheets and to 0.1 for AFRP.

FRP-wrapped members fail in cyclic loading mostly by steel rupture, but reach higher bar strains than members without FRP wrapping. The tension zone performs better inside an FRP-wrapping, because the FRP prevents the buckling of bars that precedes bar rupture in cyclic tests of members without FRPs. For this reason the strain of bars inside FRP wraps at the instant the ultimate curvature occurs in cyclic loading does not depend on the tie-spacing-to-bar-diameter ratio, nor on the number of longitudinal bars in the compression zone, as bar strains at ultimate curvature of members without FRP do. It is larger than the latter and - for probabilistic reasons explained for monotonic loading in (Grammatikou et al 2016a) - decreases with respect to the average bar strain at tensile strength in a standard bar test, \(\varepsilon_{\text{bar,nom}}\), as the number of bars in the tension zone, \(N_{\text{bar,tension}}\), increases:

$$\varepsilon_{\text{cu},\text{c}} = 0.6\varepsilon_{\text{cu,nom}} \sqrt{1-0.15\ln\left(N_{\text{bar,tension}}\right)}$$

(14)

Using an enriched experimental database, Grammatikou et al (2016a) also revised Eqs. 6 and 4 as follows:

$$\Delta\theta_{u,\text{slip}} = 4.5d_l \phi_u, \quad \text{or} \quad \Delta\theta_{u,\text{slip}} = 4.25d_l (\phi_u + \phi_f)$$

(15)

- For rectangular columns:

$$\theta_y = \phi_u \frac{L_y + a_f \varepsilon_{\text{f}}} {3} + 0.0015 \left[1 + \frac{0.355}{L_y} \frac{h}{L_y}\right] + a_f \frac{d_l f_f}{8f_c}, \quad (f_f, f_c: \text{MPa})$$

(16a)

- For circular columns:

$$\theta_y = \phi_u \frac{L_y + a_f \varepsilon_{\text{f}}} {3} + 0.0025 \left[1 - \frac{1}{2}\min\left(1; \frac{L_y}{8D}\right)\right] + a_f \frac{d_l f_f}{8f_c}, \quad (f_f, f_c: \text{MPa})$$

(16b)

Grammatikou et al (2016a) revisited \(L_y\) as well, fitting the following expressions to the measured ultimate chord rotations of over 2000 flexure-controlled reinforced concrete specimens without FRP in cyclic loading:

- For beams or columns with section of rectangular parts, walls of all types and hollow piers.

$$L_y = 0.5h \left(1 + 0.4 \left[\min\left(9, \frac{L_y}{h}\right)\right] \min\left(2.5, \max\left(0.05, \frac{b_w}{h}\right)\right) \left[1 - 0.45 \min(0.7, v)\right)\right]$$

(17a)

- For columns with circular section:

$$L_y = 0.7D \left(1 + \frac{1}{2} \min\left(9, \frac{L_y}{D}\right) \left[1 - \min(0.7, v)\right)\right]$$

(17b)

In Eq. 17a \(b_w\) is the width of one web (even in hollow or C-sections with more than one web); the axial force \(N\), positive for compression, is normalized to the cross-sectional area \(A_e\). as \(\nu=N/A_f\).

Figs. 4(a), (b) compare predictions of Eqs. 12-17 to test results of FRP-wrapped rectangular or circular columns respectively (Grammatikou et al 2016b); the associated CoV of the test-to-prediction ratio is 36.6% or 22.4%.

Grammatikou et al (2016b) also produced a set of alternatives to the empirical expression underlying Eq. 10 for members with a rectangular compression flange. These alternatives are extended for FRP-wrapping as follows:
\[ \theta_u = 0.0205 \left[ (1 - 0.4a_{uw}) (1 - 0.32a_{uw}) \right] 0.325^2 \left[ \frac{\max (0.01; \omega)}{\max (0.01; \omega_{uu} - \omega)} \right]^{0.2} \cdot \]

\[ f_r (MPa)^{0.15} \left[ \min \left( \frac{L_b}{h} \right) \right]^{0.35} 12.5 \left[ \frac{\omega_{u,exp}}{\omega_{u,pred}} \right] \]

\[ \theta_u = \theta_s + \theta_{u,p} = \theta_s + 0.0205 \left( (1 - 0.41a_{uw}) (1 - 0.31a_{uw}) \right) 0.2^{\gamma} \left[ \frac{\max (0.01; \omega)}{\max (0.01; \omega_{uu} - \omega)} \right]^{0.25} \cdot \]

\[ f_r (MPa)^{0.1} \left[ \min \left( \frac{L_b}{h} \right) \right]^{0.35} 24 \left[ \frac{\omega_{u,exp}}{\omega_{u,pred}} \right] \]

\[ \theta_u = \theta_s + \theta_{u,p} = \theta_s + 0.032 \left( 1 - \frac{1}{12} \max \left( 4 \min \left( \frac{a}{b_w} \right) \right) \right) 0.2^{\gamma} \left[ \frac{\max (0.01; \omega)}{\max (0.01; \omega_{uu} - \omega)} \right]^{0.275} \cdot \]

\[ f_r (MPa)^{0.1} \left[ \min \left( \frac{L_b}{h} \right) \right]^{0.35} 25 \left[ \frac{\omega_{u,exp}}{\omega_{u,pred}} \right] \]

\[ \theta_u = \theta_s + \Delta \theta_{u,slip} + \theta_{u,p} = \theta_s + \Delta \theta_{u,slip} + 0.013 \left( 1 - 0.27a_{uw} \right) 0.2^{\gamma} \left[ \frac{\max (0.01; \omega)}{\max (0.01; \omega_{uu} - \omega)} \right]^{0.275} \cdot \]

\[ f_r (MPa)^{0.1} \left[ \min \left( \frac{L_b}{h} \right) \right]^{0.35} 7.5 \left[ \frac{\omega_{u,exp}}{\omega_{u,pred}} \right] \]

\[ \theta_u = \theta_s + \Delta \theta_{u,slip} + \theta_{u,p} = \theta_s + \Delta \theta_{u,slip} + 0.0123 \left( 1 - 0.05 \max \left( 4 \min \left( \frac{a}{b_w} \right) \right) \right) 0.225^{\gamma} \]

\[ \left[ \frac{\max (0.01; \omega)}{\max (0.01; \omega_{uu} - \omega)} \right]^{0.175} f_r (MPa)^{0.15} \left[ \min \left( \frac{L_b}{h} \right) \right]^{0.45} 7 \left[ \frac{\omega_{u,exp}}{\omega_{u,pred}} \right] \]

The term for the confinement by FRP (the very last one appearing in exponent), is still given by Eq. 11, but with:

- \( c_f = 1.9 \) for CFRP or PAF, \( c_f = 0.9 \) for AFPRP, \( c_f = 1.15 \) for GFRP in Eqs. 18a-18c;
- \( c_f = 2.8 \) for CFRP or PAF, \( c_f = 0.95 \) for AFPRP, \( c_f = 1.15 \) for GFRP in Eqs. 18d and 18e.

Eqs. 18b-18e account separately for the chord rotation at yielding, from Eq. 16a; Eqs. 18d, 18e explicitly account for the fixed-end-rotation due to bar slippage from the anchorage zone, from Eq. 15. Eqs. 18b, 18e explain the effect of cross-sectional shape on ultimate chord rotation as one of slenderness of the web. However, the improved rationality from Eq. 18a to 18e is not translated into much better fit or accuracy: all five versions of Eq. 18 produce essentially the same median (about 1.0) and CoV (31% to 31.5%) of the test-to-prediction ratio.

![Graphs showing cyclic ultimate chord rotation of FRP-wrapped columns with continuous bars, test prediction (a), (b) Eqs 12-17; (c) Eq 18c; (a), (c): rectangular; (b) circular columns (Grammatikou et al 2016b).](attachment:graph.png)

[Note: CoV of test-to-prediction ratio: (a) 36.6%; (b) 22.4% (c) 31.5%].

### RECENT MODELS FOR THE YIELD MOMENT, THE EFFECTIVE STIFFNESS AND THE CYCLIC ULTIMATE CHORD ROTATION OF FRP WRAPPED COLUMNS WITH LAP-SPLICED BARS

For rectangular columns Biskinis and Fardis (2013a) modified Eq. 4 into Eq. 19 below. If \( l_s \) is less than \( l_{uu, min} \), the
plastic part of the ultimate chord rotation from the empirical model, Eq. 10, is multiplied by $l_ou/ou,\text{min}$.

$$
\psi_{\text{circ}} = \psi_{\text{rect}} \left( \frac{d_u f_y}{1.05 + 14.5 \left( \frac{2}{n_{\text{tension}}} \right) \left( \frac{ap_g su}{f_c} f_y \right)^{1/2}} \right) (f_y, f_u, f_c \text{ in MPa})
$$

(19)

with $(ap_g su, f_c)$ from Eq. 11, i.e., the same value as in the second term of the exponent of the confinement term (the last one) in Eq. 10. If $n_{\text{tension}}=2$ this second term in the exponent is neglected by Biskinis and Fardis (2013a).

Eq. 19 does not apply to FRP-wrapped circular columns with lap-spliced bars; for them Biskinis and Fardis (2013b) introduced a different expression:

$$
\psi_{\text{circ}} = \psi_{\text{rect}} \left( \frac{d_u f_y}{5 + 6 \left( \frac{ap_g su}{f_c} f_y \right)^{1/2}} \right) (f_y, f_u, f_c \text{ in MPa})
$$

(20)

with $(ap_g su, f_c)$ still from Eq. 11. Only the physical model of Eq. 5 is available for the ultimate chord rotation of circular columns. In that context Biskinis and Fardis (2013b) proposed to reduce the limit strain of lap-spliced bars according to Eq. 21, with $\epsilon_{ou,\text{min}}$ from Eq. 3, $l_{ou,\text{min}}$ from Eq. 20, and $\epsilon_{ou}$ equal to $(3/8)\epsilon_{ou,\text{nom}}$:

$$
\epsilon_{ou} = \left[ \frac{1.2 - \frac{l_o}{l_{ou,\text{min}}} - 0.2}{\epsilon_{ou}} \right] \epsilon_{ou} \geq \frac{l_o}{l_{ou,\text{min}}} \frac{f_y}{E_y}, \text{ if } l_o \leq l_{ou,\text{min}}
$$

(21)

The predictions of these rules per Biskinis and Fardis (2013a, 2013b) are compared in Figures 3(d)-(f) and 3(g)-(i) to the results on tests of rectangular and circular columns, respectively. The comparison is satisfactory for rectangular columns. For circular ones the yield moment, the chord rotation at yielding and - to a lesser extent - the ultimate chord rotation are overpredicted. In other words, rules mimicking those developed for rectangular columns with or without FRP wrapping do not suit well circular ones. Note also that, although for rectangular columns with FRP-wrapping and continuous bars the physical model of Eq. 5 comes out almost as accurate as the empirical one of Eq. 10, Biskinis and Fardis (2013a) could not extend it to FRP-wrapped rectangular columns with lap spliced bars in a way analogous to Eq. 21 - originally fitted to rectangular columns with lap splices but no FRP-wrapping.

Figure 5 Test results on FRP-wrapped columns with lap-spliced deformed bars v prediction of: (a), (d) yield moment; (b), (e) chord rotation at yielding; (c), (f) cyclic ultimate chord rotation; (a)-(c): rectangular; (b) circular columns (Grammatikou et al. 2017).

[Note: CoV of test-to-prediction ratio: (a) 18.9%; (b) 19%; (c) 35.1%; (d) 13.1%; (e) 25.4%; (f) 31%].

Grammatikou et al. (2016b) addressed shortcomings of the Biskinis and Fardis (2013a, 2013b) approach in a more rational model, which applies seamlessly to rectangular and circular columns, with or without FRP wraps over the lap-splice region. First, they replaced Eq. 3 with:

987
where the concrete tensile strength, $f_{ct}$, is taken per (fib 2012) as $f_{ct}(MPa)=0.3(f_c(MPa))^{2/3}$ and $c_{min}$ is the minimum concrete cover of the lapped bars, or half the clear distance to the closest lap-spliced bar, whichever is smaller.

Second, they introduced a common rule for $l_{ou,\min}$ in rectangular and circular sections and for confinement of the lap splice by an external FRP jacket or by internal steel ties:

$$l_{ou,\min} = \frac{d_k f_y}{f_{ct} \max \left( c_{min} / d_k, 0.7 \right)}$$

(22)

where:

- $a_o$ is the confinement effectiveness factor: $a_o=n_{tied}/n_{tot}$ in rectangular sections with $n_{tied}$ restrained lapped bar pairs (eg. at a chamfered corner of a FRP jacket) out of $n_{tot}$ lapped bar pairs in total; in circular sections $a_o=1$;
- $a$ is the confining medium factor: $a=9.5$ for confinement by CFRP or PAF sheets, $a=10.5$ for confinement by GFRP and $a=12$ for AFPR; $a=7.5$ for confinement by steel ties.
- $R_c$ is the confining medium radius, i.e., the bending radius of the FRP jacket or steel tie confining the splice;
- $p_{c}$ is the confinement pressure on the lap splice, equal to $t f_{cd}/R_c$ for confinement by FRP of thickness $t_i$, or $A_{dfc}(s/R_c)$ for confinement by steel ties with cross-sectional area $A_{sh}$ and spacing $s_0$.
- $a_i$ is a factor for confinement effectiveness along the length of the member, equal to 1.0 for confinement by FRP; for confinement by ties, it is equal to:

$$a_i = \left( 1 - \frac{h_o}{b_o} \right) \left( 1 - \frac{s_k}{b_p} \right)$$

(24)

with $h_o, b_o$: dimensions of the confined core to the centerline of the outer tie ($h_o=b_o=D_A$ in a circular core).

If $L_c < l_{ou,\min}$, the ultimate chord rotation is computed from the physical model, Eqs. 5, 12-17, but with the ultimate strain of tension bars reduced with respect to the value $\varepsilon_{fu}$ from Eq. 14 for bars inside an FRP jacket.

$$\varepsilon_{su,lap} = \min \left( \varepsilon_{fu} l_o / l_{ou,\min} \right) \left( 1 - l_o / l_{ou,\min} \right) f_y / E_y$$

(25)

Figure 5 compares test results from columns with FRP wrapping of the lap-splice region to predictions as given by Grammatikou et al (2006b) and gives statistics of the test-to-prediction ratio.

CONCLUDING REMARKS

After recalling the first record in the international scientific and technical literature of concrete confinement by FRP wrapping and of concrete cast in permanent FRP moulds, the paper highlighted the recent and current contributions of the author and his team to the development of practical design models for the enhancement of the cyclic deformation capacity of concrete members by wrapping their end regions with FRP. The models are seamless extensions of those proposed by the same team for all sorts of members without FRP wraps, including members with short lap splices of the longitudinal bars. They are based on the largest available databank of cyclic test results on concrete members with or without retrofitting. Earlier versions of the models for the cyclic deformation capacity and the secant-to-yield-point stiffness have been adopted in the 2005 European Standard for seismic assessment and retrofitting of existing buildings, Part 3 of Eurocode 8. In view of the upcoming revision of this European Standard, the current, enriched database of test results has been utilized to improve, harmonize and expand the portfolio of design models for the flexural resistance, the secant-to-yield-point stiffness and the cyclic deformation capacity of concrete members with or without retrofitting.

Going back to the beginning of the story, Fardis and Khalili (1982) proposed to take the ultimate strain of concrete as increased by 0.0005$E_y / \rho f_c$, (where $E_y$ and $\rho f_c$ are the FRP Elastic Modulus and geometric ratio in the circumferential direction) to account for the beneficial effect of confinement by FRP. If this, admittedly very conservative value is used in lieu of Eq. 12, the median of the test-to-prediction ratio for the cyclic ultimate chord rotation increases from 1.00 to 1.26 for rectangular columns with continuous bars and to 1.81 for circular ones; for lap-spliced bars and rectangular columns it stays at 1.00 and increases to 1.04 for circular. In all these cases the Coefficient of Variation (CoV) of the test-to-prediction ratio is about the same as when Eq. 12 is used. The different sensitivity of these results to the ultimate strain of confined concrete is due to the different failure modes: in columns with short lap-splices, the tension bars are the critical link, whereas in columns with continuous bars the FRP-confined concrete normally governs.

Biskinis, D.E. and Fardis, M.N. (2007) “Cyclic deformation capacity of FRP-wrapped RC columns or piers with continuous or lap-spliced bars, 8th International Symposium on Fiber Reinforced Polymer Reinforcement for Concrete Structures (FRPRCS-8), Patras.

ABSTRACT

Buckling of steel reinforcement usually causes a sudden loss of the load-carrying capacity and leads to the ultimate state of conventional reinforced concrete (RC) columns. However, it behaves differently in fiber-reinforced polymer (FRP)-confined RC columns due to the lateral confinement effect of FRP. This paper presents a theoretical study into the buckling behavior of longitudinal steel reinforcing bars embedded in FRP-confined concrete subjected to cyclic axial compression. An empirical monotonic compressive stress-strain model for laterally supported reinforcing bars considering the buckling effect, which was proposed in the authors’ previous study, was extended to a cyclic stress-strain model following the Menegotto-Pinto model accounting for the cyclic loops. The cyclic stress-strain models for laterally supported reinforcing bars as well as FRP-confined plain concrete were then implemented into the OpenSees platform to simulate the cyclic compressive behaviour FRP-confined RC columns and validated through comparisons with test results. The proposed cyclic stress-strain model for laterally supported reinforcing bars can serve as a fundamental law for the modelling of seismic behaviour of FRP-strengthened RC columns, especially for those with sparsely-spaced transverse ties where buckling of reinforcing bars becomes a significant concern.

INTRODUCTION

Old reinforced concrete (RC) columns, particularly those built prior to the 1970s, often had poor transverse reinforcement details. Consequently, the longitudinal reinforcing bars may buckle easily under a critical level of compressive strain due to insufficient lateral support. Buckling of longitudinal reinforcing bars in conventional RC columns is a vital damage state indicating a significant loss of the load-carrying capacity of RC columns. The effectiveness of external FRP jackets in resisting the buckling of longitudinal reinforcing bars in FRP-confined RC columns has been reported by previous researchers (e.g., Priestley et al. 1996; Bournas and Triantafillou 2011). It is generally believed that FRP can prevent, or at least postpone the buckling of longitudinal reinforcing bars (Bournas and Triantafillou 2011). In addition, because the concrete cover is confined by the external FRP jacket in an FRP-confined RC column, compared to the progressive buckling of longitudinal reinforcing bars, the brittle fracture of the external FRP jacket usually becomes a more critical factor leading to the sudden loss of the member’s load-carrying capacity and deformability. However, so far the behavior of progressive buckling of reinforcing bars, which may occur before the rupture of external FRP jackets, remains unclear.

For an accurate prediction of the strength and especially the post-peak behavior of FRP-confined RC columns under seismic loading, it is important to understand the interaction mechanism between steel reinforcing bars and FRP jackets at all deformation levels. Recently, Bai (2014) conducted an experimental study on the buckling behavior of reinforcing bars in FRP-confined RC columns subjected to monotonic axial compression. In this study, two types of FRP materials, carbon FRP (CFRP) and polyethylene terephthalate (PET) FRP, were used to compare the buckling restraining effect of FRP jacket with different jacket stiffness. PET FRP, being a new type of composite material, is characterized with a low elastic modulus but large rupture strain (Anggawidjaja et al. 2006, Dai et al. 2011). Test results showed that significant buckling was observed in PET FRP-confined RC columns before the rupture of PET FRP jacket, while no visible buckling phenomenon was found in CFRP-confined RC columns. In other words, the use of PET FRP allows the progressive buckling to occur while the rupture of CFRP preceded the occurrence of steel buckling. Therefore, the development of reinforcing bar buckling depends
strongly on the stiffness and elongation of FRP jacket. To interpret the test results, Bai and Dai (2015) further developed a “beam-on-elastic-foundation” model to simulate the compressive behavior for laterally supported reinforcing bars in FRP-confined circular RC columns based on the finite element (FE) approach. In this model, the confining effect on the longitudinal reinforcing bars provided by the FRP-confined concrete is modeled by a series of linear springs, which stiffness was evaluated based on a curved beam model. Furthermore, based on parametric studies, an empirical monotonic stress-strain model for the reinforcing bars embedded in FRP-confined RC columns considering the buckling effects was developed. Along with these previous work, this study aims to develop a cyclic stress-strain model for reinforcing bars embedded in FRP-confined circular RC columns with due consideration of the interaction between the progressive buckling of reinforcing bars and the FRP confinement effect, to facilitate the analysis of the behavior of FRP-confined circular RC columns under seismic loading. The proposed model will be implemented into the OpenSees (2009) platform and verified its accuracy through comparisons with test results.

THEORETICAL STRESS-STRAIN MODEL FOR LATERALLY SUPPORTED REINFORCING BARS UNDER CYCLIC LOADING

Monotonic Compressive Stress-Strain Model

A monotonic stress-strain model considering the buckling effects for longitudinal reinforcing bars embedded in FRP-confined RC columns was developed by Bai (2014). Revisions were then made to reflect the additional effects of lateral spring supports besides those of the slenderness ratio and yield strength of steel material, which were already considered in Dhakal and Maekawa’s (2002) three-stage model for the buckling reinforcing bars with lateral confinement. A set of empirical formulas were proposed based on extensive least-squares regressions of numerical data generated by FE analyses of the stress-strain behavior of laterally supported reinforcing bars subjected to monotonic loading. The second stage of Dhakal and Maekawa’s (2002) model was modified to account for the effect of lateral FRP confinement, and the characteristic point ($\sigma^*$, $\epsilon^*$) that intersects the second and third stages and the slope of the descending stress-strain curve of the third stage were defined (Figure 1):

$$
\begin{align*}
\sigma_i &= \sigma_0 \epsilon_i, & \epsilon_i \leq \epsilon_s \\
\sigma_i &= \frac{1 - (1 - \frac{\sigma_s}{\sigma_f}) (\epsilon_i - \epsilon_s)}{\epsilon_i - \epsilon_s}, & \epsilon_s < \epsilon_i < \epsilon^* \\
\sigma_i &= \sigma^* - E_s (\epsilon_i - \epsilon^*) \geq 0.2f_y, & \epsilon_i > \epsilon^*
\end{align*}
$$

(1)

and

$$
\begin{align*}
\frac{\epsilon^*}{\epsilon_y} &= 0.95(1.0+6.53\lambda_1 + 1.75\lambda_2)(0.90 + 1.14\lambda_3)(4.14\lambda_4-2.41) \geq 7 \\
\frac{\sigma^*}{f_y} &= 0.74(1.0+0.76\lambda_1)(0.72 + 0.24\lambda_2)(0.40 + 0.63\lambda_3) \geq 0.2
\end{align*}
$$

(2)

where $\lambda_1$, $\lambda_2$ and $\lambda_3$ are variables representing the effects of spring stiffness $K$, the slenderness ratio $L/D$ and the yield strength $f_y$, respectively, as follows:

$$
\begin{align*}
\lambda_1 &= \sqrt{K}/100 \\
\lambda_2 &= 10D/L \\
\lambda_3 &= \sqrt{450/f_y}
\end{align*}
$$

(3)

The slope of the third stage $E_3$ varies slightly with the spring stiffness $K$, the slenderness ratio and yield strength of steel material and its value can be determined using the following empirical equation:

$$
1000\frac{E_3}{f_y} = 1.31(1.0 + 1.28\lambda_1)(4.39-0.47\lambda_2\lambda_4)
$$

(4)

where $E_s$ is the elastic modulus of steel material.
Cyclic Rules

For analysis of seismic performance of FRP-confined RC columns, a cyclic stress-strain model of reinforcing bars with hysteretic loops is needed. In this study, the proposed cyclic stress-strain model for laterally supported longitudinal reinforcing bars with buckling effects simply follows the cyclic rules adopted in Menegotto and Pinto (1973) (Figure 2). In addition, it combines the monotonic tensile stress-strain model (Mander 1983) and the proposed monotonic compressive stress-strain model, which can consider the buckling effects of reinforcing bars as mentioned in the previous section.

Figure 1 Monotonic stress-strain model for laterally supported reinforcing bars

Figure 2 Menegotto-Pinto model

MODEL VERIFICATION

Bai (2014) conducted cyclic compressive tests on 12 circular circular columns (200 mm in diameter and 500 mm in height), comprising 6 FRP-confined RC columns and 6 FRP-confined plain concrete columns. The test parameters included the type of FRP [i.e., PET FRP and CFRP], the number of plies (layers) in the FRP jacket (i.e., one ply and two plies). Here only the cyclic compressive tests on two RC columns confined with one ply and two plies of PET FRP sheets (i.e., specimens PET-RC-1-c-a and PET-RC-2-c-a) were chosen for verification of the proposed cyclic stress-strain model for reinforcing bars considering the buckling effect. The OpenSees (2009) platform was used to simulate the two PET FRP-confined RC columns. The proposed cyclic stress-strain model for rebar with buckling effects was implanted into OpenSees as a new material and named “ReinforcingSteelBai”. The “NonlinearBeamColumn” element available in OpenSees, which is a force-based nonlinear beam-column element and considers the spread of plasticity, was adopted to simulate the reinforcing bars. Three Gauss-Lobatto integration points were defined along each element in the model (Figure 3).

Figure 3 Numerical model for FRP-confined RC column

The numerical simulation was conducted with the displacement control method. Unloading/reloading cycles were initiated at the same axial displacements as recorded in the tests. The analyses were terminated when the ultimate strain of FRP-confined concrete was reached. Figs.4a and 4b present the predicted axial load-displacement curves of cyclically loaded FRP-confined RC columns in comparison with the test results. For comparison purpose, there are two predicted load-displacement curves in each figure: one was based on the proposed cyclic stress-strain models of laterally supported reinforcing bars while the other was based on the theoretical cyclic stress-strain model for a bare bar without any consideration of buckling effect. It is seen that better agreement between the test results and FE predictions can be achieved when the buckling effect of laterally supported reinforcing bars is taken into account, which verifies the reliability of the proposed cyclic stress-strain model.
CONCLUSIONS

A cyclic stress-strain model for laterally supported reinforcing bars has been developed based on the combinations of the following three models: (1) monotonic compressive stress-strain model for laterally supported reinforcing bars including the buckling effect; (2) monotonic tensile stress-strain model for steel material; (3) Menegotto and Pinto model for the cyclic loops. The proposed cyclic stress-strain model for laterally supported reinforcing bars has been implemented into the OpenSees software platform. A simplified cyclic stress-strain model for FRP-confined plain concrete was also incorporated. The developed program was then used to simulate the load-displacement responses of FRP-confined RC columns under cyclic axial compression. Comparisons between test results and model predictions verified the accuracy of the proposed cyclic model for laterally supported reinforcing bars and demonstrated the significance of considering the bulking effects of reinforcing bars in the simulation.

ABSTRACT

In various countries, including France, the regulations concerning buildings and civil engineering structures contain recommendations aimed at achieving acceptable seismic performance, that is, the structures designed must withstand minor earthquakes without damage, moderate earthquakes with minimum non-structural damage and major earthquakes without collapsing. The seismic recommendations proposed in building regulations have thus been updated over the years to achieve this aim. In France, the new earthquake zone map and changes in the regulations as a result of Eurocode 8 (EC 8) have contributed to defining the performance objectives of new structures. For existing structures, at least in certain cases, reinforcement is required to reduce seismic risks. This notion is introduced in Eurocode 8 Part 3 and in the implementing decrees and orders. Seismic retrofitting can therefore be either voluntary or compulsory. Based on the current construction rate, it would take one hundred years to completely replace France's housing stock. Seismic retrofitting of existing structures therefore appears necessary to ensure the solidity of all building constructions and the safety and security of people and property. The need to reduce the effects of an earthquake on a reinforced concrete structure can correspond to two different situations:
1. the weak points identified are localised and confined within a particular area
2. there are many weak points everywhere and a global approach is necessary

In the first case, the strategy will consist in treating the problem of a single component whose probable failure would lead to consequences on a global level. In the second case, the strategy will consist in carrying out major works on the entire structure. In both cases, the retrofitting works will need to be validated on both a technical and economic level. Several reinforcement scenarios are possible: reduction in seismic loads (insulators, dissipators, change of mass and/or improvement of performance, resistance and/or rigidity of structure).

The retrofitting techniques generally used are classified according to purpose and technology:
- Retrofitting by addition (chaining, bracing, buttressing, etc.)
- Enhancement of shock absorption and/or reduction in rigidity (isolators, dissipators, etc.)
- Enhancement of strength and/or ductility (sprayed concrete, bonded composites, steel lining and bracing, etc.)
- Anchoring (floor-chaining, framework-chaining, foundation-framework)

This document presents recommendations for the seismic retrofitting of concrete structures using fibre-reinforced polymers (FRP).

INTRODUCTION

For more than fifteen years, national and international research (U. Meier [1], K. Neale [2], P. Hamelin [3], E. Ferrier [4], A. Triantafillou [5], J-L. Clément [6]), has shown that composite materials (polymer Matrix, textile reinforcements) can be used to protect, repair and reinforce not only reinforced concrete, prestressed concrete,
metal and timber structures but also masonry structural components. The technologies used are of three types (wet lay-ups, adhesive bonding of flat pultruded composites and bag moulding) and the main materials concerned are carbon, glass and aramid fibres combined with epoxy-type thermosetting Matrix.

The performance of the retrofitted system is essentially related to the load transfer between the reinforcement and its substrate, by means of adhesive bonding or confinement.

Research results have been used to draw up recommendations and design rules in the case of quasi-static loading, taking serviceability limit state and ultimate limit state conditions into consideration (ACI 440 [7], ISIS Canada [8], JCI Japan [9], AFGC [10], Fib TG9.3 [11], EC8–3).

The aim of this document is to provide in-depth information on the use of materials for the seismic retrofitting of existing structures. These guidelines are a complement to existing guidelines on earthquake engineering.

Figure 1 is a diagrammatic representation of how earthquake risk prevention regulations are organised (on the date on which the present recommendations were finalised).

The main regulations defining earthquake building regulations are:

- the environment code, particularly articles R.563-1 to R.563-8 recently updated by:
- decree n°2010-1254 of 22 October 2010 relating to earthquake risk prevention
- decree n°2010-1255 of 22 October 2010 delimiting earthquake zones on French territory
- the order of 22 October 2010 amended relating to classification and seismic construction regulations applicable to buildings in the "under no special risks" class,
- the order of 4 October 2010 concerning special risks
- the order of 24 January 2011 concerning installations requiring an environmental permit
- the order of 26 October 2011 applicable to bridges "under no special risks"

GUIDELINE DESCRIPTION

The document content 5 chapters with detailed design examples, case studies and FRP detailing.

Chapter 2
Retrofitting examples have been provided by the companies participating in the working group to qualitatively present the principles of retrofitting with adhesive-bonded composites, FRP localisation and application methods. Case studies are provided in Appendix 2. These documents, which mainly come from product suppliers and installers, do not explicitly address the dimensioning of the reinforcements applied but describe real-life examples of retrofitting which are considered to be representative. They include numerous cases relating to reinforced concrete and prestressed concrete buildings (shopping malls, production facilities, administrative buildings, skyscrapers, etc.), bridges (often old) as well as examples of application to masonry and civil engineering structures (industrial stacks). The retrofitting context is often that of seismic upgrading and/or repairs (even if the case studies proposed are more limited in the second case) that have to be carried out as a result of the repair or reinforcement of structural components to withstand static and/or service loading. In this context, in France, seismic upgrading is simply recommended for bridges while it is compulsory for buildings. In the examples proposed, structural reinforcements are aimed at offsetting inadequate detailing in terms of dynamic loading (overlap or length of rebar anchorage, the quantity of reinforcements required for shear or flexural strengthening, etc.), reinforcing the structure for a new purpose or configuration, or repairing a structure damaged by a previous earthquake. The examples provided show that the reinforcement materials currently applied are often carbon-fibre-based FRPs and that the most frequently reinforced structural component is the column. It is often wrapped with a fabric, generally applied continuously. However, confinement is sometimes completed with flexural strengthening or strengthening designed to offset inadequate detailing (overlap or anchorage lengths). This is achieved by placing FRP strips under the fabric wrapping. Industrial stacks are among the vertical elements that can be retrofitted to enhance flexural strength using FRP strips placed inside or outside the structure. The retrofitting of column/beam joints, as well as horizontal elements in relation to flexure, is also the subject of several case studies. It can be observed that these reinforcements can be anchored to the structure in certain cases. Finally, in several case studies, it appears that FRP retrofitting is not the only solution to be used to strengthen the structure with regards to seismic loading. To meet the requirements of this type of loading, a combination of several retrofitting techniques can be used, including FRP reinforcement. Thus certain structures are reinforced by combining sprayed concrete, additional prestressing, earthquake protection systems and FRPs.

**Chapter 3 : analyse the seismic risk of existing civil engineering works**

This chapter deals with the methods used to analyse the seismic risk of existing civil engineering works. It includes analysis methods and modelling methods using the different approaches defined in paragraph 3.2.3.

Table 1 gives a summary of the methods and approaches used:

To validate the retrofitting process, the reinforced structure must be analysed. Effective simulation of the reinforcement is essential. For example, if the strength of the structural member is increased, the composite strips are incorporated into the model as section reinforcements modelled with linear behaviour until failure. They are assigned a high strength and modulus of elasticity corresponding to their real characteristics. The increase in ductility can be induced by the confinement effect on the constitutive law of concrete in compression. The materials are taken into consideration in the models via their static constitutive laws.
Chapter 4: design of FRP

This chapter presents the different FRP reinforcement solutions with respect to the normal force, flexure, confinement and shear force. Since Eurocode 8-3 is entirely devoted to the retrofitting of existing buildings, it is not intended for civil engineering structures. However, in the absence of any other regulations and considering that the behaviour of a bridge pier is similar to that of a building column, the EC8-3 rules will be assumed to be applicable to civil engineering structures in this document.

The field of application of these recommendations covers the design of reinforced concrete components that need to be repaired or reinforced using composite materials (based on carbon, glass and aramid fibres). The design methods presented refer to the Eurocode 8 regulations and lie within their framework. The structural component on which the FRP is to be installed must be sound and free of any pathologies that could reduce the capacity of its surface to lastingly transfer forces to the composite. It is therefore essential to assess the state of repair of the concrete. Given the different reinforcement procedures and in order to ensure a reliable, lasting retrofitting result, it is recommended consulting chapters I, III and IV of the AGFC's guidelines [10] entitled respectively "Recommendations concerning the characterisation of composite materials used to repair concrete structures", "Recommendations concerning in situ implementation of composite materials for reinforcement" and "Recommendations concerning in situ inspection of composite materials for reinforcement", in addition to standards NF P 95101 and NF EN 1504. First, it is important to carry out a global analysis of the structure in accordance with the provisions of Eurocode 8 and the guidelines for assessing existing structures in relation to earthquakes. However, since seismic analysis is too complex a field to be addressed in detail in this document, this chapter will only provide elements relating to the detailing of composites for seismic retrofitting (accidental ULS load conditions). It must be ensured that the structure is verified not only for ULS but also for SLS load conditions and that the construction phasing is taken into account in relation to the SLS.

CONCLUSION

Fibre-reinforced polymers (FRPs) have been used to retrofit reinforced concrete structures since the 1990s in order to compensate for the flexure, shear and compression deficiencies of this type of construction. Now that the effectiveness of these materials has been largely demonstrated, they have become the subject of numerous international regulations and are now widely used in France. Due to the development of regulations aimed at achieving an acceptable seismic performance and ensuring that the designed structure can withstand minor earthquakes without damage, moderate earthquakes with minor non-structural damage and major earthquakes without collapsing, strategies to retrofit existing structures need to be developed. Among these, local retrofitting of the structure can be used to treat a type of component which would probably fail and lead to overall damage. It is also possible to treat the structure as a whole but this would require costly large-scale work that would need to be validated both technically and economically. FRPs not only offer the possibility of improving the overall strength of structural components but also of substantially improving their ductility. Eurocode 8 part 3 describes several design methods for this type of bonded composite reinforcement, mainly with respect to shear. The present document provides a summary of these methods while making suggestions (in blue) to improve and adapt several equations. The aim of this document is to provide in-depth information on the use of FRPs for the seismic retrofitting of existing structures. These guidelines are a complement to existing guidelines on earthquake engineering. In particular, a number of case studies are presented in which FRPs are used for the seismic retrofitting of columns and beams in buildings and civil engineering works.

The working group then describes the specific aspects of the work carried out and the lack of sufficient information on the behaviour of these materials when used for seismic retrofitting. The results are as follows:

- The case studies examined indicate that composite reinforcements are mainly used during seismic retrofitting to compensate for a lack of confinement or shear capacity.

- All retrofitting projects must take into account the state of repair of the structure and the initial construction period in order to define the most appropriate reinforcement method.

- A need for non-linear modelling of reinforced systems would seem necessary to gain a better understanding of the interaction between local and global reactions to seismic loading.
- Little research has been done on the mechanical behaviour of composites under load in the case of flexure with and without axial force in the case of extensive damage to concrete substrates which explains why design methods are only proposed in cases of limited ductility.

- Likewise, it seems essential to consolidate our knowledge of the mechanical behaviour of confined column/beam junctions not only with respect to design and dimensioning but also to modelling in order to incorporate approaches of the push-over type.

- With regard to anchorage, the validation and standardisation of characterisation procedures is also essential.

[8] ISIS Canada, Manual No. 4 Strengthening Reinforced Concrete Structures with Externally-Bonded Fibre Reinforced Polymers (FRPs), 2001

ABSTRACT

In many developing countries, existing reinforced concrete (RC) buildings, which were built several decades ago, were constructed with poor quality concrete and insufficient reinforcement details. Experiencing heavy damages after earthquakes, it is clear that seismic retrofit is required to minimize losses. In this paper, the results of an experimental study on seismic performance of pre-damaged and undamaged substandard RC columns retrofitted using aramid fiber reinforced polymer (AFRP) rods are presented. The columns were tested under constant axial and reversed cyclic lateral loads in the column weak-axis direction. Based on the outcomes of the experimental study, it is observed that significant enhancement is possible in flexural strength through the proposed retrofitting method up to 4% lateral drift ratio, which is generally sufficient against seismic actions.

KEYWORDS
Aramid, column, flexural performance, FRP, pre-damage, reinforced concrete, cyclic.

INTRODUCTION

Since most of the existing substandard RC structures, besides other deficiencies, suffer from lack of sufficient flexural strength, they need to be seismically retrofitted to reduce their vulnerabilities against seismic actions. Out of many obstacles for proper seismic retrofitting of these structures, three of them are remarkable: economic constraints, disturbance to the occupants, and disruption of functions of the structure. Traditional retrofitting methods such as concrete and steel jacketing, are not applicable in many cases due to high disturbance to occupants and long duration of retrofitting, which may be very critical for commercial, industrial and public buildings. Since FRPs offer feasible and innovative solutions for seismic retrofitting due to their lightweight, high tensile strength and noncorrosive character, in recent years, construction industry has shown significant interest in the use of FRPs (CEB-FIB, 2001; Lam and Teng 2003; ACI440-2R-08, 2008; Bank 2013). To the best knowledge of the authors’, reversed cyclic flexural behavior of RC members strengthened with longitudinal FRP reinforcement was studied for the first time by Ilki and Kumbasar (2002) and followed by Barros and Dias (2006), Bournas and Triantafillou (2009), Goksu et al. (2012) and Faustino and Chastre (2015) and Seyhan et al. (2015) also studied this type of behavior.

In this paper, the results of an experimental study, which was undertaken to investigate the effectiveness of longitudinal AFRP rods for seismic flexural retrofitting of pre-damaged RC columns, are presented. Aiming at this, two cantilever RC columns were constructed using low-strength concrete and plain reinforcing bars for representing structures, which were designed and constructed without considering seismic resistant design rules. Both specimens were retrofitted with embedded longitudinal AFRP rods to obtain enhancement in flexural strength. One of the retrofitted specimens was damaged before retrofitting. According to the best knowledge of the authors’, there are no comprehensive data which clearly showed the effectiveness of flexural seismic retrofitting of pre-damaged substandard columns using AFRP rods. The tests were executed under reversed cyclic lateral and constant axial loads in the weak-axis direction of the columns. A very limited amount of experimental data exists on seismic behavior of columns in case of FRP retrofitting in the weak-axis direction (Ghatte et al. 2015, Bousias 2004). The efficiency of the proposed retrofitting method is examined considering the indicators of seismic performance such as strength, drift and energy dissipation capacities.

DESCRIPTION OF THE EXPERIMENTAL CAMPAIGN

Specimens
Two symmetrically reinforced cantilever RC columns were constructed (Figure 1a). The specimens were designed to fail in flexure. The cross-section dimensions of the columns were 200 mm×300 mm while the concrete clear cover was 20 mm. The geometric ratio \( A_s/A_c \) of longitudinal reinforcing bars (14 mm) was 1\%, where \( A_s \) is the cross-sectional area of longitudinal steel reinforcing bars and \( A_c \) is the cross-sectional area of the column. The volumetric transverse steel reinforcing bar (10 mm) ratio \( A_{sv} \times D_c/A_c \times \sigma \) of the columns was 0.65\%, where \( A_{sv} \) is the cross-sectional area of transverse steel reinforcing bar, \( D_c \) is the overall periphery of transverse reinforcing bar at a section and \( \sigma \) is the spacing between the transverse reinforcing bars.

One of the specimens (specimen PD) was tested without any retrofit for representing the moderate damaged columns. The specimen PD was loaded to a drift ratio of 2\% and damaged through cyclic loading. It should be noted that at this drift, flexural cracks were occurred along the transverse reinforcing bars and the steel reinforcing bars yielded (Figure 2a). The maximum crack width and the residual lateral displacement were observed to be 1 mm at the column-footing interface and 6.9 mm at the loading height, respectively. This specimen then was retrofitted with embedded AFRP rods in longitudinal direction anchored to the footing. It is worth to note that during retrofitting, the lateral residual displacement was kept as is. Moreover, the specimen was confined with CFRP sheets in transverse direction and nominated as PD-2AR (Figure 2b). The remaining specimen (UD-2AR) was also retrofitted with embedded AFRP rods in longitudinal direction anchored to the footing and CFRP sheets in transverse direction without any pre-damage (Table 1).

Retrofit Application

The specimens UD-2AR and PD-2AR were retrofitted using AFRP rods for enhancing the flexural capacity. Since the damages on the specimen PD were limited, both specimens were retrofitted using the same procedures (without any special measure for the specimen PD-2AR). The retrofitting details and the application steps are presented in Figure 3.

As seen in these figures, firstly the weak concrete cover was removed (Figure 3a). Then, a thin layer of cement based structural repair mortar was applied to obtain a sound and flat surface over the internal steel reinforcing bars (Figures 2b and 3b). As seen from Figure 3b, diagonal scratches were formed on the surface of the cement based structural repair mortar to increase the adhesion to the next layer of mortar. Two AFRP bars of 10 mm diameter were placed symmetrically on each side using an epoxy paste (Figure 3c). Conical holes were opened in the footing for the connection of the AFRP rods to the footing (Figure 2). The 300 mm long part of the AFRP rods were then placed into these conical holes (Figure 2). Subsequently, the conical holes were filled using a high strength epoxy grout. After all, a layer of cement based structural repair mortar was applied over the column surface to bring the specimen cross-section to its original dimensions (200×300 mm) (Figure 3d). Prior to cement based structural repair mortar application, AFRP rods were covered using epoxy primer, which creates a structural bonding bridge between AFRP rods and cement based structural repair mortar. It should be noted that placing the AFRP bars inside the newly formed cement based structural repair mortar, as done in this study and in the studies by Goksu et al. (2012) and Seyhan et al. (2015), is very effective due to prevention of premature buckling of FRP reinforcement under compression. Like many existing substandard RC frame columns, the transverse reinforcement of the specimens was also insufficient causing deficiencies in terms of ductility and shear strength. Therefore, after installation of AFRP rod and formation of concrete cover with cement based structural repair
mortar, CFRP sheets were wrapped around the retrofitted specimens along their height, externally in transverse direction with 200 mm overlap (according to TSDC 2007) at the end of the wrap for enhancing the deformability through confinement and to avoid potential shear failure due to enhanced flexural strength (Figure 3e).

Material Characteristics

The average concrete compressive strength of the test columns was 15 MPa based on the compression tests of 150 mm×300 mm cylinder specimens at the time of testing (after 750 days of age). Concrete was intentionally designed to be of poor quality to represent relatively old existing buildings. All internal reinforcing bars were plain round bars, which have been used commonly until 1990s in Turkey. The average mechanical characteristics of 14 mm diameter longitudinal and 10 mm diameter transverse bars are given in Table 2. In this table, \( f_y, f_{\text{max}}, f_u \) are yield, maximum and ultimate tensile stresses, and \( \varepsilon_y, \varepsilon_{\text{max}} \) and \( \varepsilon_u \) are the tensile strains corresponding to \( f_y, f_{\text{max}} \) and \( f_u \), respectively.

Two different types of FRP reinforcement were used in retrofitting: AFRP rods in longitudinal and CFRP sheets in transverse direction (Figure 4). The geometrical and mechanical characteristics of the aramid and carbon reinforcements are presented in Table 3. In this table, \( t_f, w_f, d_b \) and \( E_f \) are the effective thickness, the effective width, the diameter and the tensile elastic modulus of FRP reinforcement. The compressive strengths of the cement based structural repair mortar used for forming the new concrete cover, the epoxy paste used for bonding the reinforcements to the member surface, the epoxy primer used as bonding bridge, the epoxy adhesive used for bonding CFRP sheets in transverse direction to the member surface, and the epoxy grout used for anchoring aramid reinforcements in the footing were 50, 75, 60, 75 and 80 MPa (TS-EN 196-1 2009). These values were given by the manufacturer and based on the test results of 40×40×160 mm prisms at 7 days of age.

Test Setup

The columns were tested in their weak-axis direction under combined action of reversed cyclic lateral and constant axial loads (Figure 1b). An axial load of 120 kN corresponding to approximately 20% of the axial load capacity of the columns (without considering the contribution of longitudinal steel reinforcing bars) was applied. Target lateral drift ratios were calculated as the ratio of the lateral displacement of the tip of the specimen (at the axis of actuator applying lateral loads) to the specimen height (from bottom of the column to the height of column at the axis of actuator) in pushing and pulling directions (drift ratios ±0.1%, ±0.25%, ±0.5%, ±1%, ±2%, ±3%, ±4%, ±6% and ±8%). It should be noted that generally drifts larger than 3-4% are expected only under severe or very severe earthquakes.

RESULTS AND DISCUSSIONS

The test results are summarized through theoretical and experimental lateral load-displacement curves and their envelopes (Figures 5-6a). The theoretical lateral load-displacement curves were obtained through moment-curvature analysis. In the moment-curvature analysis, steel reinforcing bars were assumed to behave in an elasto–plastic manner with strain hardening. Longitudinal AFRP reinforcement was taken into account as linear elastic
material in tension while the contribution in compression was neglected. The cross-section analysis was performed to be terminated when the AFRP reinforcement reached the rupture strain observed during the tests, which was around 45% of its rupture strain given by the manufacturer. The contributions of cement based structural repair mortar and confinement effect of CFRP transverse reinforcement were also considered during the analysis. After obtaining the moment-curvature relationships, the total top displacements of the columns were determined considering the elastic and inelastic deformations. The details of the theoretical analysis can be found elsewhere (Seyhan 2015). As shown in Figures 5 and 6a, the specimen PD performed in a ductile manner since it was under-reinforced and designed to fail in flexure. The retrofitted specimens (UD-2AR, PD-2AR) exhibited better performance compared to the specimen PD up to the drift ratio of 3%. At this drift, the enhancement in lateral capacities of the specimens UD-2AR and PD-2AR were around 94% and 123%, respectively, with respect to the specimen REF. The sudden remarkable loss of strength of the retrofitted specimens at around drift ratios of 3% was due to the fracture of AFRP rods at the interface of the column and the footing (Figure 7). This clearly showed that the full capacity of the linear elastic AFRP rod was utilized perfectly. The retrofitted specimens behaved similar in terms of strength after the rupture of the AFRP rod.

Energy dissipation capacities of the specimens are presented in Figure 6b. The energy dissipation capacities of the tested specimens are calculated as the areas enclosed by the load-displacement hysteresis loops. As seen from Figure 6b, it is clear that the energy dissipated by the retrofitted specimens is higher than the specimen PD specimens as expected. It can be concluded from Figures 5 and 6 that pre-damaging did not seem to have a negative effect on the seismic behavior of subsequently retrofitted specimen (PD-2AR). This observation is very valuable, which proves the effectiveness of the proposed retrofitting method for the columns with pre-damage. Since the specimens were wrapped with CFRP sheets in transverse direction along their height, the damage was accumulated at the interface of the column and the footing, where the maximum crack width reached approximately 4 millimeters.

CONCLUSIONS

In this experimental study, it is intended to develop a method for flexural strengthening of substandard pre-damaged RC columns in their weak-axis direction. For this purpose, two specimens were produced and then tested under constant axial and reversed cyclic lateral loadings. The retrofitted specimens achieved a significant enhancement in flexural strength up to 3-4% drift ratios. A dramatic loss in strength after this drift ratio was observed due to the rupture of AFRP rods at the interface of the column and the footing. Nevertheless, the ultimate drift ratios reached by the retrofitted columns may be deemed as satisfactory considering the potential drift demands that could occur during seismic actions. The outcomes of the experimental study showed that the proposed retrofitting method may provide an attractive solution for enhancing the seismic performance of substandard columns in terms of flexural strength.

ABSTRACT

Beam-column joint behaviour plays a crucial role in the seismic performance of framed Reinforced Concrete (RC) structures. Whereas several studies are available in literature about the behaviour of RC joints, a wide consensus design approach is not yet available. Hence further studies on joint behaviour represent an interesting topic through the seismic and structural engineering. Main aim of this paper is to improve the knowledge on the behaviour of RC beam-column joints and rationale Fibre-Reinforced Polymer (FRP) retrofit design according to capacity design. To this purpose, experimental cyclic tests have been carried out on full-scale beam-column joints designed according to different earthquake levels. Numerical simulations, based on an accurate finite element modelling, were performed by means of the TNO DIANA code. The analyses allowed to evaluate the stress distribution in the joint panels as well as to quantify the strains in the reinforcement bars in the beam. The main results of the experimental tests have been discussed through a comparison between experimental and numerical outcomes. Moreover, a simple analytical model is applied to simulate theoretically the seismic performance and the failure modes of beam-column joints in RC structures. The rationale of the simplified model is to identify the strength hierarchy, evaluating the available capacity for any different potential failure mode (namely failure of the cracked joint, bond failure of the bars passing through it, flexural/shear failures of beams or columns). Based on the validated simplified model, retrofit design possibilities with FRP have been discussed according to modern capacity seismic design principles.

Beam-column joints, Structural behaviour, Analysis and Design, Experimental tests, Finite elements, Seismic retrofit.

INTRODUCTION

Valuable procedures for the assessment of existing Reinforced Concrete (RC) structures are at present available, since they have been proposed in the Italian and International Building Codes with innovative rules for seismic analysis. Nonetheless, such procedures are not equally focusing on the behaviour of beam-column joints, whose role has been demonstrated to be crucial in the global seismic behaviour of RC framed structures (Masi and Santarsiero 2013).

Beam-column joints should be designed and detailed accurately. Bond and shear mechanisms are common failure modes of beam-column joints during earthquakes and they are brittle in nature. Even under moderate seismic actions the beam-column joints with deficient reinforcement details have shown poor performances. In an RC moment resisting frame beam-column joints are limited regions where large stresses transfer between the framing elements (i.e. columns and beams). Especially in seismic resistant frames the high demand activates the inelastic capacity of members to dissipate seismic energy, but their exploitation could be unfavourably prevented by poorly designed joints, thus exposing an entire structure, even if correctly designed in its other structural components (Manfredi et al. 2008).
In some cases the beams linking into a joint panel are loaded by moments in the same direction, either clockwise or counter clockwise and the bars at the same level are pulled or pushed in equal direction at both sides of the joint panel. If the column is not wide enough or if the strength of concrete in the joint is low, steel bars bond capacity to concrete is inadequate to balance the stress demand (Lignola et al. 2010).

All these concepts have been evaluated experimentally, found theoretically by means of refined FEM numerical analyses and they represent the conceptual basis of the simplified model adopted to identify the strength hierarchy and the capacity related to any potential failure mode. Hence this represents not only an assessment tool, but also a retrofit design tool to change the failure mode and tune the optimum retrofit intervention to expose the structure at hand to the most favourable failure mode preventing those undesirable.

EXPERIMENTAL PROGRAM

A wide experimental program has been performed within the framework of DPC-Reluis research project (Masi et al. 2008) at the Laboratory of Structures of the University of Basilicata (Masi et al. 2012, 2013). The whole experimental program deals with joints equipped with stiff or wide (flat) beams. The present paper is focused on joints with rigid beams, while some results on joints with wide beams can be found in Masi and Santarsiero (2013). The specimens are representative of one-way external joints belonging to the first storey of a four storey RC building with 3.0 m interstorey height. The characteristics of the two specimens discussed herein are as follows:

1. Earthquake Design level: (i) Specimen T1 - Gravity loads only (i.e. no seismic provisions, Figure 1) matching the building codes in the 70’s in Italy (D.M. 30/05/1972), and (ii) Specimen T5 - Seismic loads (i.e. with up-to-date seismic provisions, Figure 2) assuming a medium seismicity zone with a Peak Ground Acceleration (PGA) at the ultimate limit state, $a_g = 0.25g$, according to OPCM 3274 (2003) that is substantially consistent with the current Italian building code (2008) as well as with the Eurocode 8 (2004).

![Figure 1 Specimen T1, without any seismic provision, and its (B) failure mode](image1)

![Figure 2 Specimen T5, with seismic provision, and its (B+J) failure mode](image2)
2. Deformed steel bars (type B450C) with nominal yield strength $f_Y = 450$ MPa and concrete with mean cylindrical strength equal to $f_c = 21.5$ MPa.

3. Same beam cross section, which is 500 mm high, $h$, and 300 mm wide, $b$, and the same column square section with side dimensions, $s$, of 300 mm as it can be seen from Figures 1 and 2.

4. Axial load on the column equal to $N = 0.15 (s^2 f_c)$. 

The full experimental program is reported in Masi et al. (2012). The rationale to analyse, among many others, these two specimens is the opportunity to compare the behaviour of identical joints moving from a gravity load designed joint to a seismically designed joint for medium seismicity zone. This allows also the predictability of the refined numerical and simplified analytical models to be validated.

Three cycles for each drift amplitude were repeated (Figure 3a) and two different failure modes were observed. Specimen T1 showed a maximum strength $F_{max}$ equal to 18.9 kN at a drift $d(F_{max})=0.45\%$. No cracks in the joint panel were detected and starting from a drift equal to 2.5% buckling was observed in the bottom bars of the beam. A purely flexural mechanism involved essentially the beam with wide sub vertical cracks at the beam-column interface and bar rupture due to low-cycles fatigue (B mechanism, Figure 1).

Specimen T5 showed a maximum strength $F_{max}$ equal to 39.8 kN at a drift equal to $d(F_{max})=1.16\%$. In this case a mixed mechanism was observed, in which the flexural damage to the beam was accompanied by diagonal cracking in the joint panel (B+J mechanism, test T5, Figure 2). Starting from a drift equal to 0.75% a sub vertical crack in the beam at the beam-column interface was detected.

This crack grew with drift, while the first diagonal crack appeared in the joint panel at a 2.5% drift and almost the entire joint panel concrete cover spalled exposing reinforcing bars at 5.5% drift.

The shear demand $V_{jhd}$ in the joint panel can be calculated (IBC 2008) through:

$$V_{jhd} = \gamma_{Rd} \cdot A_{s1} \cdot f_{yd} - V_c$$

and $A_{s1}$ is the top reinforcement area of the beam, $V_c$ is the shear force in column, $\gamma_{Rd}$ accounts for over-strength due to steel strain-hardening (not less than 1.2). $A_{s1}$ is smaller in T1 compared to T5 (i.e. 2.26 cm$^2$ vs 6.03 cm$^2$), hence the higher shear demand explains the cracking in the T5 joint panel in spite of the higher transverse reinforcement, causing high values of the tensile principal stress. However, due to its higher strength, the behaviour of seismically designed T5 joint is globally more favourable (Figure 3).

**NUMERICAL SIMULATIONS**

Numerical simulations have been conducted at the University of Naples adopting the Finite Element code TNO DIANA 9.1. Each specimen was modelled implementing a bi-dimensional mesh with more than 1,500 plane stress nine-node elements. Bar reinforcement elements were modelled by means of uniaxial truss elements with axial stiffness only. The mechanical behaviour of the constituent materials is non-linear. Concrete was modelled by means of a smeared approach both for cracking and plasticity aspects. Post elastic behaviour in tension is governed by exponential softening. The Drucker-Prager plasticity criterion is adopted in compression. The horizontal displacement was increased monotonically and the whole time the vertical load was kept constant. The full numerical activity is described in Masi et al. (2013)

Experimental and numerical force-displacement envelope curves are depicted in Figure 3a showing good agreement. The numerical strain values (Figure 3b) of longitudinal steel reinforcement was always lower than 3% in the case of T1 joint, while it was lower than 5% in the case of T5. This finding corroborates that failure of the steel bars in T5 can be attributed to low-cycles fatigue in tension coupled to buckling in load reversals, being strain values too low for a pure tensile failure.

The principal compression stress field shows (Figure 4a) the formation of a concrete strut and T1 presents a wider strut, while in T5 the average stress is almost doubled mainly due to the higher stress transfer in the joint panel due to the larger amount of longitudinal reinforcement anchoring in the joint.

The crack pattern (Figure 4b) occurred regularly in the beams (in a smeared cracking approach), while the joint panel is mainly uncracked at peak load in T1 specimen: additionally, due to the bottom bars anchoring, cracking slightly penetrates inside the joint panel of the seismically designed joint T5. This, coupled to the principal compressive stress field explains the higher damage found in T5.
It is worth noting that the crack pattern is limited to the lower portion of the beam and of the joint panel because the joint was monotonically loaded in numerical simulations.

ANALYTICAL MODELLING

To improve knowledge on the joint behaviour in terms of capacity design and the subsequent strength hierarchy principles, the so called “quadruple flexural resistances model” (Shiohara 2001) was improved and the main unknowns, assumptions and solutions were deeply updated. The novel model (Bossio et al. 2015) considers three bodies divided by diagonal cracks in the joint panel and interacting by means of bending moment and shear (Figure 5).

The equilibrium of internal forces is taken into account, whereas the compatibility not necessarily is. Concrete and steel compression resultants are merged into a single compression resultant force at beam and column ends. In Figure 5 tension/compression forces in reinforcement layers and concrete are $F_i$, while $C$ are contact forces; $\alpha$ is the column over beam length ratio, and altogether they merge into a nonlinear system in 9 unknowns. The column shear is the main parameter to evaluate all other internal force unknowns, hence column shear capacities are provided for each considered failure mode (Bossio et al. 2015), namely: crushing of concrete strut, conventional joint failure due to longitudinal bars yielding/rupture, bond failure of longitudinal bars due to joint panel limited dimensions coupled to high anchoring demand from bars. These failure modes are coupled to beam and column common modes (i.e. flexural and shear capacity, according to classical structural analysis).

Test T1 is analysed showing the entire table of failure modes (see table in Figure 5) and the failure load is the smallest one among the possible failure loads. This test showed the rupture of longitudinal bars in the beam and for this reason the model predictions are not limited to the yielding of longitudinal reinforcement, but are extended to include also the failure of beam bars occurring at an ultimate stress approximately 23% higher than yielding.

Hence the first triggered failure mode is longitudinal bars rupture at $V_c=15.9$ kN, while joint failure due to bar yielding occurs at $V_c=13.59$ kN. Experimental failure load is 18.9 kN, with an underestimation of about 15%. The
joint shear failure with beam longitudinal bars yielding \( V_c=13.59 \text{kN} \) is almost close to the flexural failure of the beam, hence a minor strengthening of this joint panel allows to move from undesired brittle joint shear failure to the desired ductile flexural failure of beams. Analysing the table of failure modes and related loads a remarkable influence of bond capacity on the performance of such systems is observed; worsening of bar bond could impact on the first triggered failure mode up to smooth bars condition. For instance considering lower bond performance (neglecting specific anchoring solutions), reduces the ultimate capacity in terms of column shear, \( V_c \), to about 3 kN. In the same way the test T5 was modelled and a joint failure due to beam tensile reinforcement yielding at \( V_c=43.6 \text{kN} \) instead of 39.8 kN (the experimental outcome) was found, with satisfactorily agreement.

**Figure 5** Novel simplified model scheme and detailed predictions for experimental test, T1

**DESIGN OF FRP RETROFIT**

Based on the validated simplified model, retrofit design possibilities with FRP are discussed according to modern capacity seismic design principles. Force vectors \( F_9 \) and \( F_{10} \) (Figure 5) allow to include the effects of external retrofit in the model.

In the case of test T5, \( F_9 \) allows to include the effect of the six two legs stirrups (at yielding), hence assuming \( F_9=288.3 \text{kN} \), (however in this case longitudinal reinforcement in beam increases too). In existing structures \( F_9 \) and \( F_{10} \) represent, respectively, external strengthening of existing joints along the horizontal and vertical directions. A uni-axial FRP fabric provides a contribution in horizontal or vertical direction, according to fibres direction, conversely a quadri-axial, for instance, FRP fabric provides contributions in both directions (e.g. if each layer of quadri-axial has a thickness of 0.053 mm, combining the overlapping of inclined layers it is equivalent to 0.1279 mm in both horizontal and vertical directions). The total thickness, \( t_f \), multiplied by the FRP stress provides the force contribution by FRP retrofit. FRP (elastic) stress can be obtained, assuming on safe side a maximum FRP contribution, by Young modulus, \( E_f \), multiplied by the maximum strain assumed equal to debonding value (e.g. 0.4% according to Italian guidelines CNR DT200 R1 2013).

In particular, variations about the number and type of FRP layers have been considered. A Carbon CFRP horizontal uni-axial layer (\( E_f=230 \text{ GPa}, t_f=0.167 \text{ mm} \)) in one or three plies configurations (hence \( F_9=76.6 \text{kN} \) or 230.0 kN) or Basalt BFRP horizontal uni-axial layer (\( E_f=89 \text{ GPa}, t_f=0.210 \text{ mm} \)) in one or three plies configurations (hence \( F_9=37.3 \text{kN} \) or 111.8 kN) have been considered.

Obviously first four failure modes (see Figure 5) are independent on FRP retrofit of joint (to improve them it is required to retrofit beam or columns), while joint failure due to bar yielding or due to bar debond could impact on the first triggered failure. In order to understand which failure mode is independent from the retrofit and which is improvable by using it, results are plotted and compared to the reference case, to represent values of column shear (for each failure mode) related to the amount of retrofit (in terms of force \( F_9 \)) in Figure 6.
It is clearly seen that beam flexural failure is not influenced by FRP retrofit (in fact the relevant curve is perfectly flat and horizontal), conversely other joint failures are improved by FRP (in fact the relevant curves increase as FRP retrofit, i.e. $F_9$, increases). One ply of BFRP is barely sufficient to guarantee a desired ductile flexural beam failure, while even one ply of CFRP prevents the yielding of beam bars in the joint. Bond capacity is improved by FRP (reducing the bond demand) and in the case of good bond, flexural beam failure prevents joint bond failure. It is clearly noted that if smooth bars are adopted, hence in lower bond condition, joint failure can be prevented and the failure mode can be pushed to a more desired one only by applying at least a large amount of FRP, e.g. three plies of CFRP allow $V_c$ triggering flexural beam failure to exceed the $V_c$ triggering bond failure mode into joint. As previously stated, four stirrups in the joint (as in the case of the test T5) correspond to an $F_9$ close to 300 kN, however according to Figure 6 specimen failure should be due to ductile beam flexural triggered failure mode (hence $V_c$ close to 18 kN).

CONCLUSIONS

The behaviour of beam-column joints can strongly influence the seismic performance of RC structures. Experimental results showed different performances, in terms of both failure mechanism and shear-drift behaviour. Numerical simulations by means of accurate F.E.M. models have been performed to better understand the experimental results. Failure modes provided by tests have been essentially confirmed by numerical analyses, as the global shear force vs displacement curve and the local cracking pattern were adequately simulated. F.E.M. results provided the theoretical basis of the simplified model allowing not only to better understand the strength hierarchy, but also to calibrate strengthening design. The basic idea is to prevent the undesired failure modes (e.g. brittle shear failure of joint, but also of beams and columns). Once the desired failure mode is selected, then all failure mode mechanisms presenting lower column shear values should be improved. Hence the proposed simplified model represents not only an assessment tool, but also a straightforward criterion to change the failure mode and tune the optimum retrofit intervention for RC structures, e.g. by means of externally bonded FRP, thus leading the structure to the most favourable failure mode while preventing those undesirable.

ABSTRACT

The paper presents a hybrid technology tailored for the seismic upgrade of reinforced concrete (r.c.) columns. The proposed system combines steel angles with CFRP wrapping, both conceived to increase column ductility as well as axial, shear and flexural capacities. The system will be described as well as the experimental tests that have been carried out for its validation. In order to better understand the contribution of the steel angles, a robust numerical microplane based approach has been adopted for the interpretation of the test results.

KEYWORDS

FRP, RC beams, steel angle, strengthening, shear, compression, flexural.

INTRODUCTION

FRP-based technologies are worldwide applied, having 1) high stiffness and strength to weight ratios 2) corrosion resistance. Their use is moreover encouraged due to the easy handling and installation. Their pioneering application data back to mid 1980’s and thanks to the effort of many researchers are regulated by consolidated recommendation such as the American (USA) ACI 440.2R-08 (2013), the Italian CNR-DT 200 R1 (2013) and the European FIB (2006). Experimental studies have clearly been the base of the FRP development and the present effort is the implementation of database such as those recently implemented for confinement (Nisticò et al, 2014) and shear application (Rousakis \textit{et al}, 2016). In Italy, despite the existing applications, only recently the use of the FRP has been officially accepted as material for upgrading of existing structures, being required a mandatory step for the material qualification. Among the Italian companies that contributed to the technological development of the FRP system, the INTERBAU has been one of the most active, cooperating with many Italian Universities: the result of the many year research was the development of an hybrid system that, combining steel angle with FRP materials, is particularly tailored for the increase of ductility as well as strength of existing reinforced concrete columns. Preliminary experimental tests data back to 2001: the tests regard axial loaded r.c. columns wrapped with CFRP strips arranged either discontinuously or continuously. Further on different arrangements have been tested (Monti and Liotta, 2007) to validate the shear capacity of CFRP reinforced r.c. beams. The successfully validation of the adopted FRP material encouraged other studies concerning different load conditions, such as: 1) pure axial load (Monti and Nisticò, 2008) 2) axial and horizontal loads (Realfonzo and Napoli, 2009; Realfonzo and Napoli, 2012) 3) flexural (Bocciarelli \textit{et al}, 2013) and shear (Bocciarelli \textit{et al}, 2014) reinforced beams. The experimental tests stimulated the need to predict the structural behavior of this technology by means of robust structural models based on an accurate modeling of both concrete and FRP material. Among the possible models, those based on microplane theory (Bazant and Prat, 1988) have been successfully investigated, simulating at first (Gambarelli \textit{et al}, 2014) the behavior of CFRP confined concrete specimens and then (Nisticò \textit{et al}, 2016) the behavior of r.c. columns shear reinforced by means of CFRP strips. The validation of the models further stimulated the use of microplane models for the simulation of the tests (Bocciarelli \textit{et al}, 2014) concerning the INTERBAU hybrid system. In this framework the paper presents the proposed hybrid system, the carried out experimental tests as well as the numerical simulations.

HYBRID SYSTEM DESCRIPTION

The proposed system (Cersosimo and Nisticò, 2006; Monti and Nisticò, 2008) consists of (Fig. 1) 1) four steel angles adhesively applied to the four column corners 2) a CFRP wrapped system that can be either continuous or discontinuous 3) the gap between the CFRP strips and the concrete surface can be filled (Fig. 1d), or not (Fig. 1c) with thixotropic mortar. The steel angles are preformed in order to have a corner radius equal to the column
corner radius that is usually imposed to be equal to 20/30 mm in order to avoid premature FRP collapse. It is well known that 1) the concrete crack evolution strongly influences the FRP stress and strain state and 2) the presence of stress along directions different than the fiber one reduces the FRP capacity, so that 3) the interaction between FRP and concrete surface can be avoided, leaving a gap between the FRP and the concrete surface (Cersosimo and Nisticò, 2012). The CFRP wrapping clearly serves to confine the columns and to provide an additional shear resisting system. The steel angles increase the axial load capacity as well as flexural moment capacity when are properly connected in foundation or on the beam-column joints in case of frame-structure. Regarding the connection two different solutions can be adopted consisting in a) steel plates welded to the angle, conceived to transmit only tensile force avoiding bar buckling (Fig. 1g) b) a L-shape profile welded to the longitudinal angles and placed in contact with the concrete surface in order to transfer both compression and tension actions.

![Figure 1 Conventional and hybrid FRP wrapping without and with mortar (gray)](image)

The adopted steel angles have a characteristic yield stress of 260 MPa, corresponding to a yield strain of 0.13%: 1) the steel angles side length ranges between 40 and 80 mm and the thickness ranges between 4 and 8 mm. The adopted wrapping system is the CARBOSTRU® C-SYSTEM that consists of a unidirectional High Modulus (390 GPa) CFRP (400 g/m²) combined with an epoxy resin: the equivalent thickness, for each layer, is 0.225 mm. The mechanical macroscopic properties (tensile strength and Young modulus), are usually evaluated testing a 3 layer specimens with fibres oriented in the loading direction: typical obtained values together with the geometrical properties of each specimens, are reported in Table 1 where: t_i and b_i are the average thickness and width, respectively, F_u is the attained ultimate load, E_u and f_u are the Young modulus and the ultimate strength referred to the fibre area. It is well known that the FRP mechanical properties depend on the angle (θ) between the fibre orientations and the applied load, so that they have been evaluated (Nisticò et al, 2016) and reported in Table 2 that includes: 1) specimen dimensions (t_i,b_i in average), 2) average values of the ultimate load (F_u) 3) average values of mechanical properties (f_u,E_u), together with (in parenthesis) their values normalized with respect of the 0° case values. The adhesive properties (shear strength) of CFRP are measured by means of displacement control tests carried out on single-lap shear specimens that consist of two aluminium sheets, overlapped of 60 mm and glued together using the adhesive to be tested which generally has a Young modulus of 12800 MPa: typical shear strength values are close to 6 MPa.

**EXPERIMENTAL TESTS**

The carried out tests regard 1) concrete columns subjected to axial load (Monti and Nisticò, 2008) 2) r.c. columns designed and tested to emphasize either a) their shear capacity (Bocciarelli et al, 20014) or b) their flexural capacity (Realfonzo and Napoli, 2009/2012).
Confined concrete columns

Compression tests were performed on nine specimens of square (200×200 mm) and rectangular (200×300 mm; 200×400 mm) concrete columns (1400 mm long). All the specimens had rounded corners with a radius of 20 mm. For each typical section, three different configurations were considered: unwrapped (UW), fully wrapped (W) and fully wrapped, with L-shaped steel angles (4×40 mm) placed at the corners (WL). Some results, in terms of Force-Displacement curves are reported in the following Fig. 2, from which can be noticed that the ultimate load increases 1) passing from the un-wrapped (UW) to the wrapped (W) columns and 2) passing from the wrapped (W) to the wrapped column with steel angles (WL), corresponding to which the load increment (~380 kN in average) is almost equal to the yielding force (400 kN) of the four steel angles, meaning that their contribution is fully exploited.

Shear reinforced concrete columns

In the framework of the experimental investigations 10 specimens were tested under three-point bending load. Most of them were 3.45 m in length with their rectangular cross-section reinforced with 6 CFRP intermediate single layer strips and 2 double layers reinforcement at the supports and at the mid-span, were the load is applied. The Hybrid System (denoted as CWL) includes two possibilities having or not the mortar in between the steel angles (40×6 mm); the latter case is denoted with the symbol "*". Concerning the maximum achieved load it has to be observed (Table 3) that 1) the WL configuration has a load increases corresponding to the 17% of the CW configuration without steel angles 2) the CWL* configuration (without mortar) has a load increases corresponding to the 12% of the CWL configuration (with mortar).

| CWL | | | |

| 3\textsuperscript{rd} crack | 2\textsuperscript{nd} crack | 1\textsuperscript{st} crack |

Flexural reinforced concrete columns

In (Realfonzo and Napoli, 2009) the results of cyclic and monotonic flexural experimental tests have been presented (see Figure 3 and Table 4): among the others, the tests concern r.c. square (300×300 mm) concrete columns (2200 mm long) reinforced either with smooth or deformed steel bars and CFRP wrapped including or not steel angles (80×6 mm) that can be connected in foundation by means of the devises reported in Fig. 1 (f,g,h). Two values of the normalized axial load (ν) have been considered which correspond to the 14% and 40% of the ultimate load. The test highlighted that 1) the placement of longitudinal steel angles not connected to the foundation give higher ductility 2) the placement of longitudinal steel angles connected to the foundation considerably increases the flexural strength being however characterized by a reduction of the available ductility. The experimental campaign has been extended (Realfonzo and Napoli, 2012) including rectangular sections: results from cyclic tests performed on full scale RC columns (300×700 mm) allowed to conclude that despite the high side ratio, considerable ductility increases is achieved and that the proposed hybrid system works well in terms of flexural strength even if loss of ductility are consequent to the brittle failure of the connections. General remarks are that 1) the hybrid system improves the column performance in terms of ductility 2) improvements (under development) in the design of the connection are needed if strength increase has to be combined with ductility increase.

MICROPLANE BASED NUMERICAL SIMULATIONS

The previous described system represents a reliable system for RC column upgrade: the experimental tests confirmed its validity for some load conditions and further investigations are needed to evaluate the system capacity for others, such as the biaxial flexural condition, interacting with shear and axial load, that represents “the condition” for seismic action. In this direction the support of numerical models are for sure to be considerate before going forward with further experimental investigations: the selected model is based on microplane theory (Bazant and Pratt, 1988) that has been successfully validated for FRP confined specimens (Gambarelli et al, 2014) and for FRP shear reinforcement (Nisticò et al, 2016) having reproduced the experimental results of the shear reinforced column (CW) presented in the previous section: the analyses have been carried out with the program MASA (Ozbolt, 1988). Regarding shear reinforcement, the reproduced crack pattern (Figure 4) is in agreement with the experimental one (see figure in Table 3): 1) microplane models, have been adopted for both concrete and FRP, considering material non linearity 2) steel bars have been modelled by means of non linear frame elements 3) the contact between FRP and concrete has been modelled with contact elements which include shear as well as axial non linearity. It is worth noticing that the feature of the adopted model (Ozbolt et al, 2001) for FRP material was fundamental for the success of the carried out analyses, and to correlate the CFRP stress evolution (Figure 4) with the crack opening: 1) the strips are not uniformly loaded 2) the maximum stress reached in the FRP is approximately equal to 2000 MPa, which corresponds to approximately 70% (see Table 2) of the average experimental strength value when the fibre orientation is parallel to that applied load. 3) the reduction of 30% in strength can be attributed to the direction of maximum principal strains which form, with the fibre direction, an angle of approximately 8°.

Figure 4 CW column: 1) crack pattern and Force (kN) – Displacement (mm) curves (left) 2) FRP stress (MPa) distribution (centre and right)
The microplane based approach has been also applied (Polimanti, 2013) to simulate one column reinforced with the hybrid system when the mortar between the steel angle is not considered (CWL* case). The model are the same of the previous cases, specifying that: 1) the steel angle have been modelled with solid elastic elements having the steel material properties 2) the contact between steel angle and concrete as well as FRP, has been modelled through the non linear contact element previously introduced.

In the following Figure 5, the reproduced crack pattern, at the first diagonal crack propagation, is reported together with the stress evolution in the FRP sheets along the beam height (H*): it can be observed, comparing it with the one obtained without steel angle, that: 1) the FRP stress is more distributed among the strips 2) the maximum reached stress (≈ 1800) corresponds to approximately 65% of the average experimental strength value when the fibre orientation is parallel to that applied load 3) even if a gap exists, in between the concrete and FRP, there is an increases, with respect to the WL case, of the angle between the maximum principal strains and the fibre direction.

The crack pattern reported in Figure 6, outlines 1) the activation of two diagonal cracks (6a,d) which are present in the experimental test (see Figure in Table 4) and 2) the evolution of the strips activation that starts from the closest to the load (#1) and then involve in sequence the strips #2,3 2) the role of the localization which consequence is the not symmetric structural behavior characterized by a suddenly collapse of the left side strips after the propagation of the second crack. The proposed model can be considered satisfactory in reproducing the experimental test of CW columns, however more studies, currently in progress, have to be done in order to justify the experimental evidences of the proposed hybrid system.

CONCLUSIONS

The paper presented an hybrid system conceived to increase the seismic capacity of r.c. existing columns. The system, consisting in a combination of steel angle and FRP strips, have been validated through experimental tests performed to evaluate the axial as well as the shear and flexural capacities. The carried out tests were the base for microplane based models that should be more investigated to capture the complex phenomena that characterize the strong interaction between 1) concrete 2) steel angle and 3) FRP strips of the proposed hybrid system. At the present can be deduced that the use of steel angle, in the hybrid system, has a double effect that combines the shear strength increase due to the steel angles and the CFRPs characterized by better distributed stress among the strips.

ABSTRACT

The Japanese construction community started to use fiber reinforced polymers in mid-1980’s. Initially the FRP rod or strand was used as a substitute of steel reinforcing bars to avoid corrosion of reinforcement or invasion of electric stray current. An application of FRP sheet started for seismic retrofit of buildings in late 1980’s. The 1995 Kobe Earthquake and the 1999 Design Guidelines of FRP on Seismic Retrofit of RC Buildings accelerated the use of FRP sheet for seismic retrofit of buildings in damaged area since light-weight of FRP sheet makes it easy to ship and construct. Target members for FRP sheet retrofit are normally line elements such as beams and columns. Although RC walls may not be the best target to strengthen with FRP sheet, it increases the shear capacity with relatively easy construction. FRP sheet is not only used for increasing shear capacity of RC walls, but it can be also used to increase impact resistance of tsunami debris. This paper introduces two cases of FRP sheet application to RC walls. The first application is the use of soft fiber reinforced polymers to increase the shear resistance of RC walls. The second application is the use of CFRP to increase the impact resistance of RC walls against tsunami debris. Experimental programs on two cases show the effectiveness of FRP sheet to resist against in-plane shear force and out-of-plane impact force.

INTRODUCTION

Table 1 shows a history of major seismic codes and standards with related events. The civil engineering society started to study the application of fiber reinforced polymers (FRP) to reinforced concrete structures in 1980’s in Japan. Shinmiya Bridge in Hakui city is the first concrete bridge prestressed with carbon fibre reinforced polymer strands to avoid salt damage. An application of FRP sheet started for seismic retrofit of buildings in late 1980’s. Carbon FRP sheet was used for the first time to retrofit a reinforced concrete chimney in 1994. FRP was considered a good construction material due to its light-weight, good durability, and proper stiffness and strength but it was not widely used due to its high cost. The 1995 Kobe Earthquake and the Design Guidelines of FRP on Seismic Retrofit of RC Buildings published by the Japan Building Disaster Prevention Association (JBDPA 1999) accelerated the use of FRP sheet for seismic retrofit of buildings in damaged area since light-weight of FRP sheet makes it easy to ship and construct. Qualification programs by the Fibre Repair and Strengthening (FiRSt 2016) established in 1999 also enhanced the usage of FRP sheet since seismic retrofit of reinforced concrete with FRP sheet necessitates meticulous attention to details for better seismic behaviours. This paper introduces two unique cases of FRP sheet application to RC walls.

CASE 1: INPLANE STATIC EXPERIMENT ON WALLS WITH SRF

FRP with low Young’s modulus (SoftFRP) was developed in late 1990’s and early 2000’s. They were manufactured from relatively economical materials like polyacetar (Iihoshi 2005) or polyester (Igarashi 2000) to substitute expensive carbon fiber reinforced polymers (CFRP) in the beginning. FRP with high Young’s modulus like CFRP may fracture when it experiences large tensile strain at cracks. However, it was found that a large deformation capability of SoftFRP was effective to strengthen concrete structures since it is highly resistant to the local concentration of tensile strain at cracks.
Super Reinforcement with Flexibility (SRF) was developed as a construction material in 1999 and considered as one of SoftFRP’s. Its Young’s modulus is 1/40 of that of CFRP or ordinary mild steel. The tensile strength is 1/35 of CFRP and similar to that of ordinary mild steel. SRF costs 2/3 of CFRP and is easier to purchase locally. The research on SRF retrofit of RC columns was originally published in 2000 (Igarashi 2000). Since then, retrofit schemes on RC columns have been studied (Kabeyasawa et al. 2010). SRF obtained good reputation for retrofitting columns and beams of buildings and bridges. Studies on SRF retrofit of RC walls began in mid-2000’s (Sanada et al. 2005, Kabeyasawa et al. 2007, Warashina et al. 2008). This paper shows performance of RC walls strengthened with SRF by introducing an experimental work (Kono et al. 2008).

Experimental setup

Two identical structural wall specimens were constructed with eccentric openings as shown in Figure 1(a). L1 is a prototype without any strengthening and abide by the 1999 AIJ standard. L4 had identical configuration to L1 but was strengthened with SRF sheet. A single layer of SRF sheet was applied on the south face of L4 and anchored to the north face as shown in Figure 1(b). The beams of the second and third floor (B2 and B3) next to the openings...
were also strengthened with a single layer of SRF. Mechanical properties of SRF sheet is listed in Table 2. Polyurethane adhesive was used for placing SFR on the concrete surface.

The lateral load was applied to the loading beam as shown in Figure 1(c) and the drift at the midspan of loading beam was controlled. The loading protocol was two cycles each at drift angles of 0.05%, 0.1%, 0.25%, 0.5%, 0.75%, 1.0% and 1.5%. The vertical load was applied to the top of each column so that the contraflexure point stayed 2500 mm above the foundation beam, that is, shear span to depth ratio was 1.0.

Experimental Results

Lateral load – drift angle relations are shown in Figure 2. It is clear from L4 that SRF increased the shear capacity without changing the initial stiffness. The degradation of the shear strength from the positive peak to R=+1.3% in L4 was gentler than that of L1.

When the shear strength of L4 was computed, the effect of SRF was taken into account by adding the equivalent amount of shear reinforcement steel to the equation. The equivalent amount of steel was computed so that the steel at yielding carries the same magnitude of force which a given amount of SRF carries at the strain of 0.57%. The computed and experimental shear strengths agree well in the positive direction and the employed equation is considered reasonable. The first shear crack of L1 was found at the first floor wall panel at drift angle (R) of +0.04%, and the number of cracks kept increasing till R=0.5%. Then the vertical reinforcement buckled at the wall base of the first floor at the region enclosed by a circle. The concrete started to spall locally from this drift angle. Then the shear sliding failure took place along the wall base at R=+1.5% and the lateral load dropped suddenly. L4, strengthened with SRF sheet, had the initial shear cracks at R=+0.05% and the number of cracks increased until R=0.5%. At the part of the second floor beam (B2), flexural cracks opened widely and the maximum load was reached at R=0.68% in the positive direction. Peak load in negative direction was reached when the shear failure occurred at the third floor wall panel since the force path was not secured due to an opening. In positive direction, the wall resisted the external force until R=1.25%. At R=1.25%, degradation of load carrying capacity since the sliding shear failure occurred just below the loading beam.

Shear strength of the structural wall (L4) in the positive direction was enhanced by 27%. Both SRF and polyurethane adhesive have low stiffness and high deformation capability. With SRF attached on concrete surface, cracks did not concentrate locally but rather distributed evenly over wall panels, and consequently the number of cracks increased and the width of each crack decreased. The cracks with smaller width made the aggregate interlock more effective resulting in the enhancement of shear capacity. SRF also alleviated deterioration of the load carrying capacity by preventing the spalling of concrete. Even after the concrete strut failed in compression, damaged concrete stayed in the original position since SRF held it. Consequently, the degradation after the peak was gentler. Unfortunately, the ductility enhancement due to SRF was not clear due to an unexpected failure mode.

This chapter introduced SRF, one of fiber reinforced polymers with low Young’s modulus. It was used to retrofit RC structural walls with openings. Its large deformation capability improved seismic performance of structural walls and relieved stress concentration. In addition to the force resisting mechanisms stated here, SRF has a function to relieve stress concentration due to its large deformation capability. Sharp corners of the RC members do not have to be round like they should be for CFRP sheet which is sensitive to sharp corners. SRF can be also applied to large bridge columns, brick-walls and lumber structures as well for its design flexibility, ease of handling at construction and low price.
CASE 2: OUT-OF-PLANE IMPACT RESISTANCE OF WALLS WITH CFRP

The Japanese current building codes and standards for RC buildings do not have any statements on design against tsunami debris impact loads. Since there are not many experimental studies on local damage of RC buildings by tsunami debris impact load, experimental data is necessary to develop design methods. This paper presents a test result of RC walls strengthened with FRP sheet to see its effectiveness on the impact resistance (Watanabe et al. 2016).

Experimental setup

Figure 3(a) shows configuration and dimension of square wall specimens and (b) shows the layout of FRP sheet. Table 3 shows test variables with observed failure modes. The specimens are 50% scaled wall models with 1300mm by 1300mm in planar size and 120mm in thickness. Design concrete strength was 24 N/mm². Series STD were ordinary reinforced concrete walls with minimum reinforcement required by the 2010 AIJ standard and without further strengthening. Series PUA and PUT had polyurea and polyurethane resin polymer membrane of 2mm thickness, respectively. Series FRP had CFRP sheet in two transverse directions as shown in Figure 3(b). Series FPA had 2 mm thick polyurea resin polymer on top of CFRP sheet placed in two transverse directions. All strengthening was conducted only on the rear face of the specimens while impactor was designed to hit the front face. Their performance target was to prevent penetration of impactor and shattering of rear side concrete. Each series consisted of four identical specimens which were tested under different impact velocity ranging 6.54m/s ~ 13.25m/s and impactor weight, either of 104.95kg or 152.25kg as listed in Table 3. Mechanical properties of materials are listed in Table 4.

Figure 4 shows typical failure modes for each series. Red lines represent cracks for Series STD and represent boundary of delamination of strengthening materials in other series. The shading in Figure 4 (b-1) represent area of concrete spalling. Specimen STD-c, which had the impact velocity of 8.07 m/s, had a mix failure mode of scabbing and perforation. Specimen STD-d (Figure 4(b-1)) (9.07 m/s) had perforation and steel reinforcement relieved flying of damaged concrete fragments. For Series PUA and PUT, epoxy resin was torn (Figure 4(a-2))

1021
and (a-3)) when the impact velocity was close to 10 m/s, perforation happened when the velocity became as fast as 13 m/s (Figure 4(b-2) and (b-3)). In Figure 4(a-2) and (a-3), polyurea and polyurethane membrane stretched due to the scabbing of concrete but damaged concrete fragments stayed inside polyurea or polyurethane membrane. For Series FRP and FPA, perforation did not happen even if the velocity became 13 m/s with a 104.95 kg impactor. Hence, the impactor weight was increased to 152.25 kg and the impact test was continued. Then perforation was observed for velocity of 10.45 m/s as shown in Figure 4(b-4) and (b-5).

Nakamura et al. (2015) proposed the design equation for scabbing and perforation limits by modifying Hughes’ equation (Hughes 1984). If the ratio of experimental limit velocity (V_{exp}) to computed limit velocity (V_c) is larger, the velocity of perforation increased from that for a plain reinforced concrete wall due to strengthening. Table 5 shows that V_{exp}/V_c ranged from 1.07 to 1.16, the strengthened series have 7 - 16% increase of limit velocity for perforation compared to plain reinforced concrete walls. The strengthened series decreased the limit thickness of perforation to 88 – 95% of the plain reinforced concrete for an arbitrary impactor velocity.

CONCLUSIONS

Reinforced concrete walls strengthened with SRF

Fiber reinforced polymers with low Young’s modulus was used to increase the shear capacity of an RC structural wall specimen. The large deformation capability of SRF improved shear capacity of structural walls by 27% and 9% in the positive and negative directions, respectively, and relieved damage due to excessive stress concentration.
Reinforced concrete walls strengthened with CFRP
Four type of strengthening method (CFRP sheet, polyurea and polyurethane resin polymers, and combination of CFRP sheet and polyurea resin polymers) increased the velocity of penetration, scabbing and perforation and relieved flying of shattered concrete fragments behind the impact face.

- As impact velocity increased, failure modes changed from delamination of CFRP sheet to perforation for wall specimens strengthened with CFRP polymer sheet and with or without polyurea resin composite. On the other hand, failure modes changed from tearing to perforation for wall specimens with polyuria resin composite or with polyurethane.
- With strengthening materials used in this test, the limit velocity of perforation increased by 7% - 16% and the limit thickness for perforation can be decreased by 5% - 12% as conservative assessment.

ACKNOWLEDGMENTS

SRF and adhesive materials were donated by Structural Quality Assurance, Inc. and precious advice and technical support was given by Dr. Shunichi Igarashi. The authors acknowledge M. Warashina and K. Mori, former graduate students at Kyoto University, for their contribution to the experimental works and data processing.

Study on impact test was funded by Grant-in-Aid A (PI: Prof. H. Tanaka) and partially supported by the collaborative research project of the materials and structures laboratory at Tokyo Institute of Technology. The authors thank Mr. T. Matsui (Toray Industries, Inc.) and Mr. K. Ide (Mitsui Kagaku Sanshi) for donating strengthening materials and acknowledge Profs. M. Nishiyama, T. Maruyama, Y. ABSTRACT

Reinforced concrete buildings with moment resisting frames and beam-column joints (BCJ), designed prior to introduction of seismic codes, are deficient when subjected to lateral seismic loading. The weakest link in these buildings, the BCJ fail in shear under lateral seismic loads resulting in irreparable damage to the buildings and possibly a collapse. Several strategies for shear strengthening deficient joints in old buildings have been investigated and implemented in buildings over the past three decades using CFRP sheets and laminates. The shear failure in joints is successfully precluded, with the failure mode shifting to the formation of a plastic hinge at the BCJ interface. A localized failure in the connecting beams away from the joint is a more preferable failure mode rather than a plastic hinge formation at the interface. In modern BCJ with high strength concrete and shear reinforcement in joints, the plastic hinge is also formed at the BCJ interface, which is again undesirable failure mode. It is highly appropriate that all BCJ should undergo a flexural-shear failure with the plastic hinge formation away from the BCJ interface well into in the connecting beam. Based on a nonlinear finite element investigation of CFRP strengthened shear-deficient BCJ using concrete damage plasticity model in ABAQUS, experimental investigations have been conducted. The experimental investigation shows that in BCJ strengthened in shear, an appropriate scheme of CFRP strengthening results in improved ductility, energy dissipation and an increase in load capacity with a movement of the plastic hinge formation from the BCJ interface to a distance inside the beam.

KEYWORDS

Beam column joints, Plastic hinge, CFRP strengthening, ABAQUS.

INTRODUCTION

Reinforced concrete buildings are designed to withstand the moment induced in structural members from gravity, wind and earthquake loadings. Moment-resisting frames comprising beams, columns, and beam-column joints are the main elements resisting these loadings. A beam-column joint (BCJ) is that part of the RC-column, which lies within the depth of the deepest beam that frames into the column and is the most critical region which is subjected to large forces in a severe seismic event (Moehle 2014). The behavior of the BCJ has a great influence on ductility, energy dissipating capability and transfer of lateral forces and moments amongst the beams and columns framing into the joint. In a BCJ, the formation of plastic hinge and its location during a strong seismic event dictates the integrity of the moment resisting frame. In older constructions, prior to the enforcement of seismic detailing of BCJ with shear reinforcement in the joint, the formation of plastic hinge at the core of the joint, led to large deformation at the core and a brittle failure of the frame. In the recent years, these deficient BCJ are being retrofitted using carbon fibers reinforced plastic (CFRP) sheets. These sheets provide enhanced strength and stiffness to the joints, precluding the brittle joint failure. CFRP strengthening shifts the formation of plastic hinge from joint core to the beam, transforming it to strong column-weak beam joint. The modern code requirement enforces the strong column-weak beam joint philosophy by providing shear reinforcement in the joint to ensure a ductile moment resisting frame.

The location of plastic hinge in the beam both in older beam column joints with CFRP retrofit and new constructions with shear reinforcement is of critical importance. In many cases with CFRP retrofit and shear reinforcement, the plastic hinges are formed at the face of the column at the BCJ interface. In severe seismic events the plastic hinge at the joint may penetrate into the core of the joint, thereby degrading the joint strength and stiffness and loss of bond between the bars and the concrete. The effectiveness of the plastic hinge in dissipating the energy is compromised and brittle failure at the joint can ensue. It should therefore, be an important objective in retrofitting
BCJ with CFRP and shear reinforced joints in modern construction to ensure that the plastic hinge is developed at a reasonable distance away from the column face, well into the beam to ensure that the plastic hinge does not propagate into the joint under cycles of earthquake loading.

This paper presents the results an experimental program in which the CFRP strengthening was carried out for a beam-column joint, in which shear failure in joint is precluded, to ensure the formation of plastic hinge well into the beam away from the BCJ interface. Finite element simulation of a CFRP strengthened exterior beam column joint was carried out using commercial software ABAQUS, which captured the experimental response.

**PLASTIC HINGE FORMATION IN BEAM COLUMN JOINTS**

Many of the buildings built around the world in the 1980’s were mostly designed to support gravity load and these buildings suffered from extensive damage at joints resulting in their partial collapse as witnessed in the recent earthquakes in Nepal 2015, Chile 2015, Japan 2010, Taiwan 1999, and in Turkey 1999. In the past three decades, a number of researchers and research groups have committed significant efforts into studying the behavior of BCJ under shear reversals, as well as on the development of design recommendations to ensure adequate connection behavior in reinforced concrete frame structures that are designed for large inelastic deformations. Design codes have evolved over the years to improve the capacity of non-seismically designed building joints to ensure a ductile behavior, such as ACI 352 (ACI Committee 352 2002).

Ductile mode of failure is desirable in structures where plastic hinges are formed before the overall failure of the structure, but the location of the plastic hinges is of great importance to prevent its further penetration into regions with lesser capacity. In ductile moment resisting frames, which comprises of beam and columns, plastic hinges are usually formed at the interface of the BCJ, especially for short span beams, but in long span beams where the dominant load is gravity load, the plastic hinge may form outside the BCJ interface at a distance inside the beam (Paulay and Priestley, 1992). When the beam top or bottom reinforcement yields at the interface of the BCJ, the joint experiences severe shear cracks as a result of deterioration of the bond between the steel and the concrete, and thereafter leads to shear failure. To avoid the formation of plastic hinge at BCJ interface, several approaches have been proposed, which are based on the same principles. The first was proposed by Paulay and Priestley (1992). It involves a special detailing of longitudinal steel reinforcement in the beam at critical section around the joint. Fadi et al. (2014) proposed slotted-beam detailing technique for ensuring plastic hinge relocation from the face of the column to the beam. Reversed cyclic load testing experiments on BCJ with slotted-beam at the interface of the BCJ, and at 300mm away from the BCJ interface showed the viability of this approach in new constructions.

In shear reinforced BCJ, wherein the plastic hinge is formed at the BCJ interface, a proper web bonded or flange bonded CFRP can be implemented to ensure that plastic hinge formation is translated from the interface to an appropriate distance away from the interface. Mahini and Ronagh (2009, 2010, 2011) proposed web-bonded CFRP retrofitting technique for exterior beam column joints with shear reinforcement in the joint, for enhancing the strength and ductility of the joints and relocation of plastic hinge. The BCJ was designed in compliance to new seismic design code with shear reinforcement provided at the joints to preclude brittle joint failure and ensure that the plastic hinge is formed at the interface of the BCJ. Application of three layers of web-bonded CFRP sheets (0.495 mm thick) extended into the beam resulted in the translation of the plastic hinge from the face of the column to 150-300 mm away from the BCJ interface into the beam. Finite element simulation of the joint using the software ANSYS captured the response and the plastic hinge formation with a good accuracy. Dalalbashi et al. (2012) verified the experimental results of Mahini, and numerically investigated the efficiency of flange-bonded CFRP sheets in plastic hinge relocation in RC joints. The problems and difficulties encountered in retrofit of joints using web-bonded CFRP sheets were solved by using flange bonded FRP. Experimental study on the appropriate anchorage system for flange bonded CFRP in retrofitted reinforced concrete BCJ with the aim of plastic hinge relocation was carried out by Esfami and Ronagh (2013). There was a remarkable improvement in the load carrying capacity and elastic stiffness of the CFRP-retrofitted specimens, which confirmed the efficiency of the suggested system. Furthermore, the plastic hinge was relocated away from the beam-column interface.

In buildings constructed prior to the enforcement of joint shear reinforcement, the joints were mostly deficient, resulting in the formation of plastic hinge in the core of the joint as shown in Figure 1(a) (Baluch et al. 2012), which led to brittle failure. In cases where the plastic hinge is formed at the BCJ interface as shown in Figure 1(b) (Baluch et al. 2012), the penetration of yield surface into the core resulted in the failure of the joint. Several strategies for repair and strengthening of deficient beam-column joints in buildings have evolved over the years with Carbon Fiber Reinforced Polymer (CFRP) sheets and laminates being a widely adopted technique. Major repair and strengthening of earthquake damaged structure and enhancement of non-seismic designed and detailed BCJ in the recent years were carried out using CFRP. High tensile strength (both static and long term), low weight, easy
application and corrosion resistance of CFRP composite has made it a preferable choice for use in repair and strengthening of BCJ.

The strengthening technique using CFRP has successfully precluded the failure of the joint in shear, with the mode of failure changing from a brittle joint failure, which results in extensive damage to the structure to a ductile failure mode with the plastic hinge forming at the beam-column joint interface.

![Figure: 1 Formation of Plastic hinges](a) At the core  (b) At BCJ Interface (c) At BCJ interface in CFRP retrofit (d) Well into the beam in CFRP retrofit

Web bonded CFRP sheets in diagonal configuration were used by Halahla (2014) for retrofitting exterior BCJ deficient in shear. The brittle shear failure of joint and plastic hinge formation in the joint was precluded together with an enhancement of load carrying capacity by 13%. The failure mode of the CFRP retrofitted joint changed from brittle joint failure in shear to ductile beam failure with the plastic hinge forming at the BCJ interface, as shown in Figure 1(c), without significant cracks in the joint. The formation of plastic hinge at the beam column joint interface, although it prevents severe damage and collapse of the building, it may preclude the repair and rehabilitation of the building. It is therefore, important to adopt a CFRP strengthening strategy in which the plastic hinge during a seismic event is formed away from the BCJ interface, well into the beam. This will ensure a localized element level failure in beam which can be easily repaired and strengthened. Figure 1(d) shows a typical scheme of CFRP strengthening which results in the formation of the plastic hinge well into the beam at the point of truncation of the CFRP sheet (Mosallam et al., 2014).

EXPERIMENTAL INVESTIGATIONS

Details of Tests Specimens

The specimens tested in the experimental program are representative of a typical exterior beam column joint in a moment resisting frame which was fabricated using concrete with joints having no transverse reinforcement. The specimens were tested under monotonic loading to failure. The specimens designated as control sample (CS), and retrofitted sample (RS) have 250 mm x 300 mm columns and 250 mm wide x 300 mm deep beams designed with 3-16 mm diameter flexural reinforcement in the beams to generate flexural failure in the beam. The geometric configuration and reinforcement details of the test specimens are shown in Figure 2(a). Compressive strength tests and split cylinder tensile strength tests were conducted on 75 x 300 mm cylinders. The average 28-day compressive and tensile strength of the concrete used in the BCJ were 50 MPa and 2.5 MPa respectively. The 50 MPa concrete ensured that there was no shear failure in the joint due to penetration of yield zone into the joint. The average values of yield and ultimate strength of the longitudinal and stirrup reinforcements as measured experimentally was 610 MPa. The specimen RS was retrofitted with CFRP sheet attached to the flange of the BCJ as shown in Figure 2(b). The edges of the longitudinal applied CFRP sheets were wrapped with small width transverse CFRP sheets to prevent peeling of the longitudinal CFRP sheets at its edges. Sika Hex 230C unidirectional CFRP sheets was used for retrofitting the beam column joint, with a two part SIKADUR 330 epoxy, using the wet-lay procedure. The properties of CFRP sheets used for retrofitting the BCJ, as provided by the manufacturer, are shown in Table 1. The properties of SIKADUR 330 glue (a 2-part epoxy impregnation resin) are shown in Table 2.

Experimental Setup, Instrumentation and Testing protocols

The BCJ were tested in a self-reaction steel loading frame consisting of axial and lateral loading systems. The loading frame with a specimen and testing arrangement is shown in Figure 3. Two hydraulic jacks were used for the application of axial and lateral loads. One 30-tons capacity hydraulic jack was used for the application of axial load on the column and the second hydraulic jack with 10-tons capacity was attached to the tip of the beam for applying lateral loading on the beam. Load cells, LVDT’s, and strain gauges were installed on the test specimens to monitor the loads, deflections and strains. A 20-ton load cell was installed at the top of the column to measure the axial load on the column and two 10-ton load cells were installed at the top and bottom of the tip of the beam.
to measure the lateral loads under monotonic push load (Figure 3(a)). Two LVDT’s were installed in the joint region to observe the diagonal crack openings and another two LVDT’s were also installed at the top and bottom of the column to monitor the movements. One string type LVDT (Patriot) was installed at the tip of beam to measure the deflections. Strain gauges were installed on the surface of reinforcing steel, concrete and CFRP to monitor strains. The columns were initially loaded monotonically with an axial load of 150 kN, which was kept constant in both retrofitted and normal BCJ, and then the BCJ were subjected to downward displacements applied at tip of the beam at each time step until the failure of the specimen.

Figure 2: Specimen configuration (a) Control Specimen CS, (b) Retrofitting Scheme for Specimen RS.

**Flange bonded CFRP Retrofit of Exterior Beam Column Joint**

The BCJ specimen RS was retrofitted using SIKAK 230C CFRP sheets bonded to the flange of the BCJ on the top of the beam using SIKADUR 330 glue consisting of two parts, mixed in ratio 4: 1, using a wet lay procedure. Two layers of the CFRP sheet was wrapped on the beam-column joint, and 20 mm wide wraps were attached to the termination point of the CFRP sheets to ensure that the CFRP was properly held in place and do not peel at the edges. The CFRP retrofitted specimen RS is shown in Figure 3(b). The CFRP sheet applied to the BCJ with epoxy resin was allowed to cure as per manufacturer’s recommendations and then tested, under the monotonic displacement regime 7 days after the applications of CFRP.
RESULTS AND DISCUSSIONS

Failure mode and Ultimate Load of the control specimen (CS)

In the control specimen (CS), the flexural reinforcement in the beam experienced significant yielding resulting in flexural cracking in the beam, primarily at the BCJ interface. The specimen was tested under monotonically increasing load up to failure. The cracks in the specimen CS at the top of the beam are shown in Figure 4(a). The beam-tip load deflection curve for the specimen CS is shown in Figure 4(b). The first crack in the specimen was observed at a load of 36.1 kN at the beam-column joint interface. The crack at the BCJ interface became wider as the test progressed. Under increasing load, additional flexural cracks developed near the BCJ interface as shown in the figure. The flexural steel at the top of the beam yielded at a load of 105 kN after which the stiffness degraded and the deflection increased with small increase in the load. Very fine diagonal shear cracks were observed in the joint of the specimen during the experimental test. Horizontal cracks at the top of the joint also developed, which is probably caused by the penetration of yield into the joint. The yielding of the beam longitudinal reinforcement at the BCJ interface resulted in the formation of plastic hinge at the interface. The plastic hinge penetrated into the core of the BCJ and deteriorated the bond between the longitudinal steel and core concrete. The reinforcement yield penetration into the joint led to the termination of the test at an ultimate load of 115 kN at a displacement of 30.6mm.

Figure 4: (a) Failure of specimen CS (b) Load-displacement curve for CS
Failure mode and Ultimate Load of the CFRP Retrofitted Specimen (RS)

The flange-bonded CFRP retrofitted specimen RS behaved in a different manner compared to the specimen CS. The first crack occurred at the cutoff point of the CFRP on the beam at a load of 42 kN. Although, a minor flexural crack also occurred at the interface of the BCJ, and other parts of the beam, the crack at the CFRP cutoff point widened as the load increased. The bonding of the CFRP sheets on the flange of the beam at the critical section signified an additional reinforcement at that location which increased the section capacity, thereby making the section stronger. This resulted in the formation of the plastic hinge at the location where the CFRP sheets are truncated on the beam as shown in Figure 5(a). This phenomenon agrees to the reinforcement detailing of seismically designed frames suggested by Paulay and Priestley (1992). The required development length for the CFRP beyond the BCJ interface was achieved by bonding the CFRP laminate on the column, to avoid creating a groove at the BCJ interface as suggested by Eslami et al. (2013), which can be very difficult to achieve in real life strengthening of structures. Also, the grooving technique if not properly covered with good concrete can cause corrosion of reinforcement at the ingress of deleterious substances, especially in areas with harsh corrosion friendly condition. The effect of CFRP length was not considered in this study to verify the work of Eslami et al. (2013) and Dalalbashi et al. (2012). The CFRP length chosen in this study was taken as 1/3rd of the beam length, which in this case was 300 mm.

The longitudinal reinforcement in beam, in the specimen RS, yielded at a load corresponding to 114 kN with fine shear crack occurring at the core of the BCJ, which did not grow under increasing load. The yielding of bars in this specimen occurred at a higher load as compared to the control specimen CS, due to the presence of CFRP in the specimen RS. After the development of cracks at BCJ interface, CFRP sheet participates in resisting the applied loading. Yielding of the steel occurs at the location on the beam where the CFRP sheet is truncated (Figure 5(a). The specimen failed at a load of 145 kN and a beam tip displacement of 42.6mm. Comparison of the two specimens (CS and RS) showed a 26% increase in load carrying capacity, and better ductility, due to the formation of the plastic hinge away from the BCJ interface, well into the beam.

FINITE ELEMENT SIMULATION OF THE BEAM COLUMN JOINT

The commercially available nonlinear finite element software ABAQUS (2013) was used to simulate and validate the experimental results conducted on exterior BCJ. The concrete damage plasticity (CDP) model in ABAQUS proposed by Lubliner et al. (1989) was chosen. The CDP model has the capability to simulate the elastic and inelastic behavior of concrete in tension and compression with different yield stress as observed in the laboratory. The CDP model uses a yield surface for its failure criterion by combining the Drucker-Prager criteria with the Rankine criteria. To account for the complete behavior of concrete, ABAQUS requires the tension damage \( d_t \) and compression damage \( d_c \) parameters. The compression damage parameter \( d_c \) is related to the plastic strain \( \varepsilon_{pl} \) which is determined from the inelastic strain, and the tension damage parameter \( d_t \) solely depends on \( \varepsilon_{pl} \).

The steel reinforcement (longitudinal and transverse) is modeled as a truss element embedded in concrete assuming a perfect bonding between the steel and concrete, using the slave and master constraint so as to solve the problem.
with node compatibility during the meshing processes. Chen (1982) stated that if truss element is used for steel reinforcement, it is unnecessary to consider the complex behavior of steel when subjected to multi-axial stresses. Therefore, a perfect elasto-plastic material constitutive law is used to idealize the stress-curve under tension and/or compression.

The behavior of FRPs depend on their mechanical properties, fiber orientation, length, shape and constituent fibers, properties of the epoxy adhesive, and nature of the surface to which they are bonded. FRPs usually display linear elastic property until failure without any inelastic deformation. There are many proposed theories to represent the orthotropic plane stress failure of FRPs. In this study, the Tsai-Wu theory was used to simulate the failure surface of CFRP in the ABAQUS program because it is suitable for unidirectional FRP as compared to the Tsai-Hill’s criterion as it accounts for Bauschinger’s effect (Ramesh, 2014). Tensile values were taken as positive, while compressive taken as negative so as to account for FRPs behavior in both tension and compression as required in Tsai-Wu theory. Hadigheh et al. (2012) used ABAQUS FEM simulation to verify the performance of weak-beam, strong column RC frames strengthened at the joints by FRP. The epoxy was modeled as contact element and Hillerburg’s fracture energy criterion was used. The numerical result obtained was in excellent agreement with the experimental results.

Many researchers including Carlos et al. (2005), Wein et al. (2015), Priya et al. (2014) and Gopinath et al. (2014), have studied the effect of using contact element at the interface of the FRP and concrete to simulate the real life scenario in numerical modeling. Cohesive zone model (CZM) has been used by some of the authors by using the traction-separation law. It has been reported that the contact element is not a key factor for predicting behavior of the FRP-concrete bond, but the fracture energy of the concrete-epoxy interface plays an important role in the results of such prediction. Hence, many authors have assumed a perfect bonding between the FRP and concrete interface. Despite the foregoing, in this study, the epoxy bond was modeled using a plain strain element (CPE4R), since the epoxy has two surfaces: concrete-epoxy surface, and epoxy-FRP surface. The epoxy was bonded to the concrete surface using ties to ensure that nodes on the interface of the epoxy have the same displacement as nodes on the concrete surface. By doing this, normal and shear stresses along the concrete epoxy-interface would have been accounted for. The properties of epoxy SIKADUR 330 used in the FE modeling are shown in Table 2. The finite element model of the experimental beam column joint specimen in ABAQUS is shown in Figure 6(a). The control specimen was used for verification of the numerical scheme using appropriate mesh size, and termination time. Typical damage patterns in the control specimen CS and the CFRP retrofitted specimen RS are shown in Figure 6(b) and Figure 6(c).

![Figure 6. FE Modelling in ABAQUS: (a) FE Model of the BCJ (b) Damage in specimen CS, (c) Damage in specimen RS.](image)

The results obtained from the simulation of the BCJ in ABAQUS showed a similar trend as noticed in the experimental study. The ultimate failure loads and beam tip displacement for the control specimen CS from FE simulation are 116 kN and of 35 mm respectively. For the flange-bonded CFRP sheets specimen RS, the ultimate failure loads and beam tip displacement are 153 kN and 47.8 mm respectively. The load-deflection curve for both experimental and FE simulation are shown in Figure 7a and Figure 7b. Numerical results capture the experimental data in both specimens with a good accuracy. The strains in the concrete and beam longitudinal reinforcement for both experimental and numerical studies were also found in agreement.
CONCLUSIONS

This paper reports the findings of experimental and numerical investigations for relocating plastic hinges away from the interface of a non-seismically designed exterior BCJ. Two layers of externally bonded unidirectional CFRP sheet, 300 mm in length, with CFRP width covering the beam width was used for retrofitting the BCJ specimen which was tested under displacement control monotonic loading. Finite element simulation of the BCJ was carried out using the commercial software ABAQUS. It was observed that the retrofitted samples had higher ultimate capacity, higher ductility, and plastic hinge was relocated from the BCJ interface to the cutoff point of the CFRP sheets on the beam. This relocation of plastic hinge is desirable for better performance of RC frame structures subjected to lateral seismic loads, which places higher demand on the joint. The numerical results were in very good agreement with the experimental work as they give almost the same load capacity, stiffness and beam tip displacement. The finite element simulation in ABAQUS incorporated the CFRP-Epoxy-Concrete bond, material constitutive model for the FRP and fracture energy of the fiber/epoxy, which gave very close results. Further studies are being conducted by the authors to assess the response of the flange bonded CFRP retrofit and its effect on plastic hinge relocation under cyclic loading.

ACKNOWLEDGMENTS

The funding for this research was provided by the Deanship of Scientific Research under the project IN121058. The support provided by the Center for Engineering Research at the Research Institute at KFUPM and the Department of Civil Engineering is acknowledged. The CFRP and Epoxy used for the experimental work was provided by Sika, Saudi Arabia. The contribution of Dr. Ajmal and Mr. Huri are acknowledged for making ready the RC samples used for this test.

RESILIENCE RESERVE OF RC COLUMNS EXTERNALLY CONFINED WITH COMPOSITE ROPE OR FRP SHEET UNDER SEISMIC OVERLOADS

T.C. Rousakis

Department of Civil Engineering, Engineering Structures Section, Reinforced Concrete Lab, Democritus University of Thrace, Xanthi, Greece

ABSTRACT

This paper highlights unique inherent seismic resilience aspects of reinforced (RC) columns externally confined with composite rope or fiber reinforced polymer (FRP). It discusses the inherent seismic resilience reserve of this subsystem at material, at section and at structural member level, both qualitatively and quantitatively from a structural point of view. The investigation focuses on the damage control at member level that may prevent collapse of critical infrastructure. A design concept is concluded towards enhanced inherent resilience of such subsystems from a structural point of view. This concept concerns subsystems in which the weakest link (in our case also being the main bearing material, the concrete core) suffers a local damage initiation (susceptible to further accumulation) that disrupts its uniformity and homogeneity in response. In that case, adequate confining action may maintain damage-sensitive-restriction in a way that globalizes damage (damage redistribution) inside the core and makes the core again more uniform and more homogeneous in its response.

INTRODUCTION

Resilience is a multidisciplinary and interdisciplinary concept defined as “the ability to prepare and plan for, absorb, respond, recover from, and more successfully adapt to adverse events” (NAC 2012). It covers different fields such as ecology (Holling 1973), materials science and disaster mitigation. As far as the built environment is concerned, there is a need to improved performance during and after a disruptive hazard event (McAllister 2013) and metrics need to be developed to account for resilience of built environment at the level of components, infrastructure systems and whole communities. The current study is limited to earthquake induced hazard and highlights the resilience reserve of reinforced concrete (RC) columns retrofitted with composites.

Different alternatives in design of new structures or of retrofit techniques in seismic redesign of existing structures and of their structural components, may affect significantly the resilience at infrastructure and at community level. Recently, Biondini et al. (2015), presented a probabilistic analytical approach to assess the seismic resilience of concrete structures exposed to chloride-induced corrosion. They concluded that time-dependent effects of corrosion may greatly reduce functionality and resilience of the structure during a seismic event. Functionality of the structure is associated with its seismic capacity. Their research indicates the importance of including in the seismic design of resilient structures all potential hazards for the whole life-cycle. In another study, Echevarria et al. (2015) highlighted the improved resilience of critical bridge infrastructure when concrete-filled fiber reinforced polymer (FRP) tube (CFFT) columns are used, instead of RC ones. They performed a comprehensive experimental study of columns suffering blast, fire or earthquake hazards (multi-hazard experimental assessment) of different intensity and concluded lower damage of the columns, lower restoration time and lower repair costs for the case of CFFT. Of course, multilevel societal needs and potential, need to be satisfied through the development of risk-based performance goals (McAllister 2013). In that aspect, Bocchini et al. (2014) proposed a risk assessment approach to unify resilience and sustainability requirements.

The current study highlights some aspects of comparative qualitative and quantitative assessment of the inherent structural resilience of RC columns of existing structures retrofitted with composites under seismic excitations. The investigation is limited to the performance of the columns to maintain their axial capacity. Echevarria et al. (2015), acknowledge the criticality of this issue as in example, after an earthquake a bridge may be still in service to provide first responders and emergency vehicles access to exclusive regions affected. This may have a great
impact on resilience at structural and societal level. Similarly, RC critical infrastructure such as Hospitals, Fire Stations and Command Centers, etc may require similar performance levels as a whole in order to operate. In the current study the retrofitted RC column is considered mainly as a resilient subsystem, being critical component of structure that belongs to a network of critical infrastructure to fulfill resilience requirements. However, the investigation discusses also resilient aspects of the materials and sections within the subsystem.

**STRUCTURAL INHERENT RESILIENCE**

At retrofitted RC column level, the resilience may be interpreted as the ability to: absorb, resist, recover from and more successfully adapt to seismic overloads or overdisplacements with respect to ultimate limit states required by design. This study is limited to cases of columns redesigned to overcome above challenges with increased displacement ductility, through externally confined concrete. In general, increased strength, or passive control or seismic isolation could be realized instead in redesign of structures. Residual axial load capacity at high displacement ductility levels requires the suppression of fragile-type related failures such as: concrete shear failure, concrete cover spalling, concrete compression, steel bar premature buckling under compression, relative slip of steel bars at lap splices and FRP fracture in order to ensure steel yielding and full utilization at hardening stage up to emergence of global instability issues.

Figure 1. RC (or plain) concrete columns with PPFR passive or active confinement

**Composite Rope Confinement Effects on Structural Resilience**

*Fiber rope confined columns*

Composite rope wrapping may succeed in the above tasks through adequate external confinement. Furthermore, adequate composite rope wrapping ensures maximum utilization of concrete axial strain potential, as it allows for lateral strain redistribution according to varying demands of the column (affected by the concrete cover, confined core, steel stirrup yielding, bar buckling and section shape) throughout loading. Redistribution of strains causes redistributed damage and thus extensive and uniform cracking of concrete. This unique characteristic at section level contributes to enhanced resilience of the column being under axial loads, during seismic excitations (Rousakis 2014, Rousakis 2013, Rousakis and Tourtouras 2014). Figure 1 shows RC column 500PPL4 from Rousakis and Tourtouras (2014), wrapped with 4 layers of polypropylene fiber rope (PPFR). The column exhibits extensive global buckling at member level, multiple local bar buckling, multiple local bulging of the concrete core and intact composite rope, while maintaining the axial load bearing capacity (see Figure 1). This test was early stopped as depicted in Figure 1, carrying ever-increasing axial load at 0.06 concrete axial strain. Similarly, the tests of columns without steel reinforcement (PPL4) or of RC column 220PPL3P1.075% with pretensioned PPFR at 1.075% strain were early stopped without failure of the retrofitted region. The pretensioned column exhibited prolonged elastic behavior and higher bearing stress at similar strain levels than 500PPL4 despite having only 3 layers of wrapping. Higher pretension of 4 layers of PPFR at 2.65% strain (column 500PPL4P2.65%) provided
Further upgrade but the test was early stopped because of undesirable failure at the weaker, non-pretensioned base region of the column (outside the control region).

Even in cases with lower deformability basalt composite ropes (Rousakis et al. 2015), the achieved concrete axial strain ductility provides remarkable resilience as it surpasses the practical requirements in any case (higher than 0.07 strain). The unique characteristics of adequate composite rope wrapping, suppress common but low resilience failures observed in cases of concrete columns with internal steel stirrup or with external FRP jacket or with internal steel and external FRP confinement under severe axial loading that may lead to main shear-related cracks that further evolve and exacerbate non-uniformities. These irrecoverable non-uniformities initiate upon yielding of the steel stirrups or upon fracture of fibers of FRP jacket and the damage accumulates locally, leading to global column failure. In terms of axial load – axial deformation, the enhanced resilience of the column wrapped with composite rope is revealed with the temporary axial load drop of the column. Even in cases of very low rope confinement, the severe load drop may reveal a significant resilience potential of the composite rope to resume the axial load capacity to very high levels (see in example column 20PPL3R1 in Rousakis, 2013). Furthermore, in cases of fractured vinylon fiber ropes, the strand by strand fracture and FR-concrete friction provides remarkable levels of load recovery during successive cycles (see in example column VinL1v2R2 in Rousakis 2013). In cases of RC columns, the temporary load drops are even lower than corresponding plain concrete columns wrapped with composite rope. Resilience is owed to concrete deformability, rope strain redistribution, rope high deformability non-fractured, very low sensitivity to cracked-concrete-induced FR damage, strand-by-strand fracture of lower deformability rope. Maximum utilization comes with ‘spring-like’ response of bearing concrete at very high strain levels that denote significant degradation of the core “cohesion” through extensive cracking towards maximum homogeneity in response (Rousakis 2014).

The study by Kwon et al. (2016) verifies the efficiency of composite rope (or tape) reinforcement with very low effective normalized axial rigidity to enhance the lateral displacement performance of 2-column RC frames with inadequate steel stirrups (sparse stirrup spacing, low shear capacity, premature bar buckling). They use only one layer of Velcro tape of 0.3 mm thickness, made of nylon with self-anchoring detailing. This negligible Velcro confinement leads to negligible stress and strain enhancement of confined concrete section which has dimensions 200X300 mm and zero corner curvature radius. The provided confinement is at least 6 times lower than the one provided for column 500PPL4 in Rousakis and Tourouras (2014). Yet, the elastic non-bonded composite rope reveals its unique confining characteristics by restricting concrete cover spalling and delaying damage evolution, leading to increased ultimate displacement of the frame by factor of 1.25 and to increased absorbed energy by factor of 3.7 (columns VARC).

**Effects of composite rope confinement on P-δ response of RC columns**

In what follows the experimental behavior of the retrofitted RC column provided by Kwon et al. (2016) serves as the basis for comparative elaborations. The analytical σ-ε curve of the VARC column provided in Kwon et al. (2016) study under concentric axial load, is generated with Rousakis and Tourouras 2015 model (see Figure 2). This iterative model is based on Spoelstra and Monti (1999) model (fib 2001), further developed to take into account dual steel stirrup – FRP jacket effects, steel bars and pretensioned confinement. Of course, recently published studies may allow for further development of the model to incorporate additional features (see Wu and Wei 2014, Nistico et al. 2014, Wu and Wei 2015 and Li and Wu 2015 among others). In Figure 2, it is shown that the difference in terms of σ-ε between the non-retrofitted (ORC) and the retrofitted column (VARC) is negligible. The maximum effective retrofit confinement rigidity ratio (that is the maximum effective lateral stress (σjmax) divided by the lateral strain (εl) and multiplied by the effectively confined concrete core coefficient (αj) and divided by the plain concrete strength (fco) namely (fjmax/εl)*αj/fco is 0.25 and may be utilized as a measure of provided external confinement among different columns.

The corresponding confinement rigidity ratio for column 500PPL4 is 1.53 and the σ-ε curve is also shown in Figure 2. The σ-ε of the VARC column under compression with confinement rigidity 1.53 (equal to 500PL4) is shown as VARC1.53. The curve has descending post-maximum branch as the existing steel stirrups have lower efficiency than in 500PPL4 column. Moreover, degrading stress-strain behavior is commonly met in real-size RC columns. However, the load degradation for VARC1.53 is better controlled. Another interesting column under axial
compression is the specimen R-1-8H with dimensions 508 mm by 737 mm with post-rounded corners to radius of 25.4 mm (De Luca et al. 2011). It is wrapped with 8 layers of hybrid glass – basalt FRP sheet and the corresponding confinement rigidity ratio for column R-1-8H is 2.53. Its $\sigma$-$\varepsilon$ curve according to Rousakis and Tourtouras (2015) model is presented in Figure 2 as VARC2.53. There, the descending branch is further controlled and stabilized at a higher bearing stress, while the axial strain ductility of confined concrete is expected higher than 0.07 (see experiments in Rousakis and Tourtouras 2014). Yet, based on the experimental performance of the FRP confined column R-1-8H, the axial strain ductility of the VARC column would be very low if FRP retrofitted, because of the low deformability and axial rigidity of the FRP jacket and because of the zero corner radius.

![Figure 2. RC (or plain) concrete columns with PPFR passive or active confinement](image)

![Figure 3. Pushover analyses of VARC columns for different confinement rigidity ratios](image)

The predicted displacement at failure based on the pushover analysis of the columns VARC with constant axial load, using RESPONSE 2000 software (see also Rousakis et al. 2016) is 87.2 mm (experimental values are 86.9 mm or 95.4 mm). In the case the column is retrofitted with 6 layers of Velcro that equals the confinement rigidity ratio of column 500PPL4 (1.53) the analytical displacement at failure of the RC columns VARC1.53 is 107.6 mm.
(23% higher displacement). In the case the column is retrofitted with 10 layers of Velcro that equals the confinement rigidity ratio of column R-1-8H (2.53), the analytical displacement at failure of the RC columns VARC2.53 is 110 mm (26% higher displacement). Figure 3 shows all analytical curves. It is obvious that given the zero corner radius of the cross section of the VARC column, the efficiency of the FRP retrofit will be negligible as the reinforcing fibers will suffer premature failure. Even if the corner radius was adequate, the very low confinement provided, would yield similar results.

CONCLUSIONS

The unique features of RC columns confined with nonbonded composite ropes may contribute to a conceptual performance-based design towards enhanced inherent resilience of systems that contain a weak component susceptible to fatal damage accumulation. Enhanced inherent resilience of such systems may be achieved with uniform redistribution of damages inside the main bearing core mass, by peripherally confining the core through contact (not fixing) with elastic material (that does not accumulate damage). This material needs to be highly deformable and flexible (low sensitivity to damage acting as barrier) so that can locally deform and thus redistribute strains around and inside the core. In that case, total core mass under confining action is always the maximum one and the confining action is ever-increasing for higher axial compression of the core, imposing the core to higher multiaxial compression. This concept ensures that even if the weakest link (and main bearing material, the concrete core) suffers a local damage initiation (susceptible to further accumulation) that disrupts its uniformity and homogeneity in response, the confining action maintains damage-sensitive-restriction in a way that globalizes damage inside the core and makes the core again more uniform and more homogeneous in its response. In that case the energy dissipated by this subsystem is maximized.

In composite rope wrapped RC columns under cyclic axial load (i.e. induced with seismic excitations), the local concrete damage, the extensive steel bar local instability and concrete global instability is self-redistributed (inherently, if considered at structural member system level) and ever-increasing bearing axial load results (multiple buckled bars and multiple buckling modes at member level). Maximum utilization comes with ‘spring-like’ response of bearing concrete that denotes significant degradation of the core “cohesion” through extensive cracking towards maximum homogeneity in response. The concrete axial strain ductility of the column is remarkably high as well as the dissipated energy.

ABSTRACT

Fiber-reinforced polymer (FRP) jacketing of reinforced concrete (RC) columns is always considered as a very effective method to enhance the seismic performance of existing RC columns. The investigation on the plastic hinge behaviour of FRP-confined RC members has largely been experimentally based because of the high complication of the problem. Due to large number of variables involved and the high cost of testing, different works reported in the literature could only focus on a certain aspect or special cases and different even contradictory outcomes have often been reported. The present paper intends to investigate the behaviour of plastic hinge of FRP-confined RC columns numerically using three-dimensional finite element method (FEM). Lengths in the plastic hinge zones, involving rebar yielding zone, concrete crushing zone, and curvature localization zone, of FRP-confined RC columns subjected to monotonic and cyclic loading are firstly investigated in detail. It is found that all three zones are significantly affected by the loading scheme. Effect of FRP jacketing length on the length of concrete crushing zone are also analyzed. It is found that, for flexural retrofitting of RC columns, FRP jacketing length needs only to cover the concrete crushing zone, which is closely related to the FRP confinement ratio.

KEYWORDS

Plastic hinge, FRP, RC columns, confinement, FEM.

INTRODUCTION

In recent years, fiber-reinforced polymer (FRP) jackets have become popular in providing confinement to earthquake resistant reinforced concrete (RC) columns (Ibell et al. 2009). A sufficient ductility for RC columns can be achieved by FRP confinement at a potential plastic hinge region (Seible et al. 1997; Saadatmanesh et al. 1997). The plastic hinge region is defined as the physical region over which the member experiences inelastic deformations and severe damage. The plastic hinge length is critical not only for the design of new members but also for the seismic retrofitting of old structures.

Due to high nonlinearly of materials and complicate interactions between constitutive materials involved, most researchers studied the plastic hinge of RC members by experimental study and a few researchers studied the problem through numerical modeling. Zhao et al. (2012) studied the plastic hinge regions in RC beams under monotonic loading by finite element method (FEM) and a systematic parametric studies on the influence of plastic hinge length of full-scale square RC beams was carried out. Youssif et al. (2015) recently investigated the plastic hinge behavior of FRP-confined circular RC columns under monotonic loading by numerical simulations and an analytical model for ultimate drift ratio was proposed. The previous numerical studies on plastic hinge have been performed under monotonic loading and there are few studies investigating cyclic behavior of plastic hinge in FRP-confined RC members. Unlike monotonic behaviors, the cyclic behaviors of rebar yielding development, the stiffness degradation of confined concrete, as well as the bond-slip between steel and concrete are believed to have some influences on the development of plastic hinge zones of FRP-confined RC columns. This gives rise to the need for more comprehensive studies of this problem.

This paper aims to investigate the plastic hinge problem of FRP-confined RC columns in great detail through finite element simulations. The FEM model is first calibrated with test results. After that, a systematic study was
subsequently carried out to investigate the plastic hinge regions of FRP-confined RC columns subjected to monotonic and cyclic loading. Finally, the minimum FRP jacketing length for flexural retrofitting of RC columns with various confinement ratios is analysed.

**FINITE ELEMENT MODELLING AND IMPLEMENTATION**

General finite element software ABAQUS (2010) is used in this work. The constitutive models involve concrete, steel reinforcement and interfaces between concrete-steel reinforcement. Since the confinement effect of FRP jacket is embodied in the stress-strain relationship of concrete, FRP jacket is not created in FEM model. Detailed modeling and the parameters are summarized below.

The 8-node linear brick element C3D8R in ABAQUS is employed for concrete elements. The mesh size of the concrete element for RC columns is 20 mm. Elements smaller than 20 mm make little difference to the results, according to the mesh convergence study.

Damaged plasticity model is adopted to model the material behavior of concrete. The ascending section of the tensile relationship is assumed to be linear and softening is assumed to be exponential. The fracture energy method is adopted for post-peak cracking of concrete. The strain at peak stress $\varepsilon_{p,c}$ is assumed to be 0.0001. The fracture energy for concrete $G^f_c$ is assumed to be 170 N/m (Hillerborg 1985). The unloading and reloading paths of concrete in tension are taken to be linear and pointing towards the coordinate origin.

In compression, the analysis-oriented stress-strain model by Teng et al. (2007) is used to model envelop curve of both unconfined and confined concrete. The unloading and reloading paths of concrete are taken to be linear and pointing towards the zero stress points with residual strains. The modulus of the unloading and reloading paths of unconfined concrete is determined by the damage model proposed by Lubliner et al. (1989), where the damage factor is defined by:

$$d_c = 1 - \frac{\sigma_{un}^{\text{un}}}{f_c}$$

where $f_c$ is the compressive strength of concrete, $\sigma_{un}^{\text{un}}$ is the compressive stress corresponding to unloading strain.

For FRP-confined concrete, the compressive damage factor can be defined by

$$d_c' = 1 - \frac{\sigma_{un}^{\text{un}}}{E_0\left(\varepsilon_{un}^{\text{un}} - \varepsilon_c^p\right)}$$

where $\varepsilon_{un}^{\text{un}}$ and $\sigma_{un}^{\text{un}}$ are the unloading compressive strain and the corresponding stress; $E_0$ is the elastic modulus of concrete; $\varepsilon_c^p$ is the residual plastic strain during unloading and its relation to the unloading strain $\varepsilon_{un}^{\text{un}}$ can be expressed by the model proposed by Li and Wu (2015).

A 2-node truss element T3D2 in ABAQUS is employed for steel reinforcement. The mesh size is also assumed to be 20 mm. The bilinear model which considers strain hardening is adopted to model the stress-strain relationship of the steel reinforcement under monotonic load and a model proposed by Clough (1966) is employed to represent the unloading and reloading paths.

The Spring2 element is selected to define the nonlinear behavior between concrete and longitudinal tensile reinforcement. The concrete nodes and steel nodes with the same coordinates are connected by springs. A large linear stiffness is applied in the normal direction of the interface, while the unified bond-slip relationship proposed by Wu and Zhao (2012) is applied in the tangential direction to consider the nonlinear slip between concrete and steel bars. The bond stress-slip relationship can be transformed into the nonlinear spring force-relative displacement relationship in ABAQUS.

**MODEL VERIFICATION**

Two square RC columns (one with FRP confinement and another without), are simulated herein using the above described FEM model. Specimens Unit 3 (Ang 1981) and ASC-6NS (Iacobucci et al. 2003) were tested under constant axial loading and cyclic lateral deformation. It can be seen from Figure 1 that the unloading/reloading stiffness and load carrying capacity from the numerical results match well with those of measured results. Reasonable agreements are observed between measured hysteresis curves and FEM results.
The physical plastic hinge involves three different regions: the rebar yielding zone, concrete crushing zone and curvature localization zone (Zhao et al. 2012). In this section, all three regions are investigated in detail to get insight into the real plastic hinge zone of FRP-confined RC columns. Two specimens, one subjected to monotonic lateral loading and another subjected to cyclic lateral loading with fixed displacement increment of 1% drift ratio, are selected for analysis. The lateral displacement is increased under a constant axial force. The axial force is fixed to be 0.2N, where \( N = f_s A_s \) in which \( f_s \) is the compressive strength of concrete and \( A_s \) is the gross cross-sectional area of the column. Both specimens are confined with one layer (\( t_f = 0.167 \) mm) CFRP jacket with elastic modulus \( E_f \) of 245 GPa and fracture strain \( (\varepsilon_f) \) of 0.0171 and they have the same geometric dimensions and material properties. The specimen sizes are 400 x 400 x 1700 mm connected to a 600 x 800 x 1400 mm stub (Figure 2). The corner radius of the columns is 40 mm and the effective cantilever length is 1600 mm from the center of the loading to column base. Due to the symmetry of the column, half of the column is modeled. The compressive strength of unconfined concrete is 30 MPa. For both columns, steel bars of 20 mm diameter are employed as the longitudinal bar and steel bars of 10 mm diameter and spacing of 100 mm are adopted as transverse reinforcement. The steel has a yield strength of \( f_y = 460 \) MPa, an ultimate strength of \( f_u = 600 \) MPa and elastic modulus of \( E_s = 200 \) GPa. The reinforcement details and geometric dimensions of the columns are as shown in Figure 2.

**Investigation of rebar yielding zone**

The regions where the strain of tensile reinforcement has reached or exceeded its yielding value is defined as the rebar yielding zone. Figure 3 shows that although the length of rebar yielding zone varies as the deformation increases, the maximum length of this region \( L_{sy} \) from the column base is limited to a certain value. This observation is consistent with the test results in literature (Scott 1996).

It is also found from Figure 3 that \( L_{sy} \) of column under cyclic loading is larger than that under monotonic loading. The plastic hinge formation process under these two loading conditions are evidently different. Under monotonic loading, the length of rebar yielding zone increases significantly with the increase of the column deformation after it yields and keeps almost constant after the drift ratio of 3%. By contrast, under cyclic loading, evident increase in the length of rebar yielding zone is observed at each new displacement cycle and it stabilizes until the drift ratio of 5%. Residual stresses exist in longitudinal reinforcement at the beginning of new displacement cycles, which makes larger area of longitudinal reinforcement enter into the yielding phase, resulting in a larger \( L_{sy} \).

**Investigation of concrete crushing zone**

Figure 4 Concrete compressive strain distribution: (a) under monotonic loading and (b) under cyclic loading

To study the damage zone of FRP-confined RC column, the lengths of compression region \( L_{cs} \) and \( L_{cc} \), are investigated, where \( L_{cs} \) is defined as the length of the region where the concrete compressive strain is larger than the strain at peak stress of unconfined concrete (0.002) and \( L_{cc} \) is defined as the length of the region where the compressive strain is greater than the crushing strain of unconfined concrete (0.006). Careful examination of numerical results in Figure 4 shows that \( L_{cs} \) stabilizes at a certain value after the drift ratio of 2% while \( L_{cc} \) keeps increasing as displacement continues to increase. It can be also found from Figure 4 that both \( L_{cs} \) and \( L_{cc} \) for column under cyclic loading are significantly larger than those of column under monotonic loading. Compared with
monotonic loading, the stiffness degradation of concrete under cyclic loading makes it easier exceed the specified strain values (0.002 or 0.006), resulting in a larger \( L_{cs} \) and \( L_{cc} \).

Figure 2 Specimen details (unit: mm)

Investigation of curvature localization zone

Figure 5 shows the curvature distributions at different deflections beyond yielding for FRP-confined RC columns. It can be seen that the curvature varies significantly along the column length due to concrete cracking. After a column yields, most of the plastic curvature gets concentrated within a certain zone. A dividing point exists from which to the column base the curvatures increase rapidly while those outside the region remain almost constant. This numerical result is consistent with experimental observations reported in literature (Hines et al. 2004; Gu et al. 2010). The distance from the dividing point to column base is defined as the length of significant curvature localization zone \( L_{pc} \) in this work.

The influence of loading scheme on \( L_{pc} \) can also be found in Figure 5. It is clearly seen that the dividing point mentioned above moves away from the column base when the column is subjected to cyclic loading. In addition, the maximum curvature value increases from \( 6.67 \times 10^{-5} \) mm\(^{-1} \) to \( 7.74 \times 10^{-5} \) mm\(^{-1} \) when the lateral loading scheme changes from monotonic to cyclic. Both tensile strain and compressive strain contribute to curvature. Therefore, curvature concentration is caused not only by rebar yielding but also by concrete plastic deformation. Since both \( L_{sy} \) and \( L_{cs} \) of column under cyclic loading are larger than those under monotonic loading, as a result, \( L_{pc} \) are much larger for the column subjected to cyclic loading.
Figure 5 Curvature distribution of columns: (a) under monotonic loading and (b) under cyclic loading

Figure 6 Effect of length of FRP jacket on $L_{cs}$

Figure 7 Effect of confinement ratio on critical FRP length.

**MINIMUM JACKETING LENGTH FOR FLEXURAL RETROFITTING**

FRP was applied on the whole length of the columns in the above studies. However, it is not necessary for flexural retrofitting as FRP jacket is only needed in the plastic hinge zone. The length of concrete crushing zone should be known for design of retrofitting work. Figure 6 shows the effect of the length of FRP jacket on $L_{cs}$, where the FRP confinement ratio $\lambda$ is defined by

$$\lambda = \frac{f_i}{f_c} = \frac{2E_f e_{fu} f_i}{bf_c}$$

where $f_i$ is the confining pressure provided by FRP jacket; $b$ is the column depth. The length of FRP jacket is calculated from the column base. The dashed line is used to determine the minimum length of FRP jacket, referred to as the critical $L_{cs}$ in this work. A point on the dashed line means that FRP jacket length exactly equals $L_{cs}$. The points on the left side of the intersecting point between the dashed line and a curve mean insufficient FRP jacket length while the points on the right side indicate excessive jacket length. It can be seen from Figure 6 that $L_{cs}$ remains almost constant after the length of FRP jacket is larger than the critical $L_{cs}$. Considering that FRP jacket plays a role only when concrete significantly dilates or the axial strain of concrete exceeds 0.002, FRP jacket length needs to be only equal to the critical $L_{cs}$.

To validate the result, columns with full length jacketing are also shown in the figure. It is clear that the critical $L_{cs}$ is very close to $L_{cs}$ with full FRP jacketing and both decrease as confinement ratio increases.

**CONCLUSIONS**

This paper investigates the plastic hinge region of FRP-confined RC columns by the finite element method. The accuracy of the FEM model was first calibrated with test results. A systematic study was subsequently carried out to investigate the detail of physical plastic hinge regions, involving the rebar yielding zone, concrete crushing zone...
and curvature localization zone of FRP-confined RC columns. The plastic hinge lengths of FRP-confined RC columns under cyclic loading are larger than those of columns under monotonic loading. For flexural retrofitting of RC columns, FRP jacket needs only to cover the length of the concrete crushing zone, which is significantly affected by FRP confinement ratio.

ABSTRACT

Several studies available in the literature demonstrate that natural fibers can be employed in Externally Bonded (EB) Fiber-Reinforced Polymer (FRP) strips for strengthening existing Reinforced Concrete (RC) members. The study aims at demonstrating the feasibility of retrofitting RC walls by using Fiber-Reinforced Polymers with Flax fibers (FFRP). The study consists of an experimental campaign and some analytical evaluations, the latter being intended at determining the evolution of relevant damage indices during the cyclic loading process. The behaviour observed in the tests on RC walls strengthened by FFRP are compared with both a reference wall and similar specimens strengthened with more conventional composite materials (i.e. Carbon-FRP, CFRP). The test results show that FFRP have the potential to be used for seismic retrofitting as a viable alternative to more common FRP materials and other traditional techniques. Indeed, RC wall specimens strengthened with FFRP show strength increases up to 150% and a ductility gains equal to about 30%. Moreover, the tests show that the walls strengthened by FFRP generally dissipate more energy than the ones strengthened with CFRP: this is an important property for seismic strengthening and retrofitting of existing RC structures.

KEYWORDS

FRP, RC walls, seismic strengthening, natural fibers, flax fibers.

INTRODUCTION

In recent years, seismic codes and guidelines have undergone a progressive evolution, driven by both earthquake engineering and materials technology. Since a couple of decades ago, reinforced concrete (RC) structures were simply designed for resistance (Antoniades et al. 2005; Brun 2002) and no attention was placed on displacement capacity and ductility under seismic actions. Therefore, existing structures do not meet the requirements of seismic capacity design and are generally in need for strengthening and retrofitting. Reinforced Polymer (FRP) strips, mainly made with either carbon (C) or glass (G) fibers, have demonstrated to be a viable retrofitting solution for increasing both force and displacement capacity. However, more innovative composites based on employing natural fibers, such as flax ones, are emerging as a promising alternative, featuring similar mechanical behaviour and enhanced sustainability properties.

This paper presents the experimental results obtained on RC walls strengthened with Flax-Fiber-Reinforced Polymer (FFRP) strips externally bonded (EB) to the concrete surface via epoxy resins. More specifically, it reports the results of the tests carried out on strengthened RC walls subjected to horizontal cyclic actions experimental results allow assessing the consequences of alternative arrangements of FRP strips applied on five of the tested specimens, also in comparison with the performance observed on the unstrengthened one assumed as a reference. This comparison is not only carried out in terms of cyclic and envelop force-displacement curves, but also by determining the evolution of well-known damage indices describing the energy dissipation capability under cyclic actions. Moreover, the results obtained on FFRP-strengthened walls are compared with the one obtained in similar tests carried out on RC walls externally strengthened by CFRP strips. Therefore, Section 2 describes specimen characteristics and preparation process, along with the adopted testing and measurement methods. Section 3 summarises the experimental observations and Section 4 proposes the aforementioned analyses in terms of damage.
EXPERIMENTAL DETAILS
Specimens and test description

Figure 1 depicts the main geometric properties and structural details of the tested RC walls: they are similar to the ones tested by Greifenhagen and Lestuzzi (2005) and are slender in shape, with a height-to-width ratio $H/L$ slightly higher than 2.5. Moreover, the chosen dimensions ideally correspond to a 1/3 scaled wall.

The internal steel reinforcement conforms to the minimal recommendations of Eurocode 2 (CEN, 2004). The overall dimensions of walls, steel reinforcement and the properties of materials (steel and concrete) are similar for all specimens. Hence, only the composite strengthening configuration differentiates the specimens (Table 1).

</table>

The RC wall referred to as SL3 was not strengthened and, hence, it can be assumed as a reference. Conversely, the two walls SLR4 and SLR6 were strengthened by high-strength bidirectional strips of a wet lay-up CFRP system. The matrix used is epoxy type, cured at room temperature; moreover, CFRP is characterized by a modulus of elasticity equal to 105 GPa, and an ultimate strength of 820 MPa, determined for a nominal thickness of 1 mm. The other three walls (referred to as FRSL1, FRSL2 and FRSL3) were strengthened by unidirectional FFRP strips, whose modulus of elasticity is about 14.0 GPa, whereas the ultimate strength is around 120 MPa. It is worth highlighting that the FRSL3 also includes a bi-directional glass fabric, whose elastic modulus and ultimate strength are 9.0 GPa and 135 MPa, respectively. Concrete is nominally identical for all the walls: an average compressive
strength of 30 MPa was determined experimentally on samples of the materials constituting the RC walls. Figure 2 depicts the geometric layout of the various arrangements of FRP strips employed in the tested specimens.

Instrumentation and experimental protocol

The walls were tested under a constant vertical load of 90 kN, applied by an actuator, and a cyclic horizontal action, applied at a constant rate of 30 mm/min. The load procedure, taken from the literature (Inoue et al. 1997; Ile 2000) consisted of a sinusoidal load history whose amplitude grows of 1 mm every three cycles (Figure 3). As for measurements, 4 LVDTs were employed for monitoring the occurrence of possible undesired sliding or lifting of the wall specimen. Moreover, 2 LDVTs were placed along the diagonals to verify the length changes under tension or compression during the application of the cyclic action. Finally, some strain gauges were bonded on both internal steel reinforcement and externally bonded FRP strips.
RESULTS

Figure 4 reports the cyclic load-displacement curves obtained in some of the experimental tests: the two graphics document the hysteretic curves of specimens SL3 and SLR6 and, hence, it allows a first qualitative comparison between the reference specimen (SL3) and one of the CFRP-strengthened walls (SLR6).

Therefore, Figure 4 allows understanding the effect of CFRP strengthening and the corresponding enhancement the original cyclic response obtained on the reference specimen. Figure 5 highlights the difference among the responses of all tested specimens in terms of envelop curves.

The following Table 2 summarizes the main relevant quantities measured in the six experimental tests. They clearly show the effectiveness of the composite reinforcement, as load capacity increases by at least 30%. FRPR strengthening is even more effective, as the increase in resistance is about 100% (FRSL1/2) or even 140% (FRSL3). Moreover, displacement capacity is also influenced by FRP strengthening. More specifically, two kinds of behavior were observed: on the one hand, RC walls strengthened by CFRP strips collapse at displacement levels lower than the reference specimen; conversely, on the other hand, an increase of up to 30% (FRSL3) was observed for FFRP-strengthened walls. Therefore, under the seismic point of view, the FRP configuration adopted in specimen FRSL3 has a great potential for applications in seismic retrofitting: in fact, the GFRP sheet placed on the lateral face of the RC wall (Figure 2) makes it possible to bridge cracks opening in concrete between the longitudinal FFRP strips.

$X_u^-$: maximal value in push, $X_u^+$: maximal value in pull

Figure 6 Failure observed during test
Finally, CFRP strips failed due to either peeling from concrete (SLR6) or pulling of external anchorage (SLR4). The strain measurements on CFRP show a effectiveness of about 30%. As for FFRP strengthening, recorded deformations show full utilization of composite, resulting in tension failure (red circle in Figure 6).

ANALYSIS AN DISCUSSION

Stiffness analysis

Stiffness degradation can be observed in the experimental tests as the maximum displacement grows up and the number of cycles increases (Figure 4). This is witnessed by a progressive reduction in slope of the load-displacement response both in the reloading and unloading phases. In fact, the mechanical properties of materials tend to decrease, as damage develops within the tested specimen. For instance, cracking of concrete causes a loss in the monolithic structure of this material, which may also be interpreted as a reduction of the effective flexural stiffness of the cross section.

The evolution of stiffness during the cyclic load protocol was quantified by determining the average stiffness for each group of three equal cycles imposed for each displacement amplitude (Figure 3). Figure 7 shows these stiffness evolutions observed in the three walls strengthened by FFRP. Stiffness drops very quickly for both the reference walls and the three walls reinforced by FFRP. However, at the maximum displacement recorded for the unreinforced wall, the residual stiffness of FFRP strengthened walls is about three times the value determined for the reference specimen.

![Figure 7](image1.png) Evolution of stiffness in walls: reference and FFRP strengthened RC walls

![Figure 8](image2.png) Evolution of cumulative elastic energy: reference and FFRP strengthened RC walls.
Dissipated energy analysis

For each specimen, elastic and dissipated energies can be defined by processing the hysteresis curves recorded during the experimental test (Dazio et al. 1999). Figure 8 reports the evolution of cumulative elastic energy and shows that FFRP strengthened specimens (and, particularly, FRSL3) result in significantly higher values of this quantity, which, in order word, means a lower damage.

The comparison between the performance of CFRP- and FFRP-strengthened RC walls, already proposed in terms of force-displacement curves, may be further analyzed in terms of dissipated energy during the cyclic load process. Figure 9 shows that FFRP strengthened walls (FRSL3) are fairly more efficient in terms of dissipated energy (also in cumulative terms) than the corresponding CFRP strengthened specimens (SLR4).

Figure 9 Evolution of energy of walls reinforced by flax fibers FSLR3 and carbon SLR4

CONCLUSION

This experimental study investigated the cyclic response of RC walls externally strengthened by FRP strips with the main aim to compare the performance of more conventional carbon-based solutions, with more innovative ones based on using natural fibers made of flax. Besides the clear enhancement in sustainability, FFRP demonstrated several advantage in terms of mechanical performance. They may be summarized in the following:

- FFRP have shown increases up to 150% in resistance, which are similar to the effects observed on CFRP-strengthened RC walls;
- moreover, the former often led to an increase in displacement capacity (close to 30% for the specimen FRSL3, in which FFRP and GFRP were employed jointly); conversely, the response of CFRP-strengthened RC walls was generally less ductile than the one observed for the reference specimen;
- furthermore, the cyclic response of FFRP-strengthened walls was less affected by the progressive degradation in stiffness and energy dissipation that is typical in existing RC structures;
- therefore, RC walls externally strengthened by FFRP (and especially the specimen FRSL3) have a more dissipative response, which is an important property for seismic retrofitting.

Finally, these results demonstrate that FFRP is a competitive alternative to more conventional solutions based on using C- or G-fibers and, hence, further efforts are justified for advancing knowledge on this materials and their interaction with existing materials and members, toward the formulation of sound seismic design formulae.

ABSTRACT

The purpose of this study was to investigate the hysteretic behavior of shear deficient reinforced concrete (RC) walls that were strengthened with carbon fiber reinforced polymer (CFRP) strips. Totally, ½ scale five specimens with 1.5 aspect ratio walls were constructed. One of them was tested without any retrofitting as a reference specimen and four of them were retrofitted specimens with CFRP strips. All of the specimens were tested under cyclic lateral loading. CFRP strips with different configurations were tested like X-shaped, horizontal and parallel strips or combinations of them. All of the CFRP configurations were symmetrically bonded to both sides of the shear wall and were anchoraged to the wall. The research focuses on the effect of using CFRP strips for enhancing strength and increasing ductility of the non-seismic detailed shear walls. Test results shows that all of the CFRP strip configurations significantly improves the lateral strength, energy dissipation and deformation capacity of the shear deficient RC walls. The specimen that was strengthened with X-shaped CFRP strips was failed with premature shear failure. The specimen that was strengthened with horizontal strips was showed flexural hysteretic behavior and plastic hinge was developed at the wall base. CFRP strips were controlled shear crack propagation and resulted in improvement of displacement capacity.

INTRODUCTION

In earthquake resistant design, shear walls are common lateral load resisting systems found in many reinforced concrete (RC) structures. Limited numbers of RC shear walls are in use at older buildings. A number of buildings were found with walls having cross sections with relatively small aspect ratios \( h/l \), \( h \) = wall height, \( l \) = wall length, which in some cases resembled like elongated rectangular columns. These buildings survive from the earthquake with minor damages at structural framing system, but major damages at the masonry walls. Poorly designed and detailed shear walls in these buildings that are damaged with diagonal shear cracks, survived from the earthquake, and saved the structure. The shear walls of the numerous existing buildings have number of design and construction detailing deficiencies such as poor or no confinement of boundary element with enough reinforcement, poor or no bonding of the transverse reinforcement to concrete, and inadequate shear strength for preventing development of hinging. Consequently, strengthening for improving the shear capacity of the RC walls became more of a concern in the area of seismic design for RC structures (Saatcioglu et al., 2001). Researches on the strengthening of RC walls by FRP sheets are few in number. One of the firstly performed experimental study on the strengthening of RC walls is the application of FRP sheets with fibers to the wall sides in the vertical direction against the cyclic shear and flexure (Lombard et al., 2000), and the other one is the application of different configurations of externally bonded FRP reinforcement to wall like columns under uni-axial compression (Lombard et al., 2000; Neale et al., 1997). There are some other studies like the application of wing walls to RC columns and the application of unreinforced concrete infill walls (Iso et al., 2000; Sugiyama et al., 2000). Even though the strengthening of shear deficient reinforced concrete walls using FRP strips is an easily applicable and practical technique; there is a lack of information in the literature about the subject such as strip layout can be more effective on the hysteretic behavior. The main focus of the present research is the experimental analysis of the proper CFRP strip configurations for improving the hysteretic behavior of shear deficient reinforced walls under lateral loading. The goal of the retrofitting is to improve the shear strength, ductility and energy dissipation of the poor detailed RC walls. In the study, shear deficient RC walls are strengthened by four different configurations of CFRP strips and are tested under cyclic lateral loading. The different configurations of CFRP strips are cited as follows; the
lateral strips, X-shaped strips, combination of X-shaped and lateral strip, and combination X-shaped and parallel strips (Altun et al., 2013).

EXPERIMENTAL STUDY

Five shear deficient, $\frac{1}{2}$ scaled RC wall specimens were constructed and tested at the laboratory for investigating the influence of shear strengthening that were achieved by using four different CFRP configurations on the hysteretic response of structural walls. Dimensions and reinforcement details of the test specimens are given at Figure 1. Wall length, height and thickness are $l=1000$ mm, $h=1500$ mm, and $t=100$ mm, respectively. The aspect ratio of the wall ($h/l$) is 1.5. Vertical and lateral reinforcement ratios of the wall are $\rho_v=0.0183$ and $\rho_h=0.0015$, respectively. In addition, each of the lateral reinforcement in the wall is anchored by 90 degree hooks at the ends of the wall and there are no boundary members at the sides of the walls to simulate the poor details in the existing structures.

Specimen 1 was the reference specimen that was tested without strengthening. The other four specimens (Specimens 2, 3, 4 and 5) were tested after strengthening with four different configurations of CFRP strips. CFRP strips were symmetrically applied to both sides of the concrete wall. The detailed descriptions of applied CFRP configurations are given in Figure 2. All of the CFRP strips were anchoraged to the concrete wall by fan type of anchorages. The distances between the anchorages were 300 mm and 270 mm for lateral and diagonal strips, respectively. The photographs of fan type anchorages are presented in Figure 2. In the experimental study, specimens with low compressive strength were constructed to represent the concrete strength of the existing old buildings. The concrete strength of the test wall was approximately 15 MPa on the day of testing. Properties of reinforcement, CFRP and resin that are used in specimen are given in Table 1 and Table 2, respectively.

The test setup, loading system, and instrumentation are shown in Figure 3. Specimens were tested under cyclic lateral loading. Each specimen was loaded laterally as a vertical cantilever with forces applied through the top beam. No axial load was applied to specimens. In the instrumentation of the specimens, strain gauge based linear variable differential transformers (LVDTs) were used for displacement measurements. Additionally, strains in the CFRP strips were measured using strain gauge. Strain gauge locations were given in Figure 2.

Figure 2 Strengthening Schemes of Specimens and Anchorage Details (Dimensions in mm.)

Figure 3 Test Setup and Instrumentation of Specimen (Dimensions in mm.)
EXPERIMENTAL RESULTS

Response envelopes for specimens shown in Figure 4 are plotted by connecting the peak points of the base shear-top story displacement hysteretic curves for each specimen. As can be seen from this figure lateral displacement, lateral load carrying and energy dissipation capacities were significantly increased. Fan anchorages were prevented the premature debonding of CFRP strips from the wall surfaces. Hence, CFRP strips were controlled the widening of the shear cracks and lateral displacement significantly increased. Shear sliding deformation was not observed during the tests. Test results are summarized in Table 3. Initial stiffness was defined as the initial slope of load displacement curve of the first forward half cycle. The stiffness at the ultimate load was defined as the average of the slopes of linear lines connecting the ultimate loads with the origin of load displacement curves in the forward and backward half cycles. The ductility ratios of the specimens were calculated by using the ratio of lateral displacement that are measured at the first yielding of vertical reinforcements of wall side to the displacement that are measured at the point where the ultimate flexural shear capacity decreased to 85%. The area under the hysteresis loops can be used as a measure of the energy dissipation capacities. Energy dissipations capacities were determined by calculating the areas inside the hysteretic load-displacement curves for each of the specimens. The cumulative energy dissipation capacities were defined as the sum of the area enclosed by all hysteresis loops.

The photographs of specimen after failure are presented in Figure 5. Reference specimen 1 was failed due to premature shear failure due to concentrated shear cracks along both of the diagonals of the wall. Specimen 2 was reached its flexural capacity and showed a ductile flexural behavior. Vertical reinforcements on the wall sides of Specimen 2 were yielded when lateral displacements reached to 0.78% and 0.86% drifts during forward and backward loading, respectively. Plastic hinge was developed at the base of the wall. Concrete cover was crushed over the base under compression forces. Specimen 3 was failed due to shear before reaching its flexural capacity. Shear cracks were concentrated through the diagonals of the wall and these cracks were reached to the wall corners with the increasing lateral load. The concrete cover was crushed at the bottom corners of the wall. The concrete was crushed at the bottom corners of the wall under the compressive stresses caused fan anchorages to be damaged. Specimen was failed due to premature shear.

Specimen 4 was reached its flexural capacity. The vertical reinforcement at the wall sides were yielded when 0.82% and 0.90% lateral drift ratios were reached during forward and backward loading, respectively. Diagonal CFRP strips were debonded from the wall surface between the anchorages with the increased lateral drift cycles. Shear cracks were concentrated through the diagonals of the wall. Specimen 4 was failed with shear failure. Specimen 5 was reached its flexural capacity. The vertical reinforcement at the wall sides were yielded when 0.82% and 0.84% lateral drift ratios were reached in the forward and backward cycles, respectively. The CFRP strips were ruptured at the lateral drift ratio of 2.5%, and the lateral load carrying capacity suddenly decreased. Specimen was collapsed with the shear failure.

Lateral strengths of all strengthened specimens were significantly increased compared to the reference specimen. Ultimate flexural shear strengths of the strengthened specimens were 1.54-1.67 times greater than that of the reference specimen. The strengthened specimens 2, 4 and 5 were reached the flexural capacity with almost the same lateral stiffness and were showed a ductile behavior. A specimen 3 displacement capacity was remained restricted due to premature shear failure. After reaching the 18% (on the average) of the nominal flexural strength, the lateral stiffness was decreased at the specimens. However, CFRP strips were restricted the widening of shear cracks on the wall.

![Specimens after Failure](image)

Even though the similar strengthening configurations were used at Specimen 3 and Specimen 4, they were showed completely different hysteretic lateral behavior than each other. Specimen 4’s wall lateral displacement was significantly increased due to the increase in concrete ultimate strain at the lower and upper parts of the wall under compression forces. The initial stiffness of the reference specimen was 47.6 kN/mm. The initial stiffnesses that were measured for the strengthened specimens were obtained slightly greater than the reference specimen. The average of strengthened specimens’ initial stiffnesses was 56.7 kN/mm. Shear cracks were caused significant drop at the lateral stiffnesses. The average of measured lateral stiffnesses of the specimens was 17.9 kN/mm at the ultimate load. At the ultimate load, the averages of initial stiffnesses were decreased 106%. Specimen 1 and 3 were showed non-ductile, Specimen 2, 4 and 5 were showed ductile hysteretic behaviors. Ductility ratios were measured as 3.47, 2.70 and 3.05 for the Specimen 2, 4 and 5, respectively. Energy dissipation of the strengthened specimens was significantly larger than that of the reference specimen. The ratio of energy dissipation capacities of strengthened specimen to that of reference specimen changes in between 2.69–5.15. Among the strengthened specimens, the lowest energy dissipation capacity belongs to Specimen 3, and largest energy dissipation capacity
belongs to Specimen 2. Specimen 4 and 5 consumes almost the same amount of energy. The ratio of energy dissipation capacity of Specimen 4 and 5 to that of the reference specimen is 4.34 on the average.

The typical examples of strain measurements taken from the CFRP strips during the tests are given in Figure 6. The mean of the maximum strains that were measured from lateral strips was 0.0090 mm/mm for the Specimen 2. The measured maximum strains from the diagonal CFRP strips were 0.00748 mm/mm and 0.00840 mm/mm for the Specimen 3 and Specimen 4, respectively. The measured maximum strain was 0.00813 mm/mm for the Specimen 5. Deformations and shear cracks that were developed on the wall were caused debonding of CFRP from the wall surface. The debonded CFRP fibers were remained under the influence of combined stresses along with the tensile stresses and therefore this combined stress were caused fiber ruptures before reaching the ultimate strain.

CONCLUSIONS

In this study, the hysteretic behaviors of strengthened shear deficient reinforced concrete walls by CFRP strips under the lateral loading are experimentally investigated. From this study, the followings were concluded:

1. The strengthening of shear deficient reinforced concrete walls by using CFRP strips was an effective technique. Usage of CFRP strips significantly improves the hysteretic behavior of shear deficient reinforced concrete walls under the cyclic lateral loading. The strip configurations were effective on the hysteretic behavior of strengthened wall and failure mode. The best performance for the improvement of lateral displacement capacity and lateral strength of shear deficient RC walls has been obtained from the strengthening with lateral strips. The wall strengthened by lateral strips is showed a ductile flexural hysteretic behavior and at the base of the wall plastic hinge has been developed. Although the X-shaped strips is increased the wall shear strength, they are not enough to reach the flexural capacity. In the walls strengthened by X-shaped and lateral strip combination, and X-shaped parallel strips, flexural capacity has been reached.

2. CFRP strips are not effective on improving the initial lateral stiffness of the specimens. However, restriction of the widening of shear cracks are developed on the wall by the CFRP strips are controlled the decrease in the lateral stiffness. Except the Specimen 3, all other strengthened specimens are reached flexural capacity with almost the same lateral stiffness.

3. Specimens that are strengthened by lateral and X-shaped CFRP strips (Specimen 2 and 5), a significant decrease in the flexural strength of the specimen has not been observed till 2.0% lateral drift. The displacement capacities of the specimens have been improved by the applied strengthening technique without causing any significant decrease in their load carrying capacities.

4. The strengthened specimens are dissipated much more energy than the reference specimen. The ratio of energy dissipation of strengthened specimens to that of the reference specimen has been changing in between 2.69 and 5.15.

5. Fan anchorages are prevented the debonding of the CFRP strips from the reinforced concrete wall. As a result of prevention of debonding of CFRP strips totally by the anchorages, the tensile forces of the strips are provided the load carrying capacities to continue till reaching considerable lateral displacements. The maximum strains are measured on CFRP strips were 0.008-0.009 mm/mm.

ABSTRACT

The application of Fibre Reinforced Polymers (FRP) in strengthening and retrofitting of existing structures has emerged as a practical and efficient technique compared to the application of conventional materials (i.e. steel and concrete). In the case of flexural strengthening of beams, the FRP strengthening can be categorized into two main systems, the passive and the active system. The passive system doesn’t involve any prestressing to the FRP material; consequently, the passive system has minimal impact on the performance of the beam at the service conditions. On the other hand, the active strengthening involves the application of prestressing force to the FRP material, which consequently improves the beam performance at the service conditions. The challenging part of the active system is the application of the prestressing force to the FRP material. This paper presents the developments in the area of prestressing methods of FRP materials for flexural strengthening of steel and concrete structural members (beams and slabs). Several types of prestressing systems are presented with the focus on the prestressing systems where the FRP is prestressed against the member itself. The systems include prestressing of FRP materials, either as externally bonded sheets and strips at the surface of the RC beams or slabs and steel beams or as Near-Surface Mounted (NSM) strips and bars in the case of RC beams.

KEYWORDS

Active, passive, FRP, prestressing, NSM, anchorage, sheets, strips, gradient.

BACKGROUND

The high strength-to-weight ratio, corrosion resistivity and easiness of handling, are the main advantages of the FRP material compared to the conventional structural material, which made the FRP as the material of choice when it comes to strengthening and rehabilitation of concrete and steel structures. In the early applications of FRP strengthening, the FRP sheets/ strips were epoxy bonded to the tension face of concrete or steel beams and concrete slabs in a system known as Externally Bonded (EB). Later, the Near-Surface Mounted (NSM) system was introduced, where the FRP strips/bars are embedded inside a pre-cut groove in the tension face of the concrete beam filled with epoxy adhesive. Other systems have also been implemented such as the Mechanically Fastened (MF) FRP laminates or hybrid systems of MF and EB plates. Schematic of these system is shown in Figure 1. Most of the FRP applications were passive strengthening, where no prestressing force is applied to the material. In the passive system, the ultimate capacity of the strengthened beam is improved, however, it has minimal effect on the flexural behaviour at service loads. In other words, when the non-prestressed FRP is applied to the beam, the FRP will not be activated unless further deflection/load is induced to the beam (El-Hacha and Soudki 2013). In contrast, the active strengthening system with prestressed FRP enhances the flexural performance of the beam at service conditions by reducing deflection and cracking-in concrete members.–
Figure 2 shows the performance of RC beams strengthened with prestressed and non-prestressed FRP. The current paper presents a brief literature review on the mechanisms used to apply the prestressing force in the FRP material for flexural strengthening of structural steel and concrete members. More focus will be given to RC beams and slabs as most of the research on prestressed FRP was in this area.

**PRESTRESSING METHODS**

**Indirect prestressing method**

The methods used to apply the prestressing force to the FRP have evolved in the last two decades. In the early stages, researchers used an indirect system to induce the prestressing forces to the FRP material (El-Hacha and Soudki 2013). The system was first introduced at EMPA in 1992 (Meier et al. 1992, and Deuring 1993). Figure 3 shows a top view schematic diagram of the indirect prestressing system. The system involves inducing the required prestressing force to the FRP by tensioning the FRP against an external reaction frame independent of the beam until the epoxy cures. After the epoxy gains its strength, the prestressing system is released and the prestressing force is transferred to the concrete beam (Nordin et al. 2001, Nordin 2003, Casadei et al. 2006, Nordin and Täljsten 2006, Jung et al. 2007, and Wu et al. 2007). Yu et al. (2004) prestressed the FRP sheets against a steel beam before bonding the sheets to the concrete beam as shown in Figure 4. The indirect system has been criticized for the lack of practicality and the requirements for special tools and equipment.

![Figure 3 Schematic of the indirect prestressing systems (top view).](image)

**Direct prestressing method**

The direct system involves prestressing the FRP material against the beam itself directly without the need for external reaction frame. Unlike the indirect method, this system gained more acceptance in the research community and was superior over the indirect system for being more practical. Figure 5 illustrates the main features of this system. The system typically consists of a dead end, where the FRP material is connected to the concrete using anchorage plate, while the other end is the live end, where the FRP is pulled by a certain mechanism (mainly hydraulic jacks). It should be noted that recently El-Hacha and Hadiseraji (2014) substituted the hydraulic jacks with Shape Memory Alloy bars that worked as actuators. The FRP is prestressed as shown in Figure 5 and once the desired load is attained, the live end will be anchored to the concrete. Once the live end is anchored, the supplementary tools (the bearing plates and the loading tool) can be removed (El-Hacha et al. 2001, and Wu 2007). The FRP material in this system can be either NSM FRP strips/bars or EB-FRP plates/sheets.

![Figure 5 Schematic of the direct prestressing systems (top view).](image)
The earlier applications of the direct prestressing were used for prestressing EB-FRP laminates/sheets. Wight et al. (1996) and Wight (1998) used the direct system to strengthening 5 m long reinforced and prestressed concrete beams. The system was too laborious, as shown in Figure 6 consisted of round bar anchors that gripped the CFRP sheets that were then attached to anchors bolted to the sides of the beams.

Similar systems used by Izumo et al. (1997) and Saeki et al. (1997) as shown in Figure 7. Darby et al. (1999) developed a prestressing system for the strengthening of cast iron beams of the Hythe Bridge in Oxford. The prestressing system consisted of FRP plates connected to the end anchors which are clamped to the beams (without the need for drilling) as shown in Figure 8. This was the first steel structure to be strengthened with prestressed FRP sheets. El-Hacha et al. (1999, 2000 and 2001) developed an innovative system that consisted of a movable flat steel plate anchor bonded to the sheets at the jacking end and another fixed steel angle anchor bonded to the sheets at the dead end and mounted on the concrete beam permanent anchor. The FRP sheet was stressed using a simple hydraulic jacking assembly causing the sheets to be directly prestressed against the beam itself as shown in Figure 9. The system was slightly modified for strengthening pre-damaged continuous RC T-section as shown in Figure 10. Other modifications were made for the purpose of strengthening of one-way RC slabs (Wight and Erki 2001, and El-Hacha et al. 2003) as shown in Figure 20, and two-way RC slabs shown in Figure 12 (Longworth et al. 2004). Honorio et al. (2002) used the system in a field application at the Canadian Forces Base in Kingston, Ontario, to strengthen a prototype bridge constructed from 18.0m long prestressed RC girders as shown in Figure 13. The system was also used successfully in 2003, and for the first time in North America, for strengthening a highway bridge in Winnipeg, Canada, as shown in Figure 14. Another application using a similar system was carried out in the late 1990s (Garden and Mays 1999, Darby et al. 2000, Fallis et al. 2004, and Ford 2004).

Kim et al. (2004) proposed a steel anchor plates for prestressing multi-layered FRP sheets. (Franca et al. 2007) used a similar system on the both sides of T-section webs to avoid drilling the bottom side of the beam because of the narrow web width. Franca (2007) modified his system to have the FRP at the bottom face of the beam but still with using side plates without drilling in the bottom face of the beam as shown in Figure 15.

Figure 14 Strengthening of RC bridge girder using prestressed FRP sheets (Fallis, Eden et al. 2004)

Figure 15 The system developed by Franca (2007)
Many researches were carried out in the early 2000s on EB prestressed FRP plates/sheets which focused on the failure mechanisms, debonding issues, and other structural issue but there was no significant improvement on the prestressing methods. However, the development diverted to the NSM technique which started with the work of Al-Mayah et al. (2005) who used the direct system by tensioning the NSM CFRP bars against the ends of the beam. A hydraulic jack was used to tension the FRP bar against the steel wedge anchor. The system was used by other researchers with minor modifications (Badawi and Soudki 2006, Badawi 2007, Badawi and Soudki 2009). Figure 16 shows the general features of this system. This system required an access to the ends of the beams which is not practical in many cases. De-Lorenzis et al. (2002) suggested a direct system that can be used without needing the access to the sides or ends of the beam. The system consisted of threaded steel bar connected to the end of the FRP rod through a tube as shown in Figure 17. The force is applied to the FRP rod by manually rotating the steel nut. The drawback of this system is that the manually induced force (by tightening the nut), which is limited to lower values of prestressing forces. A breakthrough in the prestressing system was the work of Gaafar (2007). Figure 18 shows a schematic drawing of his system. The system was successfully used for flexural strengthening of the large-scale RC beam using NSM FRP bars and strips (El-Hacha and Gaafar 2011, Oudah 2011, Omran and El-Hacha 2014). The system was modified by El-Hacha and Hadiseraji (2014) by replacing the hydraulic jack with Shape Memory Alloy (SMA) bars as shown in Figure 19. The pre-strained SMA bars acted as actuators and the prestressing force was applied by activating the bars through heating. The same system was further modified by Hadiseraji and El-Hacha (2014) to apply a prestressing force to FRP sheets as shown in Figure 20.

**Modification to the direct system (Gradient anchorage method)**

The direct prestressing system -introduced earlier- requires end anchors to transfer the prestressing force to the concrete and to avoid premature peel-off failure. To avoid the use of anchors, while preventing the peel-off failure, the gradient anchorage method was developed at Empa (Stocklin and Meier 2001, Meier and Stocklin 2005, Motavalli et al. 2011). The system consists of two main units; the jacking unit that provides the desired prestressing force and a heating unit in front of it that accelerate the curing process of the epoxy resin. The system involves curing the resin before releasing the prestressing force. A mobile device cures the adhesive from the center of the laminate towards its ends. In such a case there is a control over the prestressing force over the length of the laminate,
and the amount of prestressing force is reduced towards the end of the prestressed sheet to reduce the risk of debonding as presented in Figure 21. The system was successfully used by Czadzierski and Motavalli (2007) for strengthening an RC bridge girder. The system was also used to strengthen RC slabs (Kotynia et al. 2011). Recently, the system was further improved by Michels et al. (2012 and 2013) to suit field applications as shown in Figure 22. Similarly, Monti and Liotta (2006) developed a system where the FRP is wrapped around a cylinder and the cylinder is mounted on a sliding car (Figure 23) that can move along the beam length and reduce the prestressing force towards the ends of the beam to eliminate the end debonding.

**Figure 21** Prestressing system developed by Meier and Stöcklin (2005).

**Figure 22** The system modified by Michels, Cruz et al. (2013)

**Figure 23** The system developed by Monti and Liotta (2006)

**Prestressing of steel girders (steel-concrete composites)**

Most of the FRP applications were used for strengthening RC structures and less work was done for steel structures. This is mainly attributed to the fact that the stiffness of the FRP material is relatively smaller than the steel; consequently, the FRP contribution in the flexural capacity of steel structures is relatively less than that for the less-stiff RC structures, unless high modulus FRP material is used to strengthen steel members. Nevertheless, prestressed FRP has been implemented in strengthening steel-concrete composite beams (Ragab et al. 2007). The first attempt to prestressed steel structure was done by Darby, Skwarski et al. (1999) as reported in the previous section. Prestressed CFRP strips were used to repair notched steel beam (Colombi et al. 2003, Zhou et al. 2013). Wipf et al. (2003) used post-tensioned CFRP rods mounted on the sides of the web of steel bridge girder. The CFRP rods we prestressed using a hydraulic jack bearing against a steel bracket bolted to the web of the beam (Figure 24). For flexural strengthening of steel-concrete composite beam Schncherch et al. (2005) used CFRP strips prestressed by the means of tightening threaded rods as shown in Figure 25. The fixed end consists of a tapered steel plate that is bolted to the beam and bonded to the CFRP while the Moveable end uses application of the load by fine-threaded bolts to prestress the CFRP. An anchoring system developed by Aly (2007) and El-Hacha and Aly (2013) was used to strengthen steel-concrete composite girders as shown in Figure 26. The system consisted of the fixed end anchor where a steel plate bonded to the FRP sheet is permanently bolted to the bottom flange of the beam, and movable end where a hydraulic jack was used to apply the prestressing force to the sheet.

**Figure 24** : Strengthening steel bridge girders with external post-tensioned CFRP rods (Wipf et al. (2003))

**Figure 25** The prestressing system developed by Schnerch (2007)

**Figure 26** Prestressing system developed by El-Hacha and Aly (2013)
CONCLUSIONS

This paper has presented a brief literature review on the development of prestressing systems for FRP flexural strengthening of beams and slabs. Most of the FRP prestressing applications were conducted on RC members and less work was done on steel members. The prestressing systems evolved from indirect system - where an external frame is used to prestressed the FRP before attaching it to the member - to a more robust direct prestressing system against the member itself, and the recent development of the gradient anchorage system which eliminates the need for end anchors. The NSM prestressed FRP become more favorable over the externally bonded prestressed FRP as it provides more protection to the FRP material and reduces the chances of debonding.

ABSTRACT

Since the early 1980ties it was the vision of Empa researchers to develop CFRP tendons for suspended bridges (Meier 1987) and for post-tensioning. The key issue was the development of a reliable anchorage system for CFRP parallel wire bundles. In 1996 there was a first real application with such an anchorage system for the CFRP stays at Stork Bridge in Winterthur. Two years later followed CFRP post-tensioning cables on the Kleine Emme Bridge as new construction and on the Verdasio Bridge as a rehabilitation project. The bicycle and pedestrian single span bridge over the River Kleine Emme near Lucerne was built in October 1998. The bridge deck is 3.8 m wide, 47 m long and has been designed for the maximum load of emergency vehicles. The superstructure is a space truss of steel pipes in composite action with the steel rebar reinforced concrete deck. The bottom chord, a tube of 355-mm diameter, was post-tensioned with two CFRP cables inside the tube. Each cable was built up with 91 pultruded CFRP wires of 5-mm diameter. The post-tensioning force of each cable is 2.4 MN. Therefore the CFRP wires are loaded with a sustained stress of 1350 MPa. The Verdasio Bridge in the south of Switzerland is a two-lane highway bridge and was built in the seventies. The length of the continuous two-span girder is 69 m. A large internal post-tensioning steel cable positioned in a concrete web was fully corroded. It had to be replaced in December 1998. Four external CFRP cables arranged in a polygonal layout at the inner face of the affected web inside of the box replaced the corroded steel cross section. Each cable was made up of 19 pultruded CFRP wires with a diameter of 5 mm. This project is as far most interesting as in this case the sustained post-tensioning stress on the cable cross sections is in average as high as 1806 MPa. The results of the long-term monitoring are for both examples excellent and prove especially the high reliability of the CFRP anchorage system.

INTRODUCTION

World’s first application of carbon fibre reinforced polymers (CFRPs) in construction happened at Ibach Bridge near Lucerne in 1991 (Meier 1995). At that time, Empa full scale laboratory experiments proved already the feasibility of the application of pre-tensioned CFRP strips for post-strengthening (Deuring 1993). Pre-tensioned CFRP strips make much better use of the high strength of the expensive material. However the responsible building authorities estimated the risk of a failure as too high. Therefore “only” not pre-tensioned, loose CFRP strips had been applied. This application still performs perfectly well after a quarter of a century. Meanwhile pre-stressed CFRP strips have also been accepted in practice (e.g. Motavalli et al. 2011, Kotynia et al. 2015, Ghafoori et al. 2015). Beside pre-stressed CFRP strips Empa research has been focused since the early 1980ties (Kim and Meier 1991) on CFRP parallel wire tendons and for this purpose on the needed anchorage systems as described e.g. in Meier 2012.

CFRP CABLES IN REHABILITATION: EXAMPLE VERDASIO BRIDGE

Damaged State in 1997

The road bridge over Ri di Verdasio in Intragna, Switzerland was designed as a two-span reinforced concrete box girder with spans of 31.4 and 37.6 m (Figure 1). The height of the central support is 25 m. The two lane roadway is 6 m wide. The two spans of the single-cell box girder are completely pre-stressed with 6 and 8 steel tendons respectively. After only 14 years' service, a routine survey (Guidotti et al. 1999) revealed serious damage, above the "usual" wear and tear. The deck drainage pipes, which are offset by approx. 2 m on the valley side and pass through the cantilever plate at the top of the corbel, were too short and leaky. At these points, salty water ran from the roadway through the cantilever plate, along the underside of the plate, over the web and around the corner to the underside of the box girder. Deposits and traces of corrosion matching the pattern of the deck drains were
visible. A thorough investigation revealed chloride contents, relative to the mass of cement, of up to 2.8 weight % at the level of the steel reinforcement and of up to 2.0 wt.% at the level of the post-tensioning members. Chlorides penetrated up to 12 cm into the web. An exploratory window at the low point of the steel post-tensioning cables on the Locarno side, revealed the following damage: the steel reinforcement exhibited localised cross-sectional losses of up to 100%. Once the corroded cable duct had been opened, the bottom exterior steel cable showed considerable traces of pitting corrosion, which was confirmed at six further points, while the remaining three cables were still intact despite the elevated chloride content. The load-bearing safety of the bridge was verified assuming failure of both the corroded cable and a second cable and taking account of locally corroded reinforcing stirrups. Primarily due to the spare load-bearing capacity created by the complete post-tensioning, the load-bearing safety of the bridge could still be proven even in this critical state. The bridge was thoroughly overhauled in order to prevent any further progress of the corrosion which was already under way and to protect the still intact post-tensioning cables from corrosion. Although load-bearing safety could still have been guaranteed even if the corroded steel cable had failed, the bridge owner specified that the original load-bearing capacity of the bridge be re-established. The load-bearing capacity of the corroded cable on the valley side was to be replaced by external post-tensioning tendons passing through the bridge box.

Figure 1 Verdasio Bridge: Photo from Camedo side, longitudinal section and cross section

Rehabilitation with Four CFRP Cables

The required bridge retrofitting was provided with four CFRP parallel wire bundles (cables) in a polygonal arrangement (Fig. 1). Deflecting CFRP cables has in the past been considered a critical factor due to the sensitivity of the CFRP wires to shear and transverse stresses. The Ri di Verdasio Bridge was the first opportunity to use CFRP tendons as external post-tensioning cables since the successful completion of Empa's series of investigations with deflected CFRP parallel wire bundles (Maissen 2000). The parallel wire bundles were assembled by Empa and BBR Ltd. personnel in the Empa laboratories and supplied to the construction site in reel form. Four CFRP tendons, each comprising 19 CFRP wires of 5 mm in diameter, as had also been tested in the stated investigations, were used. Larger units could not have been used due to the restricted space available for the anchorages in the abutment chambers. At a degree of post-tensioning of 65%, an initial nominal tensile force of 4 x 600 kN is obtained. This corresponds to a nominal stress of 1610 MPa in the CFRP wires. The four CFRP tendons are arranged in the bridge box, on the inside of the valley side web, adjacent to each other and following a polygonal path over the entire length of the bridge (Fig. 1, longitudinal section). The external diameter of the polyethylene sheath is only 32 mm. These sheaths were not injected with mortar. The tendons are provided with tensionable anchorages on both sides. The cables are each deflected twice at approximately the third points of the span and over the pier using custom made deflectors. These deflectors comprise curved steel half-tubes and the minimum radius of deflection is 3.0 m. This radius is exactly the same as used in the full scale experiments (Maissen 2000) over the support in the centre of the girder. On site, the deflection points were concreted into the boxes through holes drilled in the roadway plate. In this way, the cables could be introduced from beneath. The deflection point over the pier initially required a hole to be drilled in the solid cross girder so that the cable and anchorage could be drawn through. The deflectors were then inserted into the hole and concreted in. Holes were also drilled in the transverse abutment beams. Transfer of the cable forces also required additional reinforcing columns to be concreted in. Lining tubes were inserted into the holes drilled in the abutment and the new columns which allowed the anchorage heads and cables subsequently to be drawn in. The CFRP tendons were then drawn into the bridge boxes through an oblique hole only 150 mm in diameter drilled in the roadway, placed in the correct position and tensioned in two stages. In medicine one would speak about a non-invasive surgery. Given the confined space in the boxes and in the abutment chambers, the low weight of the cable considerably simplified handling. The CFRP cable weighs only one fifth the amount of an equivalent steel cable.
Long-Term Monitoring

The cable force on the installed four CFRP cables is measured at each of the eight terminations with load cells based on resistance strain gauges (RSG). The load cells were calibrated in a testing machine at Empa. The scatter of this calibration showed a bandwidth of 1% of the effective forces (Anderegg et al. 2014). This accuracy is sufficient to measure relevant changes of the post-tensioning forces. The coefficient of thermal expansion for the CFRP tendons is about zero or even slightly negative. In summertime, when the temperature is high, the concrete of the bridge girder expands. Due to that the CFRP cable force is increasing. In winter it is opposite (Fig. 2). Most remarkable is that the trend lines of all cable forces are in average increasing over the observed period of time for 7.2% (Fig. 3). With steel cables one could expect a loss due to stress relaxation of steel in this range (Müller and Zetterholm 2002). The average temperature increase from 12.6 to 13.6°C (Fig. 4) might be one reason for the increase of the post-tensioning forces. However it is difficult to explain the strong increase of the force at anchorage socket 7 of cable No. 3 from 747 to 945 kN (+27%). Within the last three measurements it did no longer following the upwards trend, it is now stable at 910 kN (2440 MPa). But there is a need to check the force in the socket No. 7 soon. Interesting is that for the same cable No. 3 on the other side the force in socket No. 5 increased only from 534 to 552 kN. If the force measurement in socket No. 7 is correct, there must be such a high friction around the deviation saddles that does not allow equilibrium of the forces in cable No. 3.

![Figure 2](image2.png)  
**Figure 2** The post-tensioning force [kN] of the anchorage socket No. 3 (solid line with vertical axis left) correlates with the seasonal temperature fluctuations (dashed line with vertical axis right) versus time.

![Figure 3](image3.png)  
**Figure 3** Trend lines of the post-tensioning forces [kN] (vertical axis) of all eight anchorage sockets versus time. The average post-tensioning force for all four cables is today 674 kN (1806 MPa).

![Figure 4](image4.png)  
**Figure 4** Trend lines for the temperature [°C] measured at the meteo station in Lugano near the bridge.

![Figure 5](image5.png)  
**Figure 5** Relative displacements [mm] between load transfer media and cone of socket (vertical axis) versus time. The upper two creep curves belong to the sockets No. 1 and 4. The middle line is representing socket No. 2 and the bottom line socket No. 3.

The results of the measurements of the relative displacement between the cones of the anchorage sockets and the gradient load transfer media given in Fig. 5 are very satisfying. There is, except for the first year, no creep. The
data is representative for all eight anchor heads. This is the most important outcome of the Verdasio Bridge full scale long-term pilot project.

**CFRP CABLES IN NEW CONSTRUCTION: EXAMPLE KLEINE EMME BRIDGE**

**Geometry and Loading**

The single span girder of the 47 metre long cycle/foot bridge over the Kleine Emme River near Lucerne was post-tensioned with two CFRP tendons passed through the lower chord tube (Fig. 6). This bridge was prefabricated on site, post-tensioned and set in place as a single 130 tonne structure using a mobile caterpillar-tracked crane (Burkhardt et al. 1999). The girder performs the function of both a compressive arch and a tension tie. The solid concrete slab, up to 25 cm in thickness, constituting the compressive arch simultaneously bears longitudinal and transverse loads. The tension tie consists of a steel tube (355.6 x 30 mm) with internal CFRP post-tensioning cables. The lattice struts are of the same profile as the lower chord (ROR 139.7 x 10 to 16 mm) and arranged in a V-shape both longitudinally and transversely. While the inclination is a constant 45° in the longitudinal direction, it varies between 65° and 35° in the transverse direction as the height decreases. The connection to the concrete slab is provided in the upper truss joints by gusset plates and cross members (horizontal connection of the upper chord joints with 200 x 100 x 12 mm angle plates). To ensure stability, the upper chord is pegged to the concrete plate over its entire length. The design of the support reflects the strut geometry and, as a closed box, unites the truss structure with the support plate. Both during construction and after completion, the support box transfers the forces from the bridge bearings and eccentric post-tensioning member into the pegged concrete slab.

![Figure 6 Kleine Emme Bridge](image)

**Long-Term Monitoring**

This structure saw the first use of CFRP post-tensioning cables with fibre optic sensors integrated into the CFRP wires. Two CFRP-cables each with 91 wires of 5 mm diameter were installed inside the tube of the lower chord. Each cable was post-tensioned with 2400 kN, which corresponds to a nominal stress level of approximately 1350 MPa, corresponding to a high strain level of about 8500 μm/m on the CFRP-wires. It was of great interest to monitor the wire strains not only in the free part of the cable, but also within the anchor head. To transfer safely such high strains into the cone of the anchor head it was designed to smoothly decrease the strain in the wires from the load side to the end of the termination and to avoid stress concentration on the load side (Meier et al.2013). Fibre Bragg gratings (FBGs) inside the head allowed for the first time this design to be verified (Fig. 7). To measure the strains in the wires the FBGs were directly embedded into the CFRP-wires during the industrial pultrusion process - the first application of this kind. The directly embedded FBGs allowed locating them inside the anchor, and hence to acquire the important information about axial strain distribution during the production- and post-tensioning phase as well as during the long-term operation. In the case of this bridge, 8 of 21 FBGs failed due to high strain levels in combination with an embedding process that should be optimized. The failures occurred outside the anchor heads. Many of the resistance strain gauges (RSGs) initially attached on the wires in the free part of the cable failed already during the post-tensioning process. Therefore, additional RSGs were fitted on the steel anchor heads—to obtain redundant information about force variation (Fig. 7). Similar to the situation at the Verdasio bridge there is also in the case of Kleine Emme Bridge a strong correlation between temperature cycles and the cycles of the post-tensioning force. Opposite to Verdasio Bridge there is at Kleine Emme Bridge no increase of the average forces. The trend line for the continuously measured forces is horizontal (Fig. 8). Similar like in Fig. 5 there is also for the anchorage heads of this 91-wire parallel wire bundles beside the first two years no creep. This is the most important outcome of the Kleine Emme Bridge full scale long-term pilot project.
Figure 7 Longitudinal section of the anchor head with RSG and FBG sensors on the steel sleeves and the CFRP wires inside and outside of the anchor head.

Figure 8 The post-tensioning force [kN] of a 91-wire cable of Kleine Emme Bridge (red line with vertical axis left) correlates similar like in Fig. 2 with the seasonal temperature fluctuations (blue line with vertical axis right) versus time. Opposite to Fig. 3 the trend line (dashed horizontal red line) shows no increase of the post-tensioning force. The average post-tensioning force of 2410 kN is well matching the nominal force of 2400 kN (1350 MPa). Similar to Fig. 4 there is also an increase in temperature (dashed blue line).

CONCLUSIONS

On the described two bridges, post-tensioning forces and displacements were measured with different measuring techniques. Well-established RSGs and LVDTs as well as newly developed FBG sensors have been in service for 18 years. To obtain information regarding the long-term reliability, reference sensors and redundant sensing systems have been installed, allowing one to differentiate between sensor drift and changes in the performance of the CFRP-cables. Additional long-term laboratory experiments have helped to validate sensing systems. Well planned sensing systems, verified methods and careful installation resulted in reliable long-term monitoring systems needed to proof the long-term reliability of CFRP cables. This allowed to demonstrate the very high reliability of the CFRP tendons under high stresses over a period of 18 years. The key element for the development of such tendons was from the beginning the anchorage system. With the development of a gradient load transfer media (LTM) based on aluminium oxide pellets and epoxy resin it is possible to make use of the high strength of the CFR wires and to avoid creep failure of the socket (Kim and Meier 1991).

PRESTRESSING SYSTEM OF MULTI-PLY FRP SHEETS FOR STRUCTURAL STRENGTHENING

C.Y. Zhou, J. Liu, and L. Xie

ABSTRACT

External prestressing is an appropriate technique for improving the behavior of existing structural members under service loads and increasing the ultimate strength. In view of the insufficiency of prestress provided by single layer of FRP sheet, a novel prestressing system was developed for multi-ply sheets. It consists of an anchor device and a tension one apart from FRP sheet which is combined with the devices by interlocking. Two experiments were conducted to explore the ultimate capacity for the prestressing system of 4-ply and 100-mm-wide carbon fibre-reinforced polymer (CFRP) sheets. The results showed that this prestressing system can effectively anchor multi-ply sheets of CFRP resulting in rupture and achieve the fibre strength utilization up to 83.97%. Then three steel I-beams were prestressed by the same system with different lengths and the response of prestressing are measured. It was found that the test results accorded well with the theoretical values for deflection and strain of the I-beams and uniformity of the strap strains was improved with increase of the strap length. At last further application was simply introduced for strengthening of reinforced concrete box girders with the prestressing system of more plies CFRP sheets.

INTRODUCTION

Due to high strength-to-weight ratio, good corrosion resistance and ease of installation, externally bonded fibre-reinforced polymer (FRP) straps have been widely used for the flexural strengthening of RC and steel structures. Extensive research has shown that the controlling failure mode of such a strengthened structural member often involves the premature debonding of the FRP end from substrate in a brittle manner (Smith and Teng 2001, 2002a, 2002b). Furthermore, stress hysteresis of the FRP strap generally exists in the traditional flexural strengthening, which results that the FRP cannot play its high strength characteristics unless deformation of the strengthened beam is very large. To prevent the premature debonding, researchers have actively explored the end anchoring techniques of FRP, such as anchor spikes (Lam and Teng 2001), metallic plates (Wu and Huang 2008), WSGG anchor (Zhuo et al. 2009) and double-plate anchor (Belarbi et al. 2012). In order to reduce the stress hysteresis of the FRP strap, limited literatures have reported prestressing techniques (TC Triantafillou and N Deskovic 1992; RG Wight et al. 2001; Colombi et al. 2003; Raafat El-Hacha et al. 2003; YJ Kim et al. 2008; Huawen et al. 2010; Yang and Li 2010; Shang et al. 2003; Elyas Ghafoori et al. 2015) which meanwhile reduce deflection of the member and control cracks. However, existing investigation of prestressing with end anchorage focused on FRP plates, and few on FRP sheet, particularly on multi-ply sheets. In fact, a single layer of FRP sheet can just supply low pretension for the strengthened element, leading to insignificant effect of strengthening. It is so necessary to develop a prestressing system for multi-ply sheets. This paper introduces such a new prestressing system and its application for flexural strengthening of steel or RC structures.

PRESTRESSING SYSTEM AND EXPERIMENTS

System constitution

The prestressing system consists of an anchor device, a tension device, and multi-ply FRP sheets, as shown in Figure 1. The anchor device, used to anchor one end of the FRP strap, is assembled by two anchor plates and four anchored bolts. The anchor plate invented by the first author (Zhou et al. 2012) can make the FRP strap totally fixed just by wrapping round the plate in a special method. The tension device, including an anchor box, a position
plate, four anchored bolts, and two pull rods, aims to anchor the other end of the strap and exert prestress. Either manual screwing or mechanical jacking was tried to apply the prestrain and proved feasible. During pretension the prestressing value is controlled by strain gauges on the pull-rod surface or reading meter of the jack, as shown in Figures 2a-b.

Figure 1 Prestressing system for multi-ply FRP sheets

Material tests

Toray carbon fibre-reinforced polymer (CFRP) sheets and Araldite epoxy resins were adopted in experiments. According to Chinese code for carbon fibre sheet for strengthening and restoring structures (GB/T 3354-1999), eight straps of CFRP 12.5mm wide were formed by embedding continuous fibres in epoxy resin which bonded the fibres together. Then, these specimens were tested by tension testing machine after 7 days curing, and testing result is shown in Table 1.

Tests of prestressing system

A prestressing system for 4-ply and 100-mm-wide CFRP was designed and manufactured. Two prestressed CFRP specimens numbered P1 and P2 were made for the experiment and they had the same thickness of 0.667 mm, length of 450 mm, and width of 98 mm, as shown in Figure 3. Then the ultimate capacity experiments of the specimens were carried out to observe the failure mode of the CFRP strap and verify the reliability of the anchor device and the tension device, as shown in Figure 4. In loading process, the force of 10 kN was firstly preloaded with a rate of 5 kN/min, then 180 kN was exerted with the same rate and sustained for 10 minutes. After 180 kN, further tension was applied with a rate of 3 kN/min until the specimen failed.
Results and discussions

Figure 5 shows the damage diagrams of P1 and P2. It can be seen that their failure modes are both the ruptures of the CFRP strap. The fracture location of P1 is close to the end of the anchor plate, and that of P2 is in the central part of the CFRP strap. However, the CFRP fibers in the anchor plate and the anchor box remain intact. As shown in Table 2, in average the ultimate tension of the CFRP strap is 200.3 KN, correspondingly the system strength is 3028 MPa and the utilization ratio of material strength is 83.97%. Furthermore, the average sliding distances of CFRP at the anchor-plate end and the anchor-box end are zero and 1.7 mm respectively. All these results indicate that this prestressing system is feasible and capable to anchor CFRP straps and achieve rupture failure.

PRESTRESSING RESPONSE OF STEEL BEAMS

Three steel I-beams with a length of 3250mm and a height of 250mm were strengthened by prestressed CFRP straps based on this system to verify the applicability of the prestressing method and explore the influence of the strap length on the uniformity of CFRP strain distribution across the width. The strap lengths were 1000mm, 1500mm and 2000mm respectively and the strengthened I-beams were accordingly numbered P10, P15 and P20. All the straps had a width of 98mm and a thickness of 0.667mm. In each experiment pretension of 110kN was applied by the manual screwing method, as shown in Figure 2b. Dial indicators were arranged on the midspan and the two supports of the I-beams to monitor the change of deflection. Meanwhile, strain gauges were attached to the middle of the upper flange of I-beams, and three gauges were arranged on each section of CFRP strap respectively located at section A close to the anchor plate, B in the middle of the CFRP, and C close to the anchor box, as shown in Figure 6.
The theoretical values of deflection and strain of the strengthened beam of steel are calculated based on equation (1) and equation (2) respectively.

\[ \Delta = \frac{1}{EI} \times \frac{1}{2} \times \frac{L}{4} \times T \times e = \frac{T_e L}{8EI} \]  
\[ \varepsilon = \frac{\sigma}{E} = \frac{I + A}{E} \]

where \( \Delta \) and \( \varepsilon \) are the deflection and strain of the I-beam; \( E, I, L \) and \( A \) are the elastic modulus, moment of inertia, length, and sectional area of the I-beam, respectively; \( T, e, M \) and \( y \) denote the pretension, its eccentricity, bending moment, and distance between calculated position and neutral axis.

Comparisons between the theoretical and experimental values of deflection and strain are shown in Figure 7 and Figure 8 respectively. It can be seen that the measured values of strain are very coincident with the predicted results, and the relative errors between the calculated and experimental values of deflection and strain are both about 5%. These results demonstrate the prestressing system is applicable to steel I-beams. Furthermore, coefficients of variation are adopted to express the influence of the strap length on the uniformity of CFRP strain distribution over its width. Low coefficient implies relatively even distribution of strains at a section. It can be seen from Table 3 that the strain distribution at any section will become uniform with the increase of the strap length. In addition, the variation of strain at section B, i.e. in the middle, is less than that at section A and C near the anchorage ends.

ENGINEERING APPLICATION IN CONCRETE GIRDER

The prestressing system above-mentioned was also applied for strengthening cracked RC box girder of some bridges in Shanxi and Shaanxi, two provinces in China. The CFRP straps were 6 or 8 layers and had a length of about 25000mm and a width of 100mm. The exerted pretension value of each strap was 100-150kN. The construction procedure of this system mainly contained four parts: cutting the CFRP, assembling components, applying prestress, and anticorrosion processing, as shown in Figure 9. After the bridge was strengthened, the inspection results demonstrated that the deformation of the strengthened box girders and the development of their flexural cracks were obviously controlled, which proved the applicability of the proposed system and further validated the feasibility of the construction process.

Figure 9 Construction of flexural strengthening of RC girder with prestressed CFRP sheets

CONCLUSIONS

This paper introduces an innovative prestressing system with end anchorage for multi-ply FRP sheets to prevent the premature debonding and in particular reduce the stress hysteresis of FRP in structural strengthening. The multi-ply sheets are combined at two ends with patented interlocking devices, which provide brand-new ways for anchoring FRP sheets. The experimental results indicate that this prestressing system is capable to anchor multi-ply CFRP sheets and achieve rupture failure, which supplies fiber strength utilization to 83.97%. The uniformity of strap strains for the longer FRP strap is better than that for the shorter one and strains at the middle sections of different-length straps are more uniform than strains at other sections. Their application to both steel I-beams and concrete Girders shows that the construction procedure for the system is feasible in practical engineering.

ABSTRACT

Recently, rehabilitation of concrete structures with fiber reinforced polymer (FRP) has grown to be an extensively used system in most parts of the world. The main aim for this is that it is possible to obtain a suitable strengthening effect with a relatively small work effort. Nevertheless, when strengthening a structure with FRP, it is often not possible to make full use of the FRP due to de-bonding ruptures. This disadvantage of early de-bonding can be overcome by using a near surface mounted (NSM) strengthening system. In addition, prestressing can be more effectively introduced in the NSM strengthening system than in another strengthening method. The effectiveness of strengthening reinforced concrete (RC) beams with prestressed NSM carbon fiber reinforced polymer (CFRP) systems was investigated. Three RC beams (600 mm deep by 400 mm wide by 6400 mm long) were tested under four-point loading test. One beam was kept un-strengthened as a control beam. Another was strengthened with a pre-tension NSM CFRP bar. The other was strengthened with post-tension NSM CFRP bar. The test results showed that strengthening with prestressed NSM beam enhanced the flexural behavior of the beam compared to that of the control beam. The test results indicated that the prestressed NSM beams more effectively improved the cracking, yielding and ultimate loads than the control beam. The post-tension NSM systems was determined that enhances the beam performance under concrete cracking, steel yielding and ultimate loads.

INTRODUCTION

Situations that cannot be predicted during planning often occur in the lifetimes of concrete structures. The durability of a concrete structure such as a bridge is decreased by construction defects, vehicle loads, environmental changes, and material characteristics. Bridges located on seashores are exposed to severe environments, which can lead to the corrosion of prestressed steel bars within the concrete. Corroded prestressed steel bars can cause structural problems because of the decreased premressing forces they provide. Recently, various studies have been performed on the maintenance of concrete structures. Fiber-reinforced polymer (FRP) bars, including glass and carbon fibers with advantageous corrosion resistances, have been researched extensively. Although FRP has the weakness of brittle failure, it is superior in strength, weight, durability, and resistance to creep and fatigue compared to existing construction materials. The lightweight material is also easy to use in the field. However, concrete structures externally bonded with FRP have low fire resistance and high vulnerability to vehicle collisions and bond failure. In order to compensate for the instability of externally bonded systems, near-surface mounted (NSM) systems, which embed FRP into concrete structures, have been investigated. NSM systems have been studied experimentally and analytically based on the types of FRP bars and characteristics of the materials used. Standard methods for bonding FRP bars to concrete have been proposed (ACI 2001; CSA 2002; JSCE 2007).

De Lorenzis et al. tested NSM systems using parameters of the shape of the FRP, type of filler, bond length, and size of the groove, and found that the bonding strength of the test specimen using mortar as filler was lower than that of the test specimen using epoxy (De Lorenzis et al. 2002a, 2002b). The results also showed that, when the sand was added to the filler, the viscosity could be controlled by the volumetric expansion of the epoxy. The epoxy lowered the coefficient of expansion to control the glass transition temperature (De Lorenzis et al. 2002b). Benmokrane et al. (2002) performed experimental research on the bond characteristics and fracture shapes of FRP
bars by embedding FRP bars in aluminum and PVC sleeves. Shraky et al. (2013a, 2013b) studied the bonding characteristics between filler and FRP bars by executing pullout tests with the groove size, filler, and type of FRP as parameters. Hassan et al. (2002) fabricated a half-scale reinforced concrete (RC) girder and executed load tests by placing carbon FRP (CFRP) bars and plates on the surface of the girder and evaluating the bonding characteristics of the CFRP with increases in loading. Casadei et al. (2006) produced an 11.0-m prestressed concrete (PSC) I girder, strengthened with both a prestressed external bond system and an NSM system, and performed four-point loading tests. In the study, the strengthening effects and failure modes of the NSM-strengthened girder were analyzed for varying prestressing forces and types of FRP. Al-Mahmoud et al. (2010) fabricated a 2.8-m RC beam with an NSM system and performed a four-point loading and cantilever loading tests. The test results, cracking failure, and bonding failure were compared and verified with a finite-element (FE) model. The NSM system places CFRP bars in the concrete to introduce prestressing, thereby improving the performance of the concrete structure. As stated in the literature reviews above, studies on NSM systems have focused on bonding and bending stresses. The flexural behavior of RC beams with prestressed NSM systems can ameliorate serviceability concerns, such as the deflections at different load steps in RC beams (Badawi, M., and Soudki, K 2009). Prestressed NSM systems can prevent premature de-bonding at the surfaces of concrete specimens. In addition, prestressed NSM systems significantly improve the crack, yield, and ultimate loads while reducing crack widths in strengthened beams, compared to those observed in non-prestressed strengthened RC beams. A similar study demonstrated that load cycling at room temperature (~20°C) could weaken the CFRP-concrete bond. Several analytical processes for studying and FE modeling of RC beams strengthened with prestressed NSM systems have been proposed (Rasheed et al. 2006; Soliman et al 2010).

The number of experimental studies on the strengthening of RC beams with prestressed NSM systems is limited. Most studies on prestressed NSM systems have adopted the pre-tensioning method. In this study, the flexural behavior of RC beams strengthened with both pre-and post-tensioning NSM systems is analyzed.

EXPERIMENTAL PROGRAM

Material and methods

In this study, a 6.4-m-long RC beam was fabricated for testing by four-point loading. The height, width, and concrete strength of the RC beam were 600 mm, 400 mm, and 40 MPa, respectively. The surfaces of each CFRP bar were processed by sand coating. For sand coating, sand was sprayed after applying a coating agent onto the surface of the ground CFRP bars. Figure 1 shows the prestressed NSM system dimensions.

The experimental parameters are the prestressing method, number of bars, as shown in Table 1. Five RC beams were fabricated. The first segment of the specimen name represents the prestressing method: “Pre” stands for pre-tensioning and “Post” stands for post-tensioning. The second segment represents the prestressing force. In the FRP strengthening method, prestressing forces of 40-60% of the tensile strength of the FRP bars have been proposed in the ACI committee. In this study, a prestressing force of 120 kN was applied to the CFRP bar, ~50% of the tensile strength of the CFRP bars. The third segment indicates the reinforcement length, which was selected as 83% (5.0 m) of the length of the RC beam (6.4 m). The fourth segment represents the type of filler: “M” stands for mortar. The fifth segment represents the surface treatment of the CFRP bar. “SC” indicates sand coating. The sixth segment indicates the number of FRP bars: “1” means one-line strengthening and “2” means two-line strengthening. The diameter of each CFRP bar was 10 mm, and the tensile strength and elastic modulus of CFRP bar was 3290 MPa, 171 GPa, respectively.

In this study, rebars are assembled as shown in Figure 2(a). The assembled rebar was inserted in a produced mold and arranged with precise spacing (see Figure 2(b)). Figure 2(c) depicts the pouring of concrete with a compressive strength of at least 40 MPa. After pouring, vibration compaction was performed up to three times depending on the height. After 14 days of curing, a groove measuring 30 mm in width and 40 mm in depth was fabricated in the concrete, as shown in Figure 2(d). Figure 2(e) shows the process of introducing prestressing using the pre-tensioning method. Figure 2(f) shows the process of anchoring and installing CFRP bars using the post-tensioning method. The process of applying the post-tensioning method of prestressing to the CFRP bars is shown in Figure 2(g). The fabricated groove was filled with epoxy and mortar, which were then cured (see Figure 2(h)).

Figure 2 Fabrication process of specimen

Figure 3 shows the layout of the test setup. In this experiment, the load was applied stepwise using a universal testing machine with a capacity of 200 kN. The loading positions were located 500 mm away from the mid-span on both sides of the RC beams. The displacement of the RC beam under loading was measured by a displacement transducer, which was installed at the mid-span. The displacement control method was used for the loading. A rate of 0.03 mm/s was used for the first 30 mm; after reaching this length, the rate was increased to 0.1 mm/s.
EXPERIMENTAL RESULTS

In this study, 14 days after the filler in the groove was cured, the prestressing force was removed from the RC beam strengthened with the pre-tensioned NSM system. The prestressing loss was measured at the center of the CFRP bar, the CFRP bar slip was measured at both ends of the CFRP bar. After the experiment, the CFRP bars were checked for possible slip occurrence. Slip of about 20 mm occurred in the CFRP bars, for all RC beams strengthened with pre-tensioning NSM systems after the prestressing forces were removed. The prestressing forces and prestress force losses of the CFRP bars were measured with strain gauges installed in the centers of the CFRP bars. The prestress losses of the pre-tensioned NSM-strengthened RC beams are summarized in Table 2. The losses of the Pre-50-83-M-SC-1 and Pre-50-83-M-SC-2 are 27.1 and 39.4%, respectively. As the number of bars in the pre-tensioned NSM-strengthened RC beam is increased, the prestress force losses of the bars are increased. From the results, increases in the number of the CFRP bars in an RC beam are observed to cause mutual interference between the CFRP bars and increase the prestress force losses.

Table 3 shows the comparisons of the load level for strengthened RC beams. The load levels of the RC beam are classified as the concrete cracking load, steel yielding load, and maximum load of the RC beam. For pre-tension NSM strengthened RC beams, the Pre-50-83-M-SC-2 specimen shows concrete cracking, steel yielding, and maximum loads of 17.7%, 8.4%, and 2.8% higher than those of the Pre-50-83-M-SC-1 specimen. The strengthening effect on the RC beam in the pre-tensioned NSM-strengthened RC beam is improved as the number of CFRP bars is increased. However, the prestress force loss is increased as the number of CFRP bars in the pre-tensioned NSM-strengthened RC beam without anchorage is increased; therefore, the strengthening effect of RC beam is not considerably improved.

The experimental results of post-tension NSM strengthened RC beam according to the number of CFRP bars reveal that the Post-50-83-M-SC-1 specimen shows concrete cracking, steel yielding, and maximum loads that are 17.9%, 29.4%, and 22.3% higher than those of the Post-50-83-M-SC-2 specimen, respectively. The strengthening effect on the RC beam for all load levels is increased by approximately 20% with the post-tensioned NSM strengthening systems using two CFRP bars, relative to those with one CFRP bar. In the post-tensioned NSM-strengthened RC beams, CFRP bar slip does not occur because anchorage systems are placed in the RC beams. Therefore, the prestress force loss of the CFRP bar in the post-tensioned NSM-strengthened RC beam is less than that for the pre-tensioned NSM-strengthened RC beam. This trend suggests that the post-tensioned NSM strengthening system minimizes the prestress force loss of the CFRP, thereby improving the strengthening effect for the RC beam at all load levels.

Figure 4 shows the load–displacement relationships according to the pre-stressing methods. The concrete cracking load, steel yielding load, and maximum load of the RC beam in the Post-50-83-M-SC-1 specimen are greater by 50.0%, 18.9%, and 30.8%, respectively, than those in the Pre-50-83-M-SC-1 specimen. The Post-50-83-M-SC-2 specimen shows increases of the concrete cracking load by 50.3%, steel yielding load by 42.0%, and maximum load of the RC beam by 55.5%, relative to the Pre-50-83-M-SC-2 specimen. The strengthening effect on the RC beam is not considerably improved by the Pre-50-83-M-SC-2 system because the prestress loss of the pre-tensioned RC beam without anchorage is high. However, the post-tensioned NSM-strengthened RC beam minimizes the prestress loss by anchorage. Accordingly, the strengthening effect on the RC beam by the post-tensioned NSM strengthening system is significantly improved when the number of CFRP bars is increased.

Figure 4 Load–comparison between pre-tensioned and post-tensioned beams.
CONCLUSIONS

In this study, in order to analyze the prestressed NSM system, RC beams of 6.4 m in length were fabricated and tested by four-point loading. The following conclusions were obtained:

The test results showed that the prestressed NSM beams more effectively improved the cracking, yielding and ultimate loads than the control beam. The strengthening effect of the pre-tensioned NSM strengthening system on the RC beam in which anchorage was not used was insignificant because of the considerable prestress loss. The strengthening effect on the RC beam was improved by the post-tensioned NSM strengthening for which anchorage was installed, because the anchorage minimized the prestress loss of the CFRP bars. Accordingly, the installation of anchorage is necessary for the prestressed NSM system in order to prevent the slippage of the FRP bars and to minimize the prestress loss. The strengthening effect of the post-tensioned NSM strengthening on the RC beam was improved as the number of CFRP bars was increased. However, the strengthening effect of the pre-tension NSM strengthening on the RC beam without anchorage was not improved, even for increased numbers of CFRP bars. CFRP bar slip did not occur for any number of CFRP bars in the post-tensioned NSM-strengthened RC beam because of the anchorage constraints.

ABSTRACT

This paper presents a modeling approach for prestressed concrete bridge girders strengthened with post-tensioned near-surface-mounted (NSM) carbon fiber reinforced polymer (CFRP) strips. Three methods are employed to predict the macro-, meso- and microscale behavior of anchorage zones when the CFRP strips are post-tensioned, including finite element, discrete-object physics, and analytical models. The multiscale integration used is based on domain decomposition in connection with information-passing. The macroscale finite element model provides strain softening in the vicinity of the anchorage, which is related to smaller scale responses depending upon the post-tensioning level of the CFRP.

KEYWORDS
Carbon fiber reinforced polymer (CFRP), modeling, multiscale, near-surface mounted (NSM), prestress

INTRODUCTION

Strengthening with carbon fiber reinforced polymer (CFRP) composites is proven technology to upgrade the performance of existing bridge members. Many benefits are involved, such as reasonable construction costs, reduced long-term maintenance expenses, and minimal traffic disruption (Lopez and Nanni 2006). Conventionally, two types of CFRP-strengthening methods are implemented, namely, externally bonded (EB) CFRP and near-surface-mounted (NSM) CFRP. The EB method is broadly used in the rehabilitation community, whereas the NSM method is relatively less used because of its short application history. Unlike traditional CFRP-strengthening, prestressed CFRP may be employed when upgrading existing structural members (Wight et al. 2001). The potential of prestressed NSM CFRP has been recently studied by several researchers. Badawi and Soudki (2009) tested reinforced concrete beams strengthened with post-tensioned NSM CFRP rods. The jacking system utilized was composed of clamping anchors, a jack, and load-bearing brackets. The CFRP was tensioned up to 60% of its tensile strength. Although minor slip was observed during post-tensioning, strain compatibility was well preserved across the beam section. As the strengthened beams were loaded in flexure, concrete crushing or CFRP rupture took place. Oudah and El-Hacha (2012) conducted a fatigue test to assess the performance of concrete beams strengthened with post-tensioned NSM CFRP strips. Fatigue cycles were applied at 2-4 Hz along with a stress range of 70% of the yield stress of the reinforcing steel. The variation of deflection and stiffness was monitored to evaluate fatigue-induced damage. Ye et al. (2014) loaded one-way slabs retrofitted with post-tensioned NSM CFRP bars until failure. The level of post-tensioning was 30% of the CFRP’s strength. At transfer, a 10% prestress loss was noticed. On account of the NSM CFRP, the strengthened slabs’ cracking load was improved by 60%; however, their ductility at failure was reduced.

The state-of-the-art of post-tensioned NSM CFRP includes experimental investigations in tandem with macroscale modeling. There is a need for examining various scale responses of NSM CFRP strengthening systems, and this effort is not available in most cases. It is an important subject because the damage of a strengthened member initiates at microscale and propagates to larger scales, which cannot be obtained from conventional macroscale modeling methods. As such, a comprehensive understanding of a post-tensioned NSM CFRP system can be achieved by examining the multiscale behavior of the system. As far as multiscale modeling is concerned, sequential coupling or information-passing is typical (Weinan 2011), which is formulated with a representative volume element (RVE). The information obtained from a smaller scale response is passed to a larger scale to
connect their distinct scale behavior, or from larger scale to smaller scale. This paper discusses a multiscale modeling approach to understand the response of anchorage concrete when NSM CFRP strips are post-tensioned.

**RESEARCH SIGNIFICANCE**

The anchorage concrete of a bridge girder may experience variable scales of damage, when subjected to a post-tensioning force applied to NSM CFRP strips. From a microscale standpoint, damage nucleation and progression lead to meso- and macroscale problems. These damage propagation mechanisms can influence the functionality of a post-tensioned NSM CFRP system installed to a bridge girder. Technical investigations are necessary to comprehend the significance of multiscale damage, although the macroscale behavior of concrete members with NSM CFRP is well elucidated. The proposed modeling approach connects traditional structure-level knowledge with insights from smaller scales.

**DESCRIPTION OF A POST-TENSIONING SYSTEM FOR NSM CFRP**

Three benchmark prestressed concrete girder bridges ($L = 25$ m, $30$ m, and $35$ m) were considered in this research program, as shown in Fig. 1(a). The girders had a compressive concrete strength of $40$ MPa and standard prestressing steel strands ($f_{pu} = 1,860$ MPa and $E_p = 190$ GPa where $f_{pu}$ and $E_p$ are the ultimate strength and elastic modulus of the steel, respectively) that were tensioned up to $68\% f_{pu}$. CFRP strips ($A_f = 700$ mm$^2$ where $A_f$ is the cross-sectional area of the CFRP) included a nominal tensile strength of $2,500$ MPa and a modulus of $165$ GPa, and were post-tensioned up to $60\%$ of the strength. Figure 1(b) exhibits the sequence of a proposed strengthening technique (this method was patented: 10-0653632, 10-1005347, and 10-1083626): installing an anchor plate with high-strength bolts, tensioning NSM CFRP embedded in a precut groove using a jacking apparatus, transferring the post-tensioning force to the beam, and grouting the groove and anchorage to improve aesthetics.

**MULTISCALE MODELING APPROACH**

Figure 2 illustrates the concept of a multiscale modeling approach for the proposed strengthening system. When the anchorage is tensioned by the NSM CFRP, concrete near the anchor bolts is under complex stress states in partial compression and tension. Of interest is the tensile behavior of the concrete because premature cracking occurs. The tension zone of the concrete encompasses multiple components (i.e., aggregates surrounded by cement paste), and each inclusion has a weak link called the interfacial transition zone (ITZ) where microscale damage occurs.

![Figure 1](image1.png)
(a) Benchmark bridge girders
(b) Strengthening sequence

![Figure 2](image2.png)
Figure 2 Concept of multiscale modeling
Figure 3 Multiscale modeling framework: (a) macroscale finite element model; (b) mesoscale discrete-object physics model; (c) microscale analytical model

**Macroscale model**

Finite element modeling was conducted with a commercial software package. The concrete, and prestressing strands and CFRP strips were modeled by elastic shells and spars [Fig. 3(a)], respectively, with the foregoing material properties. By constraining nodes near both ends of the girders, simple supports were represented. The prestressing forces of the strands and strips were applied based on initial strains. Further details about model development and validation are available in Kim et al. (2014).

**Mesoscale model**

The behavior of the anchorage concrete was modeled by a discrete-object physics approach, as shown in Fig. 3(b). This model was constructed according to Newton’s second law in conjunction with the interaction between element particles [Fig. 4(a)]. The 125-mm cube model had an element size of 2 mm and a Φ25 mm steel bolt. The element interaction model [Fig. 4(b)] consisted of the following properties: normal and transverse directional virtual springs ($k_n$ and $k_t$, respectively), normal and transverse directional damping ratios ($c_n$ and $c_t$, respectively), normal and transverse directional bonding ($b_n$ and $b_t$, respectively), and static and kinetic friction coefficients ($f_s$ and $f_k$, respectively). The constructed model was solved by parallel computing technologies (Gitman et al. 2008) with the aid of a supercomputer.

**Microscale model**

The microscale behavior of a single inclusion or element [Fig. 3(c)] was examined by an analytical model. The constitutive relationship of the inclusion may be expressed as:

$$\sigma_{ij} = (1 - D_{\text{micro}}) C_{ijkl} \varepsilon_{kl}$$

(1)
where $\sigma_{ij}$ is the stress vector of the ITZ with corresponding strain $\varepsilon_{ij}$; $D_{\text{micro}}$ is the microscale damage index; and $C_{ijkl}$ is the stiffness tensor. The damage index may be obtained by (Marzars 1981):

$$D_{\text{micro}} = 1 - \left( \frac{\varepsilon_{cr}}{\varepsilon_{po}} \right) \left( 1 - A \exp \left[ B \left( \varepsilon_{m} - \varepsilon_{po} \right) \right] \right) \text{ for } \varepsilon > \varepsilon_{cr} \tag{2}$$

where $\varepsilon_{cr}$ and $\varepsilon_{po}$ are the strain corresponding to the peak stress and the post-peak strain, respectively; $A$ and $B$ are empirical constants for the residual stress and post-peak softening slope, respectively; and $\varepsilon_{m}$ is the strain at an arbitrary post-peak stress. After some manipulation of a stress-strain relationship for concrete (Hsu and Zhang 1996), the empirical constants can be determined:

$$A = \frac{\sigma_{po}}{f_r} \text{ and } B = \frac{(f_r - \sigma_{po})}{(\varepsilon_{m} - \varepsilon_{cr})} \tag{3}$$

where $\sigma_{po}$ is the residual post-peak stress and $f_r$ is the modulus of rupture. Finally, the stress states of the ITZ in radial ($\sigma_r$) and circumferential ($\sigma_\theta$) directions are calculated (Ugural and Fenster 1995):

$$\sigma_r = \sigma_{xx} \cos^2 \theta + \sigma_{yy} \sin^2 \theta + 2\sigma_{xy} \sin \theta \cos \theta \tag{4}$$

$$\sigma_\theta = \sigma_{xx} \sin^2 \theta + \sigma_{yy} \cos^2 \theta - 2\sigma_{xy} \sin \theta \cos \theta \tag{5}$$

where $\theta$ is the angle measured from the $x$ axis [Fig. 3(c)].

RESULTS

Macroscale anchorage behavior

The strain development of the 30 m girder’s bottom along the span is shown in Fig. 5. Owing to the presence of camber, all strains were negative. A gradual increase in girder strain was observed until the CFRP termination point was reached, beyond which an abrupt strain change was noticed (i.e., net strain increase) because of the post-tensioned CFRP strip. This net strain increase can result in damage of the anchorage concrete when cracking takes place.

Mesoscale anchorage behavior

Figure 6(a) shows the initiation and propagation of mesoscale damage in the anchorage zone concrete (the simulation time indicates when the concrete damage initiated and propagated). The effect of post-tensioning (i.e., force applied to the anchor bolt) was insignificant until 0.59 sec; however, the change of element velocity was
noticed at 0.60 sec when the mesoscale damage nucleated. The stresses associated with these element responses are illustrated in Fig. 6(b). At a simulation time of 0.63 sec, the stress reached a maximum value of 3.4 MPa, which was close to the modulus of rupture suggested by ACI-318 (ACI 2014).

**Microscale anchorage behavior**

Figure 7(a) exhibits the damage development of the inclusion. The damage initiated at 100 microstrains and plateaued out up to 640 microstrains. This fact indicates that microscale damage rapidly increases when the NSM CFRP is post-tensioned. The variation of radial and circumferential stresses is provided in Fig. 7(b). The predicted radial stresses were gradually reduced as an angle increased, and were influenced by the degree of post-tensioning levels (20%$f_{tu}$ to 60%$f_{tu}$). The pattern of the circumferential stresses was opposite to that of the radial stresses.

**SUMMARY AND CONCLUSIONS**

This paper has discussed a multiscale modeling approach for the anchorage region of prestressed concrete bridge girders strengthened with post-tensioned NSM CFRP strips. Micro- to macroscale models were formulated to examine the damage initiation and propagation of the anchorage concrete when the CFRP was post-tensioned, based on finite element, discrete-object physics, and analytical methods. The macroscale strain response indicated that the NSM CFRP resulted in local tension near the anchorage. The nucleation of damage was sudden from a mesoscale standpoint, which was related to the interaction between the concrete and the anchor bolt. The interfacial transition zone was the place where microscale damage occurred, and its stress development was controlled by the post-tensioning level of the NSM CFRP.

ABSTRACT

The non-corrosive nature and high strength of fiber reinforced polymer (FRP) reinforcement makes it attractive for use in concrete applications. The main problem for using FRP reinforcement is its higher deformability especially for glass and basalt FRP. One of the possible approaches for reducing the deformations is via prestressing the reinforcement. This paper is a continuation of a previous research and presents experimental results of five large scale concrete beams reinforced to different levels of prestressing of the reinforcement. Four of the beams are reinforced with Basalt fibre reinforced polymer (BFRP) 10mm diameter bars. Test results showed that prestressing above 30% from the ultimate load for BFRP reinforcement results in similar or smaller deformation capacity of BFRP reinforced beam in comparison with steel reinforced for all levels of loading. The BFRP Beam with 30% and 40% of prestressing have higher capacity than the steel reinforced beam when a Serviceability Limit State (SLS) criterion is applied.

Large scale samples, RC beams, BFRP, Prestressing, Pre-tensioning,

INTRODUCTION

BFRP bars have emerged as an alternative to steel reinforcement due to their non-magnetic properties, non-corrosive nature, correspondingly lower life cycle cost and reduced CO₂ emissions. However, due to relatively a low elastic modulus, the main issue for using BFRP reinforcement is the high deformability, which can be controlled by prestressing the reinforcement. Several design codes have been proposed on carbon FRP (CFRP), glass FRP (GFRP) and aramid FRP (AFRP) bars for prestressed structures, namely in USA (ACI 440.4R.04, 2011), Canada (CAN/CSA S06-06, 2006), and Japan (JSCE CES23, 1997).

The aim of the paper is to analyse the experimental results reflecting the behaviour of BFRP reinforced beams with different level of prestressing and to compare them with a steel reinforced beams.

BACKGROUND

The use of FRP in reinforced concrete (RC) for anti-corrosion purposes is expected to find applications in structures in or near the ground, marine environments and in thin structural elements. In the early 90’s very intensive initial research and development on applications of FRP widely taking place in many countries, especially in North America, Europe and China. In 1988 the first application of FRP tendons using external prestressing for the pedestrian bridge in a Berlin park was constructed (Zia et al., 1997). In the late 80’s AFRP prestressing bars were used in the Netherlands to reinforce some of the posts of a noise barrier along a highway. This application was made because of the aggressive environment on those posts due to exposure to deicing salts and exhaust gasses of cars (Taerwe, 1993). In 1996 the Aberfeldy Footbridge in Scotland was constructed, it was the world’s first major advanced composite footbridge and remains the longest span advanced composite bridge in the world (Skinner, 2009).

Extensive research has shown that BFRP bars perform similarly to GFRP bars. RC beam with BFRP bars achieved short term strengths that are consistent with the relevant properties of the constituent materials (Patnaik et. al. 2010). Jonsson (2011) investigated RC beams pre-tensioned with BFRP tendons, he stated that the stiffness and bearing capacity of the BFRP beams significantly higher than un-prestressed beam. Pearson and
Donchev (2012) experimental results on post-tensioning BFRP RC beams with different levels of prestress showed that a significant reduction in the deformations can be achieved by applying an appropriate level of prestress. Guðmundsson (2012) investigated the moment capacity of four BFRP prestressed RC beams and commented that BFRP prestressed beams without shear reinforcement were weak in shear even if the shear span to depth (a/d) ratio was high. Revathy and Sriraman (2014) stated that the GFRP strengthened prestressed concrete (PSC) beam increased its load carrying capacity by 89 % and ductility by 90% over the control beam. Mirshekari et. al. (2015) investigated six large scale concrete beams reinforced with 6mm BFRP & steel bars and prestressed to a different degree. They pointed out that the prestressing of BFRP rebar had a significant effect on the deformability of the beams as the increasing level of prestress leads to a delay in the development of the initial cracks. The obtained Serviceability Limit State (SLS) level of capacity for prestressing at and above 40% is higher than for steel reinforced beam.

In parallel with excellent benefits from prestressing of BFRP reinforcement few disadvantages have to be considered. One of them is the reducing of the prestressing force during the process of the production of the elements (short term) and during the span of their life (long term). The estimation of the magnitude of the losses of the prestress is important factor for considering the behaviour of the elements. As indicated in (e.g. ISIS Canada 2006; Mirshekari et. al. 2016) the characteristics of the losses of prestress for FRP reinforcement are generally different from losses for steel reinforcement.

Another critical factor for consideration is the danger from creep rupture effects at high level of prestressing. From the extensive experimental work conducted in Kingston University and Reykjavík University (Jonsson 2011; Person and Donchev 2012; Guðmundsson 2012; Mirshekari et. al. 2015) the creep rupture effects have not been monitored and for this reason the creep rupture effect has been excluded from discussion in this paper.

The presented work is focused on investigating the effects of different levels of prestressing on internal BFRP and steel reinforcement on large scale RC beams. Mirshekari et al. (2015) investigated influence of the degree of prestressing on the behaviour of BFRP reinforced beams, this paper presents a second phase of this project.

METHODOLOGY

Description of Test Beams

Five RC beams with a total length of 2400 mm each are subjected of analysis in this publication. Four samples had BFRP reinforcement with a different degree of initial prestressing: 0%, 20% (16 kN), 30% (24kN) and 40% (31 kN) of the design ultimate tensile load (UTL) of BFRP reinforcement.

The beams were designed to be tested over a span of 2000 mm and supported at 200 mm distance from the specimens’ ends. A load spreader beam allowed the application of loads at two points separated by a distance of 600 mm. The load was applied symmetrically about the mid-span of each test beam, resulting in four point testing. The diameter of BFRP reinforcement was 10mm for all beams and it was supplied by Magma Tech Ltd. The high yield steel was 10 mm in diameter used in S0 Control steel beam. To prevent shear failure 6 mm diameter mild steel links were placed at 100 mm intervals in shear spans of the beams. A 25 mm cover for main longitudinal reinforcement was provided. Steel tubes attached to the ends of the BFRP bars were used to prestress them and were left to act as additional anchorage throughout the testing to prevent premature anchorage failure. The arrangement of BFRP bar reinforcement and typical cross sectional details of beams are shown in Figure 1.
Figure 1 Experimental setup and cross-sectional details of beams tested (unit: mm)

Prestressing Set-up and Instrumentation

The prestressing force was applied via a pre-tensioning technique with a prestressing equipment as shown in Figure 2a. The levels of prestress before and during the process of casting, the change in prestress during releasing from prestressing devices and the development of internal stresses during the process of loading were monitored. The applied prestressing force was measured via load cells (Novatech F207 – 100 kN) for each of prestressed beams and the resulting strains measured via strain gauges for each of the bars during the whole process of prestressing. The prestressing force was checked before and after the casting of the concrete mix. Concrete was supplied by ready mix concrete manufacturer and all five beams were cast at the same time and from the same concrete mixture, to make them sufficiently similar to ensure a good level of comparability. The beams from this series were aimed to have concrete strength designed as C35/45 concrete mix. After 28 days the anchors are released and the prestress force is transferred to the beams.

Seven linear variable differential transducers (LVDTs) were attached on the beams as shown in Figure 1 and the strain gauges were placed on the tensile reinforcing bars at mid-span, quarter-span and close to anchorage position, additional strain gauge were attached to the steel reinforcing bars in the compression zone at mid-span position. Concrete strain gauges were also attached to the concrete surface at the top and bottom sides of the beams at mid-span. Loading was applied via two equal point loads (Figure 2b) at 2 kN load steps as total load with rate of application of 0.02 kN/s. At each step the load was kept for five minutes. During the process of testing the vertical displacements at mid-span, quarter spans, supports and two ends were measured. Crack appearance and their propagation were recorded.

Figure 2 Connection of the reinforcing BFRP bars to the threaded bars for prestressing (a) and test setup (b)
RESULT AND ANALYSIS

The results for the mid-span load-deflection curve are given in Figure 3. The comparison between un prestressed BFRP and steel beams indicates that the un prestressed BFRP beam (B0) is more deformable than steel beam (S0) as expected. When comparing the difference between un prestressed and prestressed BFRP beams, it shows that 20% BFRP prestressed beam (B20) has higher stiffness than B0 for whole interval of testing, which is more visible for loading above 6kN load. Furthermore, for level of loading between 10 and 48kN the difference in the deflections is almost the same with the maximum value of about 10mm. The behaviour 30% BFRP prestressed beam (B30) is closer to S0 with exceeding stiffness of the beam for predominant part of the testing interval with small exception at about 30kN. 40% kN BFRP prestressed beam (B40) has a significantly higher stiffness than S0 and much higher ultimate capacity. For levels of displacement above 10mm al load/deflection curves for all BFRP beams are almost parallel.

The failure loads for test beams are shown in Figure 4, when the load on the beam was not possible to be increased (maximum achievable force). Failure load for all BFRP beams is higher than the steel beam. The ultimate capacity of the prestressed BFRP reinforced beams appears to be significantly higher than for the un prestressed one. This effect probably is due to the reduced deformability of prestressed beams and is connected with a better distribution of stresses over the height of the section. The obtained experimental results from the BFRP reinforced beams with different level of prestressing show that the increase in the capacity is gradual and proportional to the increase of the level of prestressing. The difference in the capacity becomes smaller with the increasing level of prestressing (Figure 4).

![Figure 3 Mid-span deflection results for all beams at various level of load](image_url)

![Figure 4 Failure loads for all beams](image_url)
Comparing the deflection at ultimate load for steel reinforced beam (38kN) the BFRP beams with all level of prestressing show significantly lower deflections than B0. The reduction of deflection of unprestressed BFRP beam (B0) is 28% for B20, 55% for B30 and 76% for B40. The deflection for unprestressed steel beam (S0) is 33% less than B0 and 4% higher than B20, 40% of B30 and 68% of B40 (Figure 5).

![Figure 5 Deflection at ultimate load for steel reinforced beam (38 kN)](image)

Figure 5 Deflection at ultimate load for steel reinforced beam (38 kN)

Figure 6 shows the maximum load achieved at SLS limit of deflections, adopted as span divided by 360 according to BSI (2005). As it is visible in the chart BFRP samples with 30% (B30) and 40% (B40) of prestressing have higher capacity than the steel reinforced sample (S0) when a SLS criterion is applied.

![Figure 6 Load at 5.5mm deflection (SLS limit)](image)

Figure 6 Load at 5.5mm deflection (SLS limit)

Typical development of strain with load is as presented by the load-strain curve in Figure 7.

![Figure 7 Load strain curves for all beams at mid-span](image)

Figure 7 Load strain curves for all beams at mid-span
CONCLUSION

The comparison was conducted on basis of the same number of main longitudinal reinforcing bars. Based on the test results, the following conclusions can be drawn:

- Prestressing above 30% for BFRP reinforcement results in similar or smaller deformation capacity of BFRP reinforced beam in comparison with steel reinforced for all levels of loading.
- The ultimate capacity of all BFRP reinforced beams is higher than the capacity of steel reinforced beam and increasing with level of prestressing. It reaches 73% difference between control beam (S0) and 40% BFRP prestressed beam (B40).
- For SLS limit of Span/360, 30% BFRP prestressed beam (B30) and 40% BFRP prestressed beam (B40) have lower deformability than the steel reinforced beam.
- The developing strain follows in general the development of the different strains for all levels of prestressing.

Further research is needed to examine and clarify a range of unknown factors connected with the behaviour of prestressed concrete (PC) elements using FRP rebars such as losses of prestress, the behaviour at different levels of prestressing, partial prestressing and others.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to Magmatech UK for Supplying this investigation with BFRP reinforcement and to the technical staff in Kingston University especially Mr. Sean Downey for their support during the experiments.

ABSTRACT

This paper introduces an approach of applying prestress/compressive stress to fatigue sensitive details of steel members using shape memory alloys (SMA) and carbon fiber reinforced polymer (CFRP) composites. The effectiveness of this approach in improving the fatigue behavior of steel members is also demonstrated. A total of 27 single edge-notched steel specimens were repaired using one of four different reinforcement configurations. The repaired specimens were tested under tension-tension fatigue loading at three different stress ranges up to failure. Test results showed that the average fatigue life of specimens that were reinforced with SMA/CFRP patches was 26 times that of the unreinforced specimens at a stress range of 155 MPa. At an applied stress range of 217 MPa the average fatigue life of the retrofitted specimens was 15 times that of the unreinforced specimens. The results indicate that the use of SMA/CFRP composites is a promising approach to extend the lives of metallic structures that are susceptible to fatigue-induced cracking.

INTRODUCTION

The use of CFRP patches has been recently demonstrated as an effective technique to improve the fatigue resistance of metallic structures (Jones and Civjan 2003; Yu et al. 2013). Using prestressed CFRP to strengthen fatigue sensitive and fatigue damaged structures is more effective than using non-prestressed patches (Taljsten et al. 2009; Huawen et al. 2010). The current technique for prestressing externally bonded FRP plates requires hydraulic jacks or heavy fixtures to apply the prestress and anchor the FRP. This strengthening method is practical for rehabilitation of individual members in a laboratory environment. However, its application may be limited on in-service structures due to accessibility constraints.

Prestrained SMA materials exhibit a unique thermomechanical response through which, when they are heated, they return to their un-prestrained geometries. By restraining this transformation, prestrained SMAs can be used to apply recovery forces, or prestress forces, to structural elements. This property of SMA materials has been exploited to develop composites that are able to actively tune their mechanical response (Shimamoto et al. 2004; Bollas et al. 2007). Similarly, El-Tahan and Dawood (2015) developed a thermally-activated SMA/FRP patch that can be anchored to structural members to apply prestressing forces through heating without the need for heavy equipment. In these patches nickel-titanium-niobium (NiTiNb) SMA wires are used to apply a prestressing force and a CFRP overlay is used to bridge the crack and protect the SMA wires. This research investigates the fatigue performance of steel members repaired using this newly developed SMA/CFRP patch. Through an experimental investigation, this research quantified the fatigue life enhancement that could be achieved using the proposed SMA/FRP patch.

DESCRIPTION OF THE SMA/FRP PATCH AND TEST SPECIMENS

The composite patch consists of martensitic SMA wires and high-modulus (HM) CFRP. The NiTiNb SMA wires used in this research were manufactured by Intrinsic Devices Inc. The wires were provided with a recoverable prestrain of 0.05 mm/mm and a grit blasted surface. These wires have a wide thermal hysteresis. The reported
austenite finish temperature, \( A_f \), and martensite start temperature, \( M_s \), of the wires are 160 and -50°C respectively. This ensures that the material will retain the recovery stress when the temperature decreases after the activation is completed. The temperature-recovery stress relationship, shown in Figure 1(a) was obtained from a single wire test. The wire was fixed between two grips connected to a load cell, and then heated to record the temperature-recovery force relationship. The wire was initially at room temperature 25°C. After heating the wire up to 160°C, the measured recovery stress in the wire was 400 MPa. When the wire was cooled to room temperature, the recovery stress remained constant as shown in the figure. The theoretical temperature-recovery stress relationship below room temperature is plotted as a dashed line in the figure.

In order to attach the SMA wires to the surface of steel members, the wires were embedded into two layers of dry HM carbon fiber at two ends as shown in Figure 1(b). Each patch included 46 SMA wires of 0.78 mm diameter \( \times \) 230 mm length. The spacing between the wires was equal to the wire diameter and the wires were embedded 76 mm into each CFRP patch. The carbon fabric was saturated with Araldite 420 resin and sandwiched between two plastic molds. The patch was left to cure for 7 days. The SMA wires in the middle segment were intentionally exposed to facilitate the heating activation after being attached to the steel surface.

Figure 1 a) Temperature and recovery stress relationship of the NiTiNb SMA material; b) SMA wires embedded into CFRP with exposed portion for heating activation

Figure 2 illustrates the procedures of using the thermally-activated system to strengthen a steel plate with a fatigue-sensitive detail. Figure 2(a) shows the 914 mm long, 102 mm wide, and 6.4 mm thick bare steel plate to be strengthened. A 6.35 mm deep, 60 degree edge-notch was generated at the center of one edge to induce a stress concentration. The SMA/CFRP patches were bonded to both sides of the steel plate using a two-part structural epoxy as shown in Figure 2(b). The SMA wires were activated after the epoxy cured for 7 days. As illustrated in Figure 2(c), the SMA/CFRP patches on both sides of the specimen were thermally insulated with glass fiber insulation and aluminum foil to provide a cool anchorage region and prevent the SMA wires from pulling out of the CFRP patch. Two strain gauges were installed close to the notch root on both sides of the steel substrate, and insulated with glass fiber, to record the strain change in the steel substrate during activation. Two thermocouples were placed under the SMA wires to record the temperature change. Subsequently, the exposed SMA wires were gradually heated up to 120°C using a digitally controlled forced-air heat gun and left to cool down to room temperature. The same procedure was repeated on both sides of the specimen. The SMA wires applied compressive stress to the steel substrate after the heating process. The results recorded by the thermocouples and strain gauges are discussed in the following sections. After activation the exposed SMA wires were covered with a structural epoxy as shown in Figure 2(d) to protect the activated wires and provide a flat surface on which to bond the CFRP overlay. Finally, two layers of unidirectional HM carbon fiber (356 mm \( \times \) 76 mm) were saturated with Araldite resin and overlaid on top of the SMA/CFRP patch using a hand lay-up technique. Figure 2(e) shows the final specimen.

Figure 2 Illustration of the procedure of reinforcing steel plate using the thermally-activated system
The prestressed SMA wires extended the fatigue life of the single edge-notched specimen primarily by reducing the stress ratio, which correspondingly reduced the effective stress intensity factor range at the crack tip. The measured modulus of the activated SMA wires is 70 GPa (data from the wire test). The ratio of the stiffness of the prestressed SMA wires to that of the steel substrate is less than 2%. As a result the stress range reduction achieved by the SMA wires was minimal. On the other hand, the prestressed SMA wires applied compressive stresses to the steel, which reduced the stress ratio. Figure 3 shows the relationship between the compressive stress in the steel and the temperature in the SMA wires during the heating process corresponding to step (c) in Figure 2. The strain in the steel close to the notch root was recorded using strain gauges. The temperature was monitored using two thermocouples. As shown in the figure, after heating the SMA wires on the first side of the sample to 120°C, an average compressive stress of 7 MPa was generated in the steel. By heating up the wires on the other side, the average compressive stress reached a peak value of 19 MPa. The resulting average compressive stress in the steel after cooling to room temperature was 17 MPa. The other specimens in the SMA and SMA/CFRP groups exhibited a similar trend with a resulting average compressive stress in the steel of approximately 17 MPa after the thermal activation of the SMA wires. Due to fabrication and specimen imperfections, the resulting stresses on both sides of the steel were not identical having a maximum mismatch of 30% based on the measured strains shown in Figure 3. The compressive stress provided by the SMA wires reduced the stress ratio in the steel, while the stress range in the steel remained unchanged.

**EXPERIMENTAL PROGRAM**

*Specimen description and test setup*

In order to evaluate the effectiveness of the SMA/CFRP system, four groups of coupons were prepared and tested under high-cycle, tension-tension fatigue loading. The tested groups included: (i) un-strengthened, plain steel control coupons; (ii) coupons patched with bonded CFRP only; (iii) coupons patched with prestressed NiTiNb SMA wires only; and (iv) coupons patched with SMA/CFRP composite. Three stress ranges, 217 MPa, 155 MPa and 93 MPa were considered. Each testing configuration was assigned a two-part designation. The first part indicates the specimen detail: plain steel control coupons (Steel), samples repaired with a CFRP patch (CFRP), samples repaired with SMA wires (SMA), and samples repaired with SMA wires overlaid with a CFRP patch (SMA/CFRP). The second part indicates the far-field stress range of the fatigue test in MPa. Table 1 summarizes all of the specimen configurations. Three repetitions were conducted for each configuration; each specimen has a unique third part serial number to distinguish between multiple repetitions of the same test configuration.

Three steel tension coupons and three Charpy test coupons were fabricated and tested according to ASTM E8 (2013) and ASTM E23 (2012) respectively. The average measured elastic modulus, yield stress, and room-temperature Charpy V-notch energy of the steel are 200 GPa, 400 MPa, and 67 J respectively. All the steel plates used in this research were fabricated from one batch of material to minimize inter-sample variability. The tensile strength, elongation and elastic modulus of the HM CFRP obtained from tension coupon tests according to ASTM D3039 (2014) are 345 MPa, 0.0025 mm/mm, and 138 GPa, respectively. The elastic modulus, ultimate strength and ultimate strain of the Araldite 420 resin obtained from coupon tests according to ASTM D638 (2010) are 3.05 GPa, 62 MPa and 0.022 mm/mm respectively.

The tests were carried out using a MTS servo-hydraulic testing frame with a capacity of 500 kN. All the specimens were tested under constant amplitude, sinusoidal, tension-tension fatigue loading with a load ratio of 0.1 and frequency of 10 Hz. To determine the crack length in the steel substrates at different numbers of fatigue cycles, the beach marking technique was employed (Yu et al. 2013). Figure 4 shows part of the loading history of a specimen and the fracture surface with beach marks to illustrate this technique. Half-amplitude loading cycles were conducted at predefined intervals, as shown in Figure 4(c). During these reduced amplitude loading packets the crack propagation rate decreased substantially generating a dark band on the fracture surface as shown in Figure 4(b). These bands, which were formed at known cycle counts were used to calculate the crack length for a given number of applied cycles. Since the half-amplitude cycles did not substantially propagate the crack, they were not considered in the total cycle count. The maximum and minimum applied loads were recorded every ten cycles to ensure consistency of the loading protocol. The beach marks were slightly asymmetric with respect to the mid-thickness plane which may have been due to the difference of the recovery forces of the SMA wires on both sides.

Figure 4(a) shows the crack front trace on the fracture faces of a single specimen after complete fracture. For convenience, the behavior of the coupons was compared at different stages throughout the loading corresponding to the instances of the reduced-amplitude beach marking cycles. At a given stage in the loading, the applied number of load cycles, N, was related to the beach marks by counting from the last beach mark and calculating the associated number of full-amplitude loading cycles. If the sample failed during the full-amplitude loading cycles, the number of cycles at failure was taken directly from the test frame controller (after subtracting the cumulative number of reduced-amplitude beach marking cycles). If failure occurred during the reduced-amplitude beach marking cycles, the number of cycles at failure was conservatively taken as the last number of full-amplitude cycles prior to failure. As illustrated in Figure 4(a), the crack length corresponding to the $i^{th}$ beach mark, $a_i$, in this research was measured from the root of the 60° edge-notch to the $i^{th}$ beach mark at the mid-thickness of the specimen.

Figure 4 Part of the loading history including the beach marking cycles

Results and discussion

All the specimens experienced abrupt failures due to the rupture of steel when the crack reached a critical length after a certain number of fatigue loading cycles. The patches that were attached to the surface of the steel either fractured at the location of the crack or debonded from the substrate with the rupture of the steel plate. Figure 5 plots the measured fatigue lives of the tested specimens against the stress range. The fatigue lives corresponding to the American Association of State and Highway Transportation Officials (AASHTO) and American Institute of...
Steel Construction (AISC) fatigue categories B’ and E fatigue details are indicated in the figure for reference. As a baseline, it can be seen that the unpatched control specimens had fatigue lives that fall below the AASHTO and AISC fatigue category E. Fatigue lives of all of the tested specimens are summarized in Figure 5. Specimens that were patched with CFRP only and tested at a far-field stress range of 93 MPa exhibited fatigue lives of more than 2 million cycles without any appreciable crack propagation, which is consistent with the constant amplitude fatigue threshold for a fatigue category B’ detail. For samples that were tested at a stress range of 155 MPa, installation of the CFRP patch increased the average fatigue life of the fatigue detail to 8.7 times that of the unpatched control samples, while for a stress range of 217 MPa the average fatigue life of the CFRP-patched samples was 3.0 times that of the unpatched samples. This is equivalent to upgrading the fatigue detail to an AASHTO/AISC category C detail.

The specimens that were retrofitted with only SMA wires bridging the crack (without a CFRP overlay) exhibited an average fatigue life that was 70% greater than that of the control group for a far-field stress range of 155 MPa. It can be seen that the influence of the prestressed SMA wires only was relatively minor compared to that of the CFRP patches. The samples that were retrofitted with the thermally-activated SMA/CFRP patches and tested at stress ranges of 155 MPa and 217 MPa exhibited average fatigue lives that were, respectively, 26 and 15 times those of the control group. As such, installation of the thermally-activated SMA/CFRP patch increased the fatigue lives of the specimens from below that of a category E detail to above that of a category B’ detail.

* fatigue testing runout of 2,000,000 cycles

Figure 6 compares the crack growth (a-N) curves of the specimens that were patched with CFRP only to those of the specimens that were patched with the thermally-activated SMA/CFRP patches. Figure 6(a) shows the specimens that were tested with far-field stress range of 217 MPa. The fatigue life was substantially increased by the SMA/CFRP reinforcing system compared to the CFRP reinforced specimens. Further, among the specimens that were retrofitted with the SMA/CFRP patches even the specimen with the lowest fatigue life exceeded the life of the fatigue category B’ detail. The specimens reinforced with CFRP exhibited lower fatigue lives than AASHTO fatigue category C. Figure 6 b) shows the specimens tested at a far-field stress range of 155 MPa. The scatter of the fatigue lives may have been due to the combination of the inherent variability in crack initiation and differences between the recovery stresses generated by the SMA wires. However, the shortest fatigue life among these specimens still exceeded the fatigue life of an AASHTO category B’ detail.
CONCLUSIONS

This paper discusses the effectiveness of a newly-developed thermally-activated SMA/CFRP patch for extending the fatigue lives of fatigue-sensitive steel details. The approach exploits the unique thermomechanical properties of SMA wires to apply compressive stresses to the steel elements. Four groups of single edge-notched specimens were reinforced with different reinforcement configurations and tested under tension-tension fatigue loading up to failure at three different stress ranges. The results showed that the thermally-activated SMA/CFRP composite patches increased the average fatigue lives of edge-notched steel plates to 26 and 15 times those of the un-patched plates at 155 MPa and 217 MPa far-field stress ranges, respectively. This improvement was equivalent to upgrading the fatigue detail from worse than an AASHTO category E detail to better than a category B’ detail. In comparison, the specimens that were patched with CFRP only had average fatigue lives that were 3 and 8.7 times those of the unpatched samples at stress ranges of 155 and 217 MPa, respectively. The prestressed SMA wires alone prolonged the average fatigue life by 70% at the 155 MPa stress range. This indicates that the thermally-activated SMA/CFRP patching system is much more effective than the simple sum of the reinforcing effects of CFRP and prestressed SMA wires. It is evident that there is a synergistic effect between the CFRP and prestressed SMA wires in strengthening fatigue sensitive steel details. The results suggest that the thermally-activated SMA/CFRP patch is a promising system for improving the lives of fatigue-sensitive metallic members.

ABSTRACT

The application of Carbon Fibre Reinforced Polymers (CFRP) in strengthening and retrofitting of existing structures has emerged as a practical and efficient technique compared to the application of conventional materials (i.e. steel and concrete). In case of flexural strengthening of reinforced concrete (RC) beams, prestressed CFRP provides better performance at service conditions compared to non-prestressed CFRP. Recently, researchers have utilized the Iron-based Shape Memory Alloy (Fe-SMA) reinforcement (bars or strips) for strengthening applications of RC beams. The Fe-SMA reinforcement is a metallic alloys that can recover part of the induced tensile strain upon heating. If the pre-strained Fe-SMA reinforcement is restrained (i.e. anchored to the tension side of the beam), the heating will trigger the inherited shape memory recovery property to be initiated. However, because the SMA reinforcement is restrained, a prestressing force will be developed instead. This paper presents a numerical comparison between large-scale RC beams strengthened with prestressed Near-Surface Mounted (NSM) CFRP rods and self-prestressing NSM Fe-SMA strips with a comparable amount of prestressing forces. Both techniques show a similar performance at the service load conditions. While the beams strengthened with prestressed NSM CFRP rods show strength-ductility trade-off, the beams strengthened with NSM Fe-SMA strips exhibited more ductile behaviour, this is attributed to the yielding nature of the Fe-SMA material.

INTRODUCTION

Strengthening RC structures with externally bonded (EB) or near-surface mounted (NSM) CFRP reinforcement (sheets, rods, strips) has become one of the major research topics in structural engineering. This is driven by the need to retrofit/strengthen deteriorated infrastructures around the globe. Most of the CFRP-strengthening applications are passive techniques, where the CFRP reinforcement are applied to increase the ultimate capacity of the structures (El-Hacha and Rizkalla 2004). Passive strengthening techniques have minimal effect on the serviceability performance of the structure. To improve the performance of structures at service conditions, researchers introduced the prestressing CFRP as an active strengthening technique (El-Hacha et al. 2001, Wight et al. 2003, El-Hacha and Soudki 2013). In the case of RC beams, the CFRP material is prestressed against the RC beam in a way to counteract the applied loads, and consequently, improve the cracking load, yielding load, and the ultimate load of the beam. While the prestressing technique contributes significantly in improving the serviceability performance of RC beams, this comes at the cost of reducing the ductility. The more strain utilized for prestressing the more brittle the beams become (El-Hacha and Gaafar 2011). In addition to that, the application of prestressing force to the CFRP requires special end anchorage system and jacking tools. These are two main concerns that were the driving force behind the current research project that involves the utilization of the Iron-based Shape Memory Alloys (Fe-SMA) for flexural strengthening of RC beams.

The SMAs are metallic alloys that are mainly characterized by the ability to recover their original shape upon heating (Lagoudas 2008, Cismasiu 2010). The Fe-SMA is relatively inexpensive compared to the common shape memory alloys such as Nickel Titanium (NiTi), which makes it more suitable for large-scale structural engineering applications (Cladera, Weber et al. 2014, Czaderski, Shahverdi et al. 2014). Recently, Fe-SMA bars and strips for were used for flexural strengthening of small-scale RC beams using the Near Surface Mounted (NSM) strengthening technique (Rojob and El-Hacha (2016), Shahverdi, Czaderski et al. (2016)). In the NSM technique, the strengthening materials is embedded in a pre-cut groove at the tension side of the beam. The initial strain was
applied to the Fe-SMA materials before being anchored to the ends of the beam. The Fe-SMA material was placed inside the groove, then heated to the activation temperature which triggered the Shape Memory Effect (SME) and caused the prestressing force to be developed in the Fe-SMA bars or strips (Rojob and El-Hacha 2016).

The Fe-SMA reinforcement have a great potential in the field of cast-in-place prestressed concrete as an alternative to the high-strength steel cables or CFRP tendons. However, the current available Fe-SMA reinforcement are not comparable in strength to the steel cables nor to the CFRP tendons. In spite of the advantages of the strengthening system using the self-prestressing NSM Fe-SMA strip mentioned above, it is a steel-based material which makes it susceptible to corrosion. Although materials such as Chrome and Nickel could be added to develop a high corrosive-resistant SMA reinforcement, there is a need to study the long-term behaviour of this material under different environmental conditions.

This paper is part of an ongoing research project that involves strengthening of large-scale RC beams using NSM Fe-SMA strips. The beams were built to match other beams strengthened with prestressed CFRP rod and tested by El-Hacha and Gaafar 2011). The current paper presents a numerical comparison between the beams strengthened with NSM CFRP rods and similar beams strengthened with NSM Fe-SMA strips as part of the ongoing project. No experimental results are available at the time this paper is being prepared.

DETAILS OF THE RC BEAMS

Geometry

Figure 1 shows the details of a typical RC beam used in this study. The beam was reinforced with 3-15M bars in tension and 2-10M bars in compression with total cross-sectional area of 600 mm² and 200 mm², respectively. 10M bars were also used to form the shear stirrups. The spacing was 300 mm in the region of zero shear and 200 mm elsewhere. The beams were tested on four-point bending set-up. The NSM technique was used for strengthening using both CFRP rods and Fe-SMA strips.

Material Characteristics

The concrete compressive strength was 40 MPa and the steel yield strength was 475 MPa. The CFRP rods are 9 mm in diameter possessing linear elastic behaviour up to failure, with a modulus of elasticity of 130 GPa and an ultimate tensile strength and strain of 2167 MPa and 1.66% respectively (El-Hacha and Gaafar 2011). The Fe-SMA strips are non-linear material as shown in the stress-strain curve in Figure 2. Figure 3 shows the shape memory effect process of the Fe-SMA strips. The induced initial strain for the strip was 4%. During the heating and cooling process, the ends of the strips are restrained. The reduction in the stress at the beginning of the heating process was due to the thermal expansion effect, the stress started to pick up at temperature of 65 °C. During the cooling process, the stress increased due to the removal of the thermal expansion effect. The difference between the stress at the end of the cycles and the stress at the beginning of the cycles is the total recovery stress. The recovery stress of this Fe-SMA strips is about 260 MPa. The total area of the Fe-SMA strips was chosen such that the amount of prestressing force will match the prestressing forces induced in the CFRP rods as reported by El-Hacha and Gaafar (2011). Table 1 shows the beams to be modeled and the details of the strengthening materials.

DESCRIPTION OF FE MODEL

A 3D finite element model of the RC beams was developed using ABAQUS. Only quarter of the beams was modelled making use of two planes of symmetry. To insure the symmetry, boundary conditions were imposed at the symmetric surfaces as shown in Figure 4. The mesh sensitivity analysis was conducted to make sure that the
results are mesh independent. The concrete, and the steel plates used at the loading points and at the supports were modelled using linear solid elements, while the internal steel, CFRP and Fe-SMA reinforcement were modelled using linear truss element. The interaction between the reinforcements and the concrete were imposed through the embedded region option, were the translation of the reinforcements nodes are restricted by the translations of the concrete nodes. The beams were loaded in a displacement-controlled mode to get the full load-deflection response.

Material Models

Concrete

The concrete behaviour in compression was modelled using the stress-strain model developed by Carreira and Chu (1985) as presented in Equations 1 to 3 and shown in Figure 5.

![Stress-strain curve of Fe-SMA strip](after Re-fer, 2015)

![SME process](after Re-fer, 2015)

![Configuration of the FE model for Beam C](loading plate, support, Uy=0, Uz=0, Ux=0)
\[ f_c = f_c' \left( \frac{Bx}{8 - 1 + x} \right) \]  \hspace{1cm} (1)

\[ B = \left( \frac{1}{1 - f_c'/\varepsilon_0} \right); \text{ and } x = \frac{\varepsilon_c}{\varepsilon_o} ; \varepsilon_o = 0.0029 \]  \hspace{1cm} (2)

\[ E_{it} = 3320\sqrt{f_c'} + 6900 \text{ MPa} \]  \hspace{1cm} (3)

where, \( f_c \) is the concrete stress in MPa, \( \varepsilon_c \) is the concrete strain, and \( E_{it} \) is the initial tangent modulus of the concrete in MPa.

The concrete in tension was modeled using the stress-displacement model developed by Coronado and Lopez (2006) as shown in Figure 6. The concrete tensile strength and fracture energy were calculated based on the CEB-FIP (1993) model as shown in Equations 4 and 5, respectively.

\[ f_t = 1.4 \left( \frac{f_c' - 10}{8} \right)^{2/3} = 3.04 \text{ MPa} \]  \hspace{1cm} (4)

\[ G_F = \left( 0.0469d_a^2 - 0.5d_a + 26 \right) \left( \frac{f_c'}{10} \right)^{0.7} = 0.0917 \text{ N/mm} \]  \hspace{1cm} (5)

where \( f_t \) is the concrete tensile strength, \( G_F \) is the fracure energy of concrete, \( f_c' \) is the concrete compressive strength, and \( d_a \) is the maximum aggregate size in mm.

**Steel**

The actual stress-strain curve of steel as reported by El-Hacha and Gaafar (2011) was simplified into a tri-linear curve as shown in Figure 7.
**Strengthening Materials**

The CFRP rod was modelled as linear elastic up to failure. The Fe-SMA strip was modelled using the actual nonlinear stress-strain curve as shown in Figure 2. The prestressing force was modelled as a predefined value of stress in the second step of the analysis.

**RESULTS AND DISCUSSIONS**

**Validation of the FE model:**

To validate the FE model, the predicted load-midspan deflection curves of beams B-C, CFRP-1, were compared to the experimental results reported by El-Hacha and Gaafar (2011) as shown in Figure 8. The results show a good agreement between the numerical and experimental results. The FE model results are a bit stiffer than the experimental results especially for beam CFRP-1. This is attributed to the fact that in the actual test results, there was a slip between the CFRP rod and the epoxy adhesive filling the groove and the surrounding concrete as reported by El-Hacha and Gaafar (2011) which was not accounted for in the FE model. As the model is verified, it will be used in the following section to compare between the beams strengthened with prestressed NSM CFRP rods and the beams strengthened with NSM Fe-SMA strips.

**Comparison between the CFRP and Fe-SMA**

Figure 8 FE results versus experimental results for beams C and CFRP-1

Figure 9 FE results of the load deflection curves for beams strengthened with CFRP and Fe-SMA

Figure 9 shows the load-midspan deflection curves of the beams strengthened with NSM Fe-SMA strips and those strengthened with NSM CFRP rod. Beam CFRP-1 and beam SMA-1 have a prestressing force of 28 kN and 27.3 kN, respectively. Both beams have a comparable behaviour at service load (i.e. cracking and yielding loads) as presented in Table 2. Beam CFRP-1 has a higher ultimate load compared to beam SMA-1, however, this comes at the cost of reducing the ductility of the beam and results in a sudden failure by rupture of the CFRP rod at a relatively small deflection. On the contrary, beam SMA-1 shows a 60% increase in the ultimate load over the control beam (only 10% less than beam CFRP-1) without compromising the ductility. In fact, the failure pattern of beam SMA-1 is not different than the behaviour of an under-reinforced concrete beam that starts with the yielding of the reinforcements (i.e. the internal steel rebars and the Fe-SMA strips) before the crushing of the concrete. This is due to the yielding nature of the Fe-SMA material that allows the RC beam to deflect significantly before the crushing of the concrete.

The same scenario can be observed when comparing beam CFRP-2 and beam SMA-2. Both beams with prestressing forces of 56 kN and 54.6 kN, respectively, have a comparable behaviour at the service load. While beam CFRP-2 experienced more brittle behaviour than beam CFRP-1, beam SMA-2 had a ductile failure comparable to beam SMA-1 and to the control beam. Because the axial stiffness of the Fe-SMA strips in beam SMA-2 is higher that the axial stiffness of the CFRP rod in beam CFRP-2, this allows beam SMA-2 to have a higher ultimate capacity. In addition to the ductile nature of the beams strengthened with Fe-SMA strips, the other advantage of the self-prestressing NSM Fe-SMA strengthening technique over the prestressed NSM CFRP strengthening is the easiness of applying the prestressing force. The prestressing force in the Fe-SMA strips can be applied by heating the Fe-SMA material through electric current (or other heating procedures) just above the activation temperature (150 °C for the Fe-SMA strip used herein); a process that is done after the curing of the grouting material while no anchorage or jacking tools are needed.

CONCLUSIONS

This paper has presented a comparison between two active strengthening techniques, prestressed NSM CFRP rod and self-prestressed NSM Fe-SMA strips with comparable induced prestressing force on the RC beams. The Fe-SMA strips show a potential capability in strengthening RC beams for flexure while not compromising the ductility. Additionally, applying the prestressing force is much easier in the case of NSM Fe-SMA strips compared to the NSM CFRP rods due to the inherited shape memory effect phenomena which can be triggered by heating. More research is required to examine the corrosion-resistivity of this material, also a higher strength Fe-SMA is required if the material is to be used for cast-in-place prestressed concrete applications.

ACKNOWLEDGEMENT

The authors would like to acknowledge the University of Calgary and the Natural Sciences and Engineering Research Council of Canada (NSERC) for their financial support towards the research project. The authors are also grateful to Sika Canada for providing the epoxy and Hughes Brothers for providing the CFRP rods.

ABSTRACT

Fatigue is one of the most important failure mechanisms that affect steel structures during their design life. Therefore, fatigue problems affecting steel structures due to external effects (cyclic loading, dynamic loading, etc.) have become a major concern for structural engineers. Conventional methods for fatigue life improvement of steel structures include attaching external steel plates. This has many disadvantages and deficiencies, as the steel plates are large in size, heavy in weight and they use the same material (steel), which is also subject to corrosion and fatigue. Therefore, there is a need for new advanced methods for fatigue life enhancement of steel structures. This paper reports the development of an active hybrid CFRP/SMA composite made of unidirectional normal modulus carbon fibre reinforced polymer (CFRP) fabric embedded with pre-strained body temperature nickel titanium (NiTi) shape-memory alloy (SMA) wires. The study involved the fabrication of CFRP/SMA composites with different levels of pre-stressing capabilities. The composites were then attached using a strong structural epoxy adhesive to initially notched steel plates to study their effectiveness in improving the fatigue life of the steel plates. The experimental work included cyclic fatigue testing on un-strengthened steel plates, cyclic fatigue testing on steel plates strengthened with CFRP patches and cyclic fatigue testing on steel plates strengthened with CFRP/SMA patches. It was found that embedding pre-strained body temperature NiTi SMA wires inside the CFRP/SMA patches effectively increases the fatigue life of initially cracked steel plates.

INTRODUCTION

Steel structures subjected to cyclic loading such as bridges and offshore platforms, are at risk of failure due to the presence of fatigue cracks created by fatigue. Therefore, it is very important that these fatigue cracks are repaired in an efficient and safe way to prevent any possibility of failure of the steel structure. Fatigue life enhancement is one of the most important parts of the repair and rehabilitation process in steel structures. In this paper, an advanced method using active smart composites is proposed for use in improving the fatigue life of steel structures subjected to cyclic loading. CFRP and SMAs with their unique properties and behaviour are very important materials, because of their great potential for application in civil engineering. Therefore, the combination of CFRP and SMAs will produce a smart active hybrid composite patch with many possible capabilities and applications in civil engineering. Active hybrid CFRP/SMA composites could be effectively used for improving the fatigue and creep properties of structures, or improving their damping capacity, or controlling their shape or vibration properties. Liu and Li (2006) presented an innovative repair method for strengthening damaged reinforced concrete (RC) beams using CFRP plates in combination with SMA wires. Wierschem and Andrawes (2010) studied experimentally and analytically the use of super-elastic SMA-FRP composites for the reinforcement of concrete structures. Zhang et al. (2006) presented the use of CFRP matrix composites embedded with SMA wires for vibration control under impact loading. Xu et al. (2003) investigated the development of shape-memory alloy/carbon fibre reinforced plastic hybrid composites for damage suppression at ambient temperature. In addition, Lee et al. (2004) proved that crack closure is greatly improved by the application of NiTi SMA- CFRP composites.
EXPERIMENTAL WORK

Fabrication of CFRP and CFRP/SMA Patches

Five types of patches were fabricated in the experimental work reported here. The first type was CFRP fabric patches with two 0° direction CFRP layers and without embedded SMA wires. This was given the name CFRP-2L. The second type was CFRP fabric patches with two 0° direction CFRP layers plus one 90° direction CFRP layer and without embedded SMA wires. This was given the name CFRP-(2+1)L. The third type was CFRP fabric patches with two 0° direction CFRP layers plus one 90° direction CFRP layer embedded with 15 non-pre-strained body temperature SMA wires. This was given the name CFRP-(2+1)L/15BT-SMA(NP). The fourth type was CFRP fabric patches with two 0° direction CFRP layers plus one 90° direction CFRP layer embedded with 9 pre-strained body temperature SMA wires. This was given the name CFRP-(2+1)L/9BT-SMA(P). The fifth type was CFRP fabric patches with two 0° direction CFRP layers plus one 90° direction CFRP layer embedded with 15 pre-strained body temperature SMA wires. This was given the name CFRP-(2+1)L/15BT-SMA(P). Two fabrication methods were adopted in this study to manufacture the five types of composites. The first fabrication method was designed to produce the first and second type of patch. The second fabrication method was designed to produce the third, fourth and fifth type of patch.

Fabrication Method 1

The fabrication process for the first type (CFRP-2L) and the second type (CFRP-(2+1)L) of patches was conducted following the procedure presented below and shown in Figure 1:

(a) Cut the CFRP fabric sheets to the required dimensions (50mm x 250mm). Next place the first bottom CFRP (0° ply) on a plastic sheet and then apply a uniform thin layer of epoxy adhesive on it. Then turn the CFRP ply to the other side and apply a uniform pressure using a roller to help the epoxy to be absorbed by the CFRP fabric;
(b) Place the saturated CFRP ply on a flat bottom steel plate and then apply layer of the epoxy adhesive on it;
(c) Place the middle layer of the CFRP (90° ply) fabric over the epoxy adhesive and then apply a uniform pressure on the CFRP fabric surface using a roller to help the epoxy adhesive to be absorbed by the CFRP fabric (This step is omitted for the first type (CFRP-2L);
(d) Apply a second layer of epoxy adhesive over the middle layer of the CFRP (90° ply) fabric and distribute the epoxy adhesive evenly along with the fibre direction (This step is omitted for the first type (CFRP-2L);
(e) Place the top layer of the CFRP (0° ply) fabric over the epoxy adhesive and then apply uniform pressure on the CFRP fabric surface using a roller to help the epoxy to be absorbed by the CFRP fabric. Two aluminium plates are attached to both sides of the CFRP fabric patch to provide a uniform thickness for the patch;
(f) Place the top flat steel plate over the top layer of the CFRP fabric. Press the top steel plate to remove the excess epoxy adhesive and to maintain a uniform epoxy adhesive thickness between the top CFRP layer and bottom CFRP layer. The patch is left to cure at room temperature for a minimum of seven days.

![Figure 1 Fabrication process for the first type (CFRP-2L) and the second type (CFRP-(2+1)L) of patch](image)

Fabrication Method 2

The fabrication process for the third type (CFRP-(2+1)L/15BT-SMA(NP)), the fourth type (CFRP-(2+1)L/9BT-SMA(P)) and the fifth type (CFRP-(2+1)L/15BT-SMA(P)) of patches was conducted following the procedure presented below and shown in Figure 2:
(a) Cut the SMA wires (1.00 mm in diameter) to the required length (approximately 400 mm), then sand-blast the SMA wires to increase their surface roughness for better bonding inside the CFRP/SMA patch. Then pre-strain the SMA wires to an approximate value of 6% using a special pre-straining device (This step of pre-straining is omitted for the third type of patch):
(b) Attach the pre-strained or non-pre-strained SMA wires on a special frame (called Frame 1). Frame 1 is used to restrain the pre-strained wires and prevent the loss of the pre-straining during the fabrication process. The frame helps to maintain uniform spacing between the SMA wires inside the CFRP/SMA patch;
(c) Cut the CFRP fabric sheets to the required dimensions (50mm x 250mm) and then place the first bottom CFRP (0° ply) on a plastic sheet and apply a uniform thin layer of epoxy adhesive to it. Then turn the CFRP ply over and apply uniform pressure using a roller to help the epoxy to be absorbed by the CFRP fabric;
(d) Place the saturated CFRP ply on a flat bottom steel plate and then apply layer of the epoxy adhesive to it;
(e) Place the special frame with the pre-strained or the non-pre-strained SMA wires over the epoxy adhesive and the bottom CFRP sheet. Add more epoxy to cover the SMA wires and smooth and level the epoxy surface;
(f) Place the middle layer of the CFRP (90° ply) fabric over the epoxy adhesive and the SMA wires, then apply uniform pressure on the CFRP fabric surface using a roller to help the epoxy adhesive to be absorbed by the CFRP fabric;
(g) Apply a second layer of epoxy adhesive over the middle layer of the CFRP (90° ply) fabric and distribute the epoxy adhesive evenly along with the fibre direction;
(h) Place the top layer of the CFRP (0° ply) fabric over the epoxy adhesive and then apply uniform pressure on the CFRP fabric surface using a roller to help the epoxy adhesive to be absorbed by the CFRP fabric. Attach two aluminium plates to both sides of the CFRP/SMA patch to provide a uniform thickness for the patch;
(i) Place the top flat steel plate over the top layer of the CFRP fabric. Press the top steel plate to remove the excess epoxy adhesive and to maintain a uniform epoxy adhesive thickness between the top CFRP layer and bottom CFRP layer. The patch is left to cure at room temperature for a minimum of seven days.

Figure 2 Fabrication process for the third type (CFRP-(2+1)L/15BT-SMA(NP)), the fourth type (CFRP-(2+1)L/9BT-SMA(P)) and the fifth type (CFRP-(2+1)L/15BT-SMA(P)) of patch

Attaching the CFRP and CFRP/SMA Patches on the Steel Plates

The five types of fabricated CFRP and CFRP/SMA patches were attached to steel plates 500 mm in length, 90 mm in width and 6 mm in thickness. The procedures followed for attaching the CFRP fabrics and CFRP/SMA patches to the initially cracked steel plates are listed below and shown in Figure 3:
(a) Clean the initially cracked steel plate using acetone and then sand-blast it to increase its surface roughness for better bonding between the CFRP fabric patch or the CFRP/SMA patch and the steel plate. Place the sand-blasted steel plate on a flat bottom steel plate and then apply the epoxy adhesive to the sand-blasted area;
(b) Apply the epoxy adhesive to one side of the CFRP fabric patch or CFRP/SMA patch;
(c) Place the epoxy side of the CFRP fabric patch or CFRP/SMA patch on the initially cracked steel plate;

1114
(d) Place the top flat steel plate over the CFRP fabric patch or CFRP/SMA patch. Press the top steel plate to remove the excess epoxy adhesive and to maintain a uniform epoxy adhesive thickness between the CFRP fabric patch or CFRP/SMA patch and the initially cracked steel plate. The whole set-up is left to cure at room temperature for a minimum of seven days.

![Figure 3 Attachment process of the CFRP fabrics and CFRP/SMA patches to the initially cracked steel plates](image)

**Fatigue Tests on the Un-strengthened and Strengthened Initially Cracked Steel Plates**

Fatigue tests were conducted on the un-strengthened initially cracked steel plates and the initially cracked steel plates strengthened with CFRP fabric and CFRP/SMA patches using a 250 kN MTS testing machine to determine their fatigue life, defined as the number of loading cycles required to fracture the specimens. During the fatigue tests, the specimens were subjected to a cyclic loading range of 9.2 kN - 92 kN for 60000 cycles at a frequency of 10 Hz followed by a cyclic loading range of 9.2 kN - 50.6 kN for 30000 cycles at a frequency of 20 Hz, and this cyclic loading is repeated until the total fracture of the specimen. For the initially cracked steel plates strengthened with CFRP/SMA patches, the pre-strained SMA wires embedded inside the patches were activated using the heat produced by halogen lamps to generate stress recovery before applying the cyclic loading. The initially cracked steel plates were prepared following the procedure given by the ASTM Standard E647 (2013). The notch in the steel plate was located in the centre of the steel plate for the purpose of specifying the place where the steel plate should fracture. The experimental test set-up for fatigue testing using the MTS testing machine and a schematic of the initially cracked steel plates are shown Figure 4.

![Figure 4 Experimental test set-up for fatigue testing using the MTS testing machine and a schematic of the initially cracked steel plates](image)
RESULTS AND DISCUSSION

From the fatigue tests conducted on the un-strengthened initially cracked steel plates and the initially cracked steel plates strengthened with CFRP fabrics and CFRP/SMA patches, the fatigue life of the specimens was determined. Six groups of specimens with two repeats for each group were prepared and tested under cyclic loading fatigue. The first group was the un-strengthened initially cracked steel plates which was the control group and given the name SP-(Control). The second group was the initially cracked steel plates strengthened on both sides using the first type (CFRP-2L) of patch and was given the name SP-(CFRP_2L2S). The third group was the initially cracked steel plates strengthened on both sides using the second type (CFRP-(2+1)L) of patch and was given the name SP-(CFRP_(2+1)L2S). The fourth group was the initially cracked steel plates strengthened on both sides using the third type (CFRP-(2+1)L/15BT-SMA(NP)) of patch and was given the name SP-(CFRP_(2+1)L2S)-(15BT_SMA(NP)). The fifth group was the initially cracked steel plates strengthened on both sides using the fourth type (CFRP-(2+1)L/9BT-SMA(P)) of patch and was given the name SP-(CFRP_(2+1)L2S)-(9BT_SMA(P)). The sixth group was the initially cracked steel plates strengthened on both sides using the fifth type (CFRP-(2+1)L/15BT-SMA(P)) of patches and was given the name SP-(CFRP_(2+1)L2S)-(15BT_SMA(P)). The fatigue life test results for the six groups of the un-strengthened and strengthened initially cracked steel plate specimens are shown in Figure 5.

From Figure 5, by comparing the fatigue life of the first and second group, it can be seen that the fatigue life of the initially cracked steel plate is significantly increased by an increment factor of 2.97, due to the effect of the attached CFRP fabric patches. By comparing the fatigue life of the second, third and fourth groups, it can be seen that the fatigue life of the initially cracked steel plate is slightly increased, which indicates that adding the 90° ply CFRP fabric to the composite has a very small effect on increasing the fatigue life of the initially cracked steel plate. The reason for adding the 90° ply CFRP fabric to the CFRP/SMA composite was to prevent the SMA wires from peeling out of the CFRP/SMA patch during the activation process required to generate the recovery stress using the halogen lamps. It also indicates that embedding the non-pre-strained body temperature NiTi SMA wires inside the CFRP/SMA patches has no effect on increasing the fatigue life of the initially cracked steel plate. On the other hand, by comparing the fatigue life of the fifth and sixth groups with that of the fourth group, it can be seen that embedding the pre-strained body temperature NiTi SMA wires inside the CFRP/SMA patches can effectively increase the fatigue life of the initially cracked steel plates.

Figure 5 Fatigue life results of the un-strengthened and strengthened initially cracked steel plate specimens
CONCLUSION

This paper presents the development of an active hybrid CFRP/SMA composite made of unidirectional normal modulus carbon fibre reinforced polymer (CFRP) fabric embedded with pre-strained body temperature nickel titanium (NiTi) shape-memory alloy (SMA) wires. The study mainly involved the fabrication of CFRP fabrics and CFRP/SMA patches. The patches were then attached using a strong structural epoxy adhesive to initially cracked steel plates. The experimental work included conducting cyclic fatigue testing on un-strengthened initially cracked steel plates, cyclic fatigue testing on initially cracked steel plates strengthened with CFRP fabric patches, and cyclic fatigue testing on initially cracked steel plates strengthened with CFRP/SMA patches. From the results of the fatigue life tests conducted on the un-strengthened and strengthened initially cracked steel plate specimens, it was found that the fatigue life of the initially cracked steel plates was increased by an increment factor of 2.97, 3.19 and 3.17 for the second, third and fourth groups of specimens, respectively. In addition, and most importantly, it was found that the fatigue life of the initially cracked steel plates was increased by an increment factor of 4.0 and 4.76 for the fifth and sixth groups of specimens, respectively. This strongly indicate that embedding pre-strestrained body temperature NiTi SMA wires inside the CFRP/SMA patches used to strengthen initially cracked steel plates can effectively increase their fatigue life.

ABSTRACT

Carbon fiber reinforced polymer (CFRP) materials have been used for strengthening of concrete and metallic structures. There are several differences between the behavior of bonded joints in CFRP-strengthened concrete and metallic members. One of the main differences between CFRP–concrete and CFRP–metal bonded joints is that in the latter, failure will likely occur in the adhesive layer and in the former failure is expected to occur in the concrete. Furthermore, in the concrete girders, cracks are often initiated at low load levels in the tension face, and the bonded CFRP strip tries to close the crack, and consequently increase the stiffness and cracking load. Nevertheless, metallic girders do not crack even after yielding and the effect of having adhesive between the CFRP laminate and steel substrate is limited to transferring the shear stresses from the steel substrate to the CFRP laminate along the connection. Because of these differences, the strengthening concepts for steel and concrete are different, and, therefore, different CFRP prestressing systems are required. This paper provides a short review for different CFRP retrofit systems that have been recently developed at Empa for concrete and metallic members. Details about strengthening of a concrete and a metallic bridge using prestressed CFRP strips are given. At the end, a novel pre-stressing system, which is based on iron-based shape memory alloy (Fe-SMA), is presented.

INTRODUCTION

History of CFRP Composites for Structural Strengthening

Application of adhesively bonded fibre composite reinforcement for strengthening of aircraft structures has begun in mid-1870s (i.e., Baker 1975). Carbon-fiber-reinforced polymer (CFRP) or boron-fiber-reinforced polymer (BFRP) were used for strengthening of fatigue- and corrosion-cracked aircraft structures made of aluminum alloys (e.g., Baker 1978).

About twenty years after the first CFRP-strengthening application in aerospace engineering, the application of CFRP materials for rehabilitation of civil structures has been started by Professor Urs Meier and his team in mid-1890s, for the first time, at the Swiss Federal Laboratories for Materials Science and Technology (Empa). Meier and his (e.g., Meier 1987, Meier 1995, Meier and Deuring 1991) team have done the first studies worldwide on the use of CFRP composites for strengthening of civil structures.

Nowadays, the use of CFRP composites is common for strengthening of concrete (e.g., Czaderski and Motavalli 2007, Michels et al. 2014, Motavalli et al. 2011) and metallic (e.g., Ghafoori and Motavalli 2015b, Ghafoori and Motavalli 2015c, Ghafoori and Motavalli 2015a) structures. Despite of the common use of CFRP materials for civil strengthening applications, only 20 to 30% of the high strength of CFRP strips is used (Motavalli et al. 2011). One reason that can be contributed to this poor material efficiency is that most strengthening tasks are stiffness controlled rather than strength-controlled (Meier 2007). Therefore, a more efficient use of the high strength of the CFRP is achieved by prestressing the CFRP material.

Prestressed CFRP Strips for Structural Strengthening

In the early 1990s, the first worldwide research on prestressing CFRP strips for strengthening of reinforced concrete structures was initiated by Meier and his team (Meier 1995). In this research, CFRP strips were prestressed using different prestressors such as conventional concrete prestressing tendons, cold-formed stainless steel wires, and glass and carbon fiber composite tendons. The investigation showed that prestressing of CFRP strips could increase the strain capacity of the strips and lead to a better utilization of the high strength of the CFRP material. However, the use of conventional prestressing tendons is limited by the high initial cost and the need for dedicated prestressing equipment. Furthermore, the use of cold-formed stainless steel wires is limited by the low strength of the wires and their poor durability in adverse environments.

In order to overcome these limitations, new prestressing systems have been developed and reported in the literature. These systems include the use of self-locking steel bolts, mechanical devices, and shape memory alloy (SMA) wires. Among these systems, the use of SMA wires has attracted significant interest due to their ability to withstand high temperatures and to provide a high level of resistance to corrosion.

The use of SMA wires for prestressing CFRP strips has several advantages. First, SMA wires can be easily manufactured with a high level of resistance to corrosion and high temperature. Second, SMA wires can be easily installed using conventional prestressing equipment. Third, SMA wires can be easily adjusted to the desired prestress level, which is an important advantage when prestressing CFRP strips for strengthening of concrete structures.

In this paper, a novel pre-stressing system, which is based on iron-based shape memory alloy (Fe-SMA), is presented. This system allows for the easy installation of the prestressors and provides a high level of resistance to corrosion. The prestressors can be easily adjusted to the desired prestress level, which is an important advantage when prestressing CFRP strips for strengthening of concrete structures.

The use of Fe-SMA wires has several advantages over other prestressing systems. First, Fe-SMA wires can withstand high temperatures and provide a high level of resistance to corrosion. Second, Fe-SMA wires can be easily installed using conventional prestressing equipment. Third, Fe-SMA wires can be easily adjusted to the desired prestress level, which is an important advantage when prestressing CFRP strips for strengthening of concrete structures.

In this paper, a novel pre-stressing system, which is based on iron-based shape memory alloy (Fe-SMA), is presented. This system allows for the easy installation of the prestressors and provides a high level of resistance to corrosion. The prestressors can be easily adjusted to the desired prestress level, which is an important advantage when prestressing CFRP strips for strengthening of concrete structures.

In summary, the use of Fe-SMA wires for prestressing CFRP strips has several advantages over other prestressing systems. First, Fe-SMA wires can withstand high temperatures and provide a high level of resistance to corrosion. Second, Fe-SMA wires can be easily installed using conventional prestressing equipment. Third, Fe-SMA wires can be easily adjusted to the desired prestress level, which is an important advantage when prestressing CFRP strips for strengthening of concrete structures.
Concrete (RC) girders was started at Empa (Deuring 1993). In this study, mechanical anchorages were used to attach the prestressed CFRP strips to the RC girders. After some years, also at Empa, the gradient end anchorage technique was invented and patented by Meier and his team (e.g., Meier and Stocklin 2005, Stocklin and Meier 2001, Stocklin and Meier 2002). More recent developments in the field are given in Ghafoori and Motavalli 2016b. The current paper aims to present the different prestressing techniques that have been developed recently at Empa for strengthening of concrete and also metallic structures. The strengthening material for the majority of the applications was the CFRP composites, however, this paper also presents a new prestressing system, which is based on using iron-based shape memory alloy (Fe-SMA). The paper has three main sections. Each section focuses on a specific strengthening topic. The first section gives a brief review on the Empa research on strengthening of RC girders. The second section focuses on CFRP strengthening of metallic members, and the third section gives a short overview about the ongoing research at Empa on development and application of Fe-SMA products as a new prestressing member in civil engineering.

**STRENGTHENING OF RC GIRDERS WITH PRESTRESSED CFRP STRIPS**

When RC girders are strengthened with prestressed bonded CFRP strips, prestressing decreases existing crack widths, deflections and stresses, and hence enhances durability and serviceability of the retrofitted member. Moreover, prestressed bonded reinforcement (PBR) system decreases the stress range in the steel rebars, and, therefore, it improves the fatigue behavior.

An innovative CFRP prestressing technique without using a mechanical anchorage system for strengthening of RC girders has been developed at Empa. In this method, the prestressing force in the CFRP plate is gradually decreased to zero at both end of the strip, with intermediate sector-wise accelerated curing of the epoxy resin. This method uses a special prestressing and heating device so that there is no need for a mechanical anchorage system. As mentioned, the gradient in the prestress force in the CFRP strip is applied by a sector-wise heating and curing of the adhesive, while the force in the CFRP strip is released step-wise, as illustrated in Figure 1. The efficiency of such a retrofitting system with gradient anchorage system was demonstrated by static loading tests on 17-m-
long concrete girders taken from an existing bridge in Ticino (Switzerland) (Czaderski and Motavalli 2007). The maximum loads reached with the girders were 24% (for non-prestressed CFRP, girder 4) and 45% (for prestressed CFRP, girder 2) higher than that of the reference girder (girder 3), as shown in Figure 2.

Tulcoempa project: Similar experimental investigation has been performed in the framework of a Polish-Swiss Research project ‘Tulcoempa’. Prior to strengthening of existing prestressed concrete girders on an existing bridge in Poland, two girders were re-produced at Empa according to the original drawings. Subsequently, one girder was retrofitted with two prestressed CFRP strips (total prestress force 2 x 120 kN=240 kN) with a gradient anchorage. A shear strengthening with a CFRP fabric was also applied. As shown in Figure 4, an increase in cracking, yielding and ultimate load could be reached. Additionally, the ultimate load was reached by tensile failure in the CFRP strip at around 1.6% strain Gafoori and Motavalli 2016a.

Similar girders of a bridge in Poland were afterwards strengthened, also with prestressed CFRP laminates with gradient anchorage. The sole difference in this case was a reduced prestress force per strip of 75 kN and 90 kN, respectively. The existing upper concrete deck was also replaced in the framework of this reparation work. A photo of the bridge is given in Figure 5.

**Figure 5.** a) The road RC bridge in Poland (b) bridge RC girders after strengthening.

**STRENGTHENING OF METALLIC STRUCTURES WITH CFRP STRIPS**

As it has been discussed in the last section, application of CFRP materials for retrofitting concrete girders has been extensively investigated and used in practice. Many studies demonstrated the beneficial influence of such composite strips for flexural, shear and confinement strengthening of concrete structures. However, strengthening techniques and the accompanying theory for metallic structures have not been developed as thoroughly as those for concrete structures. There are several differences between the behavior of bonded joints in CFRP-strengthened concrete and metallic members, which will be briefly explained in this section.

**Differences between Strengthening of Concrete and Steel Members**

*Failure mode:* The main difference between CFRP–steel and CFRP–concrete bonded joints is that in the former, failure will likely occur in the adhesive layer and in the latter failure is expected to occur in the concrete. Therefore, by providing an adequate bond length, the optimal strength of a bond joint is dependent on the fracture energy of the adhesive for the former and the fracture energy of the concrete for the latter. Based on Teng 2012, in the FRP-strengthened steel structures, interfacial failure should happen within the adhesive layer in the form of cohesion failure to maximize the effectiveness of FRP strengthening and minimize variations of the interfacial bond capacity as a result of different surface preparations. Furthermore, Teng 2012 reported that the inappropriate surface preparation of the steel substrate prior to the bond application will result in an adhesion failure at the steel-to-adhesive interface. Assuming the adhesive as the weakest point of a CFRP-steel bond joint, Gafoori et al. [15,16] have developed a prestressed unbonded reinforcement (PUR) system that can be used as an alternative to the bonded CFRP reinforcement.

*Stiffness and deformations:* Recent experimental and numerical results studies at Empa (Gafoori and Motavalli 2015b, Gafoori and Motavalli 2015c) have shown that pre-stressing the CFRP strips does not increase the stiffness of the retrofitted steel beams. This finding is in contrast to retrofitted concrete beams, in which the cracks are often initiated at even low load levels. In the latter case, pre-stressed laminates can close the existing cracks more efficiently than non-pre-stressed laminates, and thereby, the overall cross-section area of the concrete beam is increased, which results in increased stiffness. For the same reason, pre-stressed laminate can increase the stiffness of the cracked steel members.
Strengthening Steel Members using Prestressed Bonded and Un-bonded CFRP Strips

Bonded Systems: Ghafoori and Motavalli 2015c have used bonded non-pre-stressed normal modulus (NM), high modulus (HM) and ultra-high modulus (UHM) for flexural strengthening of steel beams. It has been shown that UHM CFRP strip are effective in increasing the stiffness of the metallic girders and reducing the deformations. Metallic members have been traditionally strengthened using non-pre-stressed CFRP plates. However, in non-pre-stressed retrofit systems, the dead loads are not transferred to the CFRP plates and only a portion of the live load is transferred to the CFRP plates. As an alternative, by using pre-stressed CFRP plates, a portion of the dead load is transferred to the CFRP plates in addition to the live load (Ghafoori 2013, Ghafoori and Motavalli 2013). It has been shown that prestressed CFRP strips can increase the flexural yield and ultimate load capacity of steel beams substantially. Ghafoori and Motavalli 2015b have shown that prestressed CFRP strips can be used for strengthening of steel beams that are prone to lateral-torsional buckling (LTB) to increase the LTB strength. Moreover, Ghafoori et al. 2012b studied the performance of notched steel beams retrofitted with CFRP patches under high-cycle fatigue loading regime. The test results for a four-point bending test scheme with a cyclic loading frequency of 4.2 Hz showed that the CFRP patch extended the fatigue life substantially, and in some case, a complete fatigue crack arrest was achieved.

Un-bonded Systems: The majority of the existing research on CFRP strengthening of metallic members has used CFRP material bonded to the steel substrate. As it has been discussed before, the efficiency of the bonded retrofit system is mainly dependent on the behavior of the CFRP-to-steel bond joint. Sophisticated surface preparation is required prior to bonding the CFRP to the steel member to maximize the efficiency of the composite system and reduce the risk of debonding. Many studies have raised concerns about the influence of environmental conditions (e.g., elevated or subzero temperatures, water and moisture and ultraviolet light) and dynamic loads (e.g., fatigue, impacts and earthquakes) on the behavior of the CFRP-to-steel bond joint (e.g., Al-Zubaidy et al. 2012, Dawood and Rizkalla 2010, Wu et al. 2013). Because of these concerns, which are mainly associated with the long-term performance of the CFRP-to-steel bond joints, a pre-stressed un-bonded retrofit (PUR) system has been recently designed and tested at Empa (Ghafoori and Motavalli 2015b, Ghafoori and Motavalli 2015c, Ghafoori and Motavalli 2015a). In contrast to the PBR system, the PUR system works without using any bond; instead, it uses a pair of friction clamps to connect the CFRP plates to the steel member. An independent reaction frame to pull the CFRP strips was developed, as shown in Figure 6. The pre-stressed CFRP strip was then attached to the steel beam using mechanical clamps. The force in the actuator was then released and the CFRP strip out of mechanical clamps was cut.

Because of these concerns, which are mainly associated with the long-term performance of the CFRP-to-steel bond joints, a pre-stressed un-bonded retrofit (PUR) system has been recently designed and tested at Empa (Ghafoori and Motavalli 2015b, Ghafoori and Motavalli 2015c, Ghafoori and Motavalli 2015a). In contrast to the PBR system, the PUR system works without using any bond; instead, it uses a pair of friction clamps to connect the CFRP plates to the steel member. An independent reaction frame to pull the CFRP strips was developed, as shown in Figure 6. The pre-stressed CFRP strip was then attached to the steel beam using mechanical clamps. The force in the actuator was then released and the CFRP strip out of mechanical clamps was cut.

Figure 6. Elements of the prestressing set-up, which uses an independent reaction frame to pull the CFRP strip (Ghafoori and Motavalli 2015b).

Figure 6. Elements of the prestressing set-up, which uses an independent reaction frame to pull the CFRP strip (Ghafoori and Motavalli 2015b).
The retrofitted beams were tested in a four-point bending static loading test set-up, as shown in Figure 7.a. It has been shown that prestressed unbonded and bonded CFRP strip have almost identical effect on the behavior of steel beams. Prestressed unbonded CFRP strips could prevent fatigue crack initiation (Ghafoori et al. 2015b) and propagation (Aljabar et al. 2016, Ghafoori et al. 2012a) in steel beams. In summary, the results of the extensive tests have shown that the static and fatigue behavior of steel beams are strongly governed by the prestress level in the CFRP strip, rather than the effect of the adhesive bond (Ghafoori and Motavalli 2016b). Bonded and unbonded systems have shown relatively similar results, particularly in the elastic domain (Ghafoori 2015).

**Trapezoidal PUR system:** Figure 7.a shows a PUR system with straight CFRP strips. Ghafoori and Motavalli 2015a have recently developed a trapezoidal PUR system for strengthening of a historic metallic railway bridge in Switzerland. A summary of the prestressing procedure is explained as follows. Assume an I-beam as shown in Figure 7.b (i). First, the mechanical clamps are placed near two ends of the beam, and three parallel CFRP plates are placed and tightened inside the clamps, as shown in Figure 7.b (ii). Each CFRP plate has dimensions of 50 mm width and 1.2 mm thickness. Each friction clamp is consisted of a lower plate, a middle plate and two upper plates. The middle and the lower plates consist of three hard plates, which provide a uniform stress distribution along the CFRP anchorage length. Each CFRP plate is anchored between the lower plate and the middle plate and is subjected to compressive force, which is applied by pre-tensioned bolts. The beam flange is also gripped between the middle plate and the upper plates and subjected to the compressive force of pre-tensioned bolts. A pre-stressing chair is used to increase the eccentricity between CFRP plates and steel beam, as shown in Figure 7.b (iii).

![Figure 7](image-url)  
(a) Trapezoidal PUR system with straight CFRP strips: (a) Example of a PUR system with straight CFRP strips. (b) The cross-girders were retrofitted with pre-stressed unbonded CFRP strips. (c) The prestressing chair consists of a saddle that can move along two vertical threaded bars. The distance between the saddle and the beam can be manually changed by turning the threaded rods using a wrench. Thus, by turning the threaded rods, the saddle pushes the CFRP plates away from the beam, and the CFRP pre-stress is increased. A larger eccentricity between the CFRP plates and the beam corresponds to a larger CFRP pre-stress level. After the desired pre-stress level is achieved, two plates are placed between the CFRP plates and the beam (see Figure 7.b (iv)). Each plate is positioned between the saddle and a shoe. The two shoes are connected by two steel bars and four nuts, as shown in Figure 7.b (v), and then the pre-stressing chair is removed. Figure 7.b (v) shows the final configuration of the strengthened beam. More details can be found in Ghafoori and Motavalli 2015a, Ghafoori et al. 2015a.

After the trapezoidal PUR system has been tested under static and fatigue tests in laboratory, the system has been used for fatigue strengthening of a 120-year-old railway metallic bridge in Switzerland, as shown in Figure 8.a and 8.b (Ghafoori et al. 2014). In order to monitor the performance of the girder and retrofit system, a wireless sensor network (WSN) system was used for about one year, which showed the successful implementation of the system. The PUR systems can have different other configurations, as has been explained by Kianmofrad et al. 2016.

**STRENGTHNEING USING IRON-BASED SHAPE MEMORY ALLOYS**

Shape memory alloys (SMAs) have several unique properties. The most important properties are the shape memory effect and the superelasticity (Janke et al. 2005). Iron based shape memory alloys were discovered by Sato et al. Sato et al. 1982. For civil engineering applications, Fe-based shape memory alloys represent a promising technology because of their properties and lower cost when compared to NiTi. An iron-based shape memory alloy

![Figure 8](image-url)
(Fe–17Mn–5Si–10Cr–4Ni–1(V,C) (ma.–%)) has been developed and patented at Empa (Dong et al. 2009). In fact, in the early 2000s at Empa, possible application ideas were mainly for NiTi-SMAs such as controlled or fixed prestressing, superelasticity with high energy dissipation or for sensors (Czaderski and Motavalli 2003). In 2003, a concrete beam was reinforced with shape memory alloys (SMA) wires (Czaderski et al. 2006). NiTi wires were used to reinforce the tensile zone of a concrete beam with a span of 1.14 m. In 2003-2004, shape memory alloy (SMA) NiTi wires were embedded in mortar to demonstrate the feasibility of prestressed short fiber reinforced concrete (Moser et al. 2005).

The new Fe-based SMA for civil engineering applications has been developed at Empa during 2005-2009 (Dong et al. 2009) and patented in 2009. A feasibility study on the usage of the developed Fe-SMA for the strengthening of reinforced concrete structures has been done in 2013 (Czaderski et al. 2014). Furthermore, lap-shear tests on the Fe-SMA strip that were glued in grooves using cement based grout were performed (Czaderski et al. 2014), which resulted in a good bond behavior.

![Figure 9](image1.png)

**Figure 9.** Setup for activation of strengthened beams by Fe-SMA strips/bars (Shahverdi et al. 2016b): (a) Fe-SMA strips in grooves, (b) Fe-SMA bars in shotcrete layer.

In another work at Empa Shahverdi et al. 2015, several reinforced concrete (RC) beams were strengthened using the near surface mounted (NSM) reinforcement technique with ribbed Fe-SMA strips (see Figure 9.a). Embedding ribbed Fe-SMA bars in a new shotcrete layer has been done as another promising method to strengthen RC structures Shahverdi et al. 2016a (see Figure 9.b). Similar to NSM, shotcreting is a well-known technique to strengthen and repair existing RC structures. It is therefore an adequate material in combination with the ribbed Fe-SMA bars. In comparison with conventional shotcreting techniques, application of Fe-SMA bars allowed the prestressing of the shotcrete layer. The load-displacement diagrams for some of Beam 1 (reference), NSM strengthened beams (Beams 2, 3 and 6) and prestressed shotcrete beams (Beams 9 and 10) are shown in Figure 10.

CONCLUSIONS

The key differences between CFRP strengthening of metallic and concrete structures were discussed. The two main differences between the behavior of CFRP–concrete and CFRP–metal bonded members are concerned with
the failure mode and the stiffness of the retrofitted members. These differences resulted in development of different CFRP prestressing concepts for strengthening of concrete and metallic members at Empa, which were briefly explained in this paper. The application of gradient anchorage system for strengthening of concrete girders with prestressed CFRP strips was explained. The results of laboratory tests as well as details about the filed application on a RC bridge in Poland were briefly discussed.

For strengthening of metallic members, laboratory test results showed that adhesive bond does not have much influence on the static and fatigue behavior of retrofitted steel beams, however CFRP prestressing plays an important role. Therefore, in order to minimize the concerns related to effects of high ambient temperatures, moisture, water or fatigue loading on the CFRP-to-metal bond behavior, a prestressed unbonded retrofit system has been recently developed at Empa. Mechanical anchorage system was used to attach prestressed CFRP strips to metallic members. Details about fatigue strengthening of a 120-year-old railway metallic bridge in Switzerland using prestressed unbonded CFRP strips were given. Finally, ongoing studies at Empa on characterization and application of FE-SMA, a new retrofit material, were briefly explained.

ABSTRACT

CFRP strengthening of steel structures has proved to be an effective method of repair of metallic structures. Under life time cyclic events cracks can initiate and propagate in metallic structures. In order to repair a fatigue induced crack, an effective repair configuration must be chosen. To meet this requirement, understanding the effect of different strengthening parameters on the crack propagation is required.

CFRP strengthening has been used in this research to retard the crack growth in initially cracked steel plates. 6mm thick steel plates with two different initial notch lengths were chosen in this study.

In order to add to the efficiency of the results, prestressing has been introduced to the CFRP patches. The prestressing load is applied by a hydraulic actuator prior to bonding the CFRP patch to the cracked steel plates. After preparation, the specimens were all tested under a constant amplitude fatigue load.

Fatigue life and the crack propagation measurements is the main outcome of this research. This is while strain gauges were also attached to the specimens and the effect of CFRP type and prestress level are also measured. The results show that the CFRP thickness and modulus of elasticity are effective parameters on the enhancement of the fatigue life. Though, application of prestressed CFRP can significantly improve the fatigue life of the cracked members.

INTRODUCTION

Overall, there are three main phases where the upgrading or repair process occurs (Hollaway (2014)):

- In order to upgrade the structure as a reason of change in application thus difference in loading conditions of the structure.
- Before any visible damage to prolong the life of the structure.
- After visible damage has occurred in order to repair the structure.

Fibre reinforced polymer composites are now frequently used in civil and structural applications. Utilising the conventional methods of rehabilitation in steel structures had the disadvantage of making the structures heavier by attaching bulky and heavy steel plates. The attached plates are also prone to fatigue and corrosion themselves (Zhao et al. (2007)). To attach these bulky and heavy steel plates a lifting system is required which has to be powerful enough, while the CFRP patches are very light and can be lifted much more easily. Attaching steel plates to the existing structure can be done by welding or bolting. However, the weld is subject to fatigue and using bolts elevates the cost and workmanship required.

Figure 27 shows some examples of cracks that can be repaired using bonded CFRP patches. This figure shows cracks that have initiated from locations with high local stresses and their propagation under imposed traffic loads on the bridge.

Use of bonded CFRP patches has been tested in the literature frequently. Works of Jones et al. (2003), Liu et al. (2009), Wu et al. (2012) have all concluded the effectiveness of CFRP patching on cracked steel plates. However,
some researchers have tested the effect of CFRP patching beyond its passive effect by applying prestressing to the CFRP patches before bonding them to the cracked region.

Täljsten et al. (2009), carried out experimental and numerical investigations on the effect of prestress and non-prestressed CFRP laminates. They tested old steel plates which were taken from an old bridge. In order to simulate the crack propagation they drilled a hole and two notches at the edge of the hole. The notches represent crack initiation. They applied a tension force to the CFRP before bonding them to the steel.

In this paper the experimental work performed includes the study of the passive effect and active effect of CFRP patching on cracked steel plates.

Figure 27 Cracks in a bridge structural member

METHODOLOGY

The fatigue life of initially cracked steel plates is studied in this research. Steel plates with a hole in the centre and two notches emanating from the edges of the hole is a typical sample that has been studied. The notch represents the crack initiation. The centre-notched steel plates are then repaired with CFRP patches. In order to bond the CFRP to the steel, Araldite 420 (a two part adhesive) is used. After the CFRP strengthened steel plates are prepared they are all tested under cyclic fatigue. In some specimens prestressing was applied to the CFRP. Different specimens are prepared and tested as listed below:

- 6 mm CNS plates without repair (Reference Plate)
- 6mm CNS plates repaired with normal modulus CFRP sheets
- 6mm CNS plates repaired with prestressed normal modulus CFRP sheets

The main aim of this research was to understand the behaviour of cracked steel plates under fatigue and identifying suitable repair mechanisms. Therefore, different parameters were studied in the experiments such as:

- Effect of number of layers of CFRP
- Effect of prestressing
- Effect of initial notch length

EXPERIMENTS

Material

In this study 6mm thick steel plates were used. Since the major aim of this study was to measure the cracked life of the specimens, centre-notched steel (CNS) plates were utilized. This means that the load cycles applied to the specimens will contribute to crack growth rather than crack initiation. The dimensions of the CNS plates are given in Figure 28.
Normal modulus CFRP sheets are used in this study. The material properties of the CFRP are given in Table 1. For the means of bonding the CFRP patch to the steel plates Araldite 420 was used. This adhesive has a pot-life of about 1 hour which is a benefit and makes working with the adhesive easier. The mechanical properties of Araldite 420 has a tensile strength of 28.6MPa, shear strength of 36MPa, ultimate strain of 0.024, Elastic modulus of 1901MPa and poison’s ratio of 0.36 (Fawzia et al. (2006)). Araldite 420 curing time in room temperature (25°C) is 7 days. According to the manufacturer’s datasheet, araldite 420 will cure in 1 hour in 100°C.

**Preparation of specimens**

*Set A) Reference Plates*

Details of this set of specimens are shown in Figure 28. A hole with 2 notches emanating from the sides is located at the centre of the plate. The dimensions of the plate are 90mm width and 500mm length. The plates tested in this research were all 6mm thick, with an elastic modulus of 212000 MPa and yield strength of 335 MPa.

*Initial crack length*

As mentioned earlier, in this practical research the crack growth phase of the fatigue life was of interest. Therefore, the specimens were all initially notched. The notch was emanated from a centre hole in the steel plate. The geometry of the notch is shown in Figure 28. Two different notch lengths were studied in this research for the unstrengthened plates. In one set of specimens the total initial crack length size was 7mm (including the hole diameter) and in the second set of specimens the total crack length was 11.5mm.

*Set B) 6mm CNS plates repaired with normal modulus CFRP sheets*

The strengthening configuration of the specimens is shown in Figure 29. One, two and three layer CFRP strengthening configuration was investigated. The patch dimension was 50mm x 250mm and it was bonded to the steel at the location of the crack.

*Set C) 6mm CNS plates repaired with prestressed normal modulus CFRP sheets*

CFRP strengthening benefitting from prestress was performed in this set of specimens. The prestress levels and the prepared specimens are shown in Table 2.
The strengthening patterns (CFRP location and size) in all the specimens were the same. The only difference was the number of layers and the prestress level applied.

Specimen preparation

For preparation of the specimens several steps were completed to ensure a quality bond between the CFRP patch and the steel plate. These steps were similar for both types of CFRP used in this research. The first step was to sandblast the steel surface at the area where the CFRP was to be attached. Sandblasting removes rust or paint on the surface and provides a rough surface to provide better interlocking at the bond between the CFRP and steel. The second step was cleaning the surface of the sandblasted steel using acetone. This action helped to remove dust and grease which can harm the bond. When this action was completed the adhesive (in this case Araldite 420) was applied to the desired location. The CFRP was then left for curing. The curing time for all specimens in this study was 7 days at room temperature.

In the specimens for which prestressing was involved, the procedure was quite different, as explained in the next section.
Prestressing

After sandblasting and cleaning the surface of the steel, prestressing of the CFRP was done. The prestressing process had four main stages:
1- Tensioning of the CFRP patch
2- Attaching the patch in tension to the CNS plate
3- Curing of the loaded specimen
4- Unloading of the patch

In this research the pretensioning was done using an MTS hydraulic actuator in force control mode. First the CFRP was located in the grips. The appropriate amount of Araldite was then spread on the CFRP patch with the length being equal to the desired bond length. Then the steel plate was located in place. After this the CFRP patch was pulled up to a desired amount. This action caused tensile levels in the CFRP. While the patch was in tension the desired bond length of the CFRP formed a bond between the CFRP and the steel. It was ensured that the CFRP and steel plate were aligned perfectly in order to prevent eccentric loading. The specimen was then left under load for 5-7 days for curing. After curing, the load was removed from the CFRP, causing compressive stress formation in the steel. The extra CFRP was then cut off.

Fatigue loading

After preparing, the specimens were tested under cyclic fatigue. The stress ratio for the fatigue tests was set 0.1. The specimens were tested under two different loads. The details of the cyclic loads are given in Table 4. The loads were both sinusoidal waves applied to the specimen continuously. As seen in Figure 32, there were two blocks in each load type. The reason for using a double block fatigue load was to benefit from the beach marking technique to measure the crack propagation. The first block had a stress range double that of the second block. The crack growth in the specimen was mainly caused by the first block, while when the second block was applied, striations were created on the crack front, representing the crack growth length to the specific number of cycles that were applied. As the fatigue load was applied the crack propagated from the notch through the width of the plate.

The specimens investigated had two different initial notch lengths: specimens with notch type (N1) and specimens with notch type (N2). To compare the effect of the initial crack length, these specimens were tested under load II.

RESULTS

Fatigue life

All the prepared specimens were tested under uniaxial tensile fatigue under the cyclic loads shown in Figure 32. The fatigue lives of all specimens are tabulated in Table 5 and Table 6. The results of the CFRP strengthening show the effectiveness of the patch repair technique on the cracked life of the CNS plates. As the number of CFRP layers increases, the fatigue life increases. This is due to stress reduction at the crack tip.

In the specimens strengthened with prestressed CFRP, the fatigue life enhancement extends up to 35 times. The effect of prestressing is even greater than increasing the number of CFRP layers. Prestressing can contribute to the enhancement of fatigue life in two ways, depending on the level of prestress compared with the fatigue load levels (Huawen et al. 2010). Assuming the crack does not propagate when the stress levels are negative (the specimen is in compression), and if the prestress level is high enough to move the stress range to compression–tension, as is the case for all specimens tested in this study, the stress range reduction contributes to the fatigue life improvement. If the stress range remains in the positive zone (tensile-tensile fatigue), reduction in the stress ratio improves fatigue life. The crack length versus number of cycles is plotted for all the specimens in Figure 30 and Figure 31.

Beach marking technique

To trace the crack propagation as the number of cycles increases, the beach marking technique is used. In this technique a double block fatigue load as explained earlier is applied to the specimens. The first block has a stress range double the stress range of the second block. Therefore, the first block contributes much more to the crack propagation, while the crack propagation due to the second block causes dark marks on the crack front, as shown in Figure 33.

*Stress levels are calculated based on gross areas.

CONCLUSIONS

As the results show, the fatigue life of the specimens under load II which acquires a higher stress range is lower than that of specimens tested under load I. In the specimens without prestress the average decrease in the fatigue life of the specimens from when they are tested under load I to when they are tested under load II is about 0.6.
Table 6 shows that the initial notch length affects the fatigue life of the specimens. The longer the initial crack, the shorter the fatigue life. In order to compensate the reduction in the fatigue life due to the effect of a longer crack, either additional layers of CFRP can be used or prestress can be applied.

The results of this research indicate that CFRP strengthening of cracked steel members can be used for crack growth retardation. Furthermore, prestressing can be applied to make the strengthening more effective by using the full capacity of the CFRP patch. The effect of initial crack size investigated in this study suggests that postponing strengthening of early cracks in structural elements can cause a significant decrease in the life of the member. The study showed that using prestressed CFRP patches can compensate the fatigue life loss indicated above.

ABSTRACT

In this paper, mixed-mode fatigue crack propagation of steel panel was analysed by boundary element method. Both maximum circumferential stress criterion and minimum stress energy density criterion were used to predict crack propagation. Thereafter, FRP patched specimens were modelled and analysed. The effect of FRP modulus was investigated. Prestressing technique was introduced to improve repairing efficiency. Several prestressing levels were considered. Numerical results showed significant crack retardation was achieved with the increase of prestress.

KEYWORDS

Steel panel, fatigue, FRP, prestress, inclined crack.

INTRODUCTION

Fatigue fracture usually occurs in steel structures which are subjected to repeated loads. It happens suddenly without macroscopic plastic deformation. Therefore, effective methods are necessary to repair fatigue cracks. Fiber reinforced polymer (FRP) is widely used in strengthening of steel structures for the superiority of adhesively bonded composite repair method. Liu et al. and Yu et al. performed a series of numerical and experimental researches to study the fatigue behavior of CFRP repaired steel panels with initial notch (Liu et al. 2009; Yu et al. 2013, 2014, 2016). Results revealed that patching CFRP plates can improve the fatigue performance of steel panels. And crack growth can be simulated accurately by boundary element method (BEM) software BEASY. Emdad et al. investigated the effect of prestressed CFRP patched on crack growth of center-notched steel plates (Emdad et al. 2015). They found that prestressing can delay the fatigue crack propagation significantly. However, the previous research only focused on the growth of pure mode I fatigue crack. In practical steel structures, fatigue crack is usually mixed-mode I-II crack. Therefore, Alegre et al. simulated the mixed-mode fatigue crack propagation using Tanaka formula and maximum circumferential stress criterion (MCSC) by finite element method (FEM) (Alegre et al. 2010). The numerical and experimental results consist with each other. However, It’s tedious to remodel and remesh step by step during crack growth simulation by FEM software. This paper examined fatigue behavior of prestressed and non-prestressed FRP repaired steel panels with initial inclined crack by BEM. MCSC and minimum stress energy density criterion(MSEDC) were compared. Results revealed that crack growth criteria have negligible influence on the crack shape when mode I crack plays a dominant role. It was also observed that fatigue life was extended significantly with FRP patching. When prestressed FRP was used to repair the fatigue crack, pretension should be large enough to keep the crack closed under the minimum load, otherwise it has no effect.

NUMERICAL WORK

Crack Propagation Rate and Material Properties

BEASY, a commercial BEM software, was employed in this study to analyze crack propagation. The crack propagation life was integrated using Paris Law as expressed in Eq.(1), where $\Delta K_{eff}$ is effective mixed-mode stress intensity factor (SIF) and calculated by Tanaka Formula as expressed in Eq.(2). Material properties of steel are revealed in Table 1 (BSI 2005). $\Delta K_{II}$, in Eq.(2), should be the positive part of entire $\Delta K_{I}$. Crack may keep closed under minimum load when steel panels are repaired by prestressed FRP. In this case, $K_I$ is negative and should not be accounted. Considering a wide variety of FRP can be applied to strengthen steel structure (YU et al. 2014; MEI et al. 2001; WANG et al. 2015), two kinds of FRP were used in this paper, as shown in Table 2.
\[
\frac{da}{dN} = C(\Delta K_{\text{eff}})^m \tag{1}
\]

\[
\Delta K_{\text{eff}} = \sqrt{(\Delta K_I)^4 + 8(\Delta K_{II})^4}
\tag{2}
\]

\[
\Delta K_I = K_{\text{I max}} - \max(K_{\text{I min}}, 0)
\tag{3}
\]

**Modeling**

In this paper, steel panel and FRP plates were modelled by 3D zones in BEM software BEASY, and internal spring was applied to simulate the adhesive layer. Stiffness of internal spring was determined by Young’s modulus, Poisson ratio and thickness of adhesive. Figure 1 and Figure 2 show the dimensions of steel panel and patching configuration. The width of FRP plates is 25 mm. Half of the specimens was modelled due to the symmetry of the geometry and boundary conditions. Then, only the boundary of zones need be meshed in BEM, and quadratic element was selected. Rigid body displacement was constrained by boundary spring shown in Figure 3. In this way, the displacement field near crack tip could be restricted, but it would not have a significant impact on the stress field near crack tip.

Seven models were simulated using BEM as shown in Table 3. All of them were subjected to cyclic tensile load with a stress ratio of 0.1, and a constant stress range of 153 MPa.

**COMPARISON OF CRACK GROWTH CRITERIA**

The influence of crack growth criterion was studied with U-MCSC and U-MSEDC. Figure 4 plotted crack length and fatigue cycles curves of U-MCSC and U-MSEDC. Crack length $S$ is defined in Eq.(4). The fatigue lives of U-MCSC and U-MSEDC are 111497 and 110494, respectively. Deviation between them is only 0.85%. Figure 5
presents the crack paths of two models in Cartesian coordinates that origin is the center of steel panel. We can find that the two paths are almost same.

\[ S = \int \sqrt{dx^2 + dy^2} \]

Figure 4 Number of fatigue cycles vs. crack length S

Figure 5 Crack path

Figure 6 shows the relationship between crack length and SIF. It reveals that the values of SIF are almost same, when crack length is less than 23 mm. Then, \( K_I \) of the model U-MCSC has a sudden drop. This corresponds to the fluctuation of \( K_{II} \), and also leads to the difference of crack paths. However, when the crack length is 23mm, the number of fatigue cycles reaches about 95% of fatigue life. So, only MSEDC was applied in the following simulations.

![Comparison of FRP-1 and FRP-2](image)

COMPARISON OF FRP-1 AND FRP-2

FRP-1 and FRP-2 were used to strengthen the cracked steel plates. The tensile stiffness of FRP-1 plate and FRP-2 plate was same, as expressed in Eq.(5), where \( E_1 \) and \( E_2 \) are Young’s modulus of FRP-1 and FRP-2, \( t_1 \) and \( t_2 \) are thickness of FRP-1 and FRP-2.

\[ E_1 \cdot t_1 = E_2 \cdot t_2 \]  

(5)

Figure 7 shows the relation curves between fatigue cycles and crack length of R-MSEDC-0-(1.45) and R-MSEDC-0. The fatigue life of R-MSEDC-0-(1.45) is 169277. It is 1.5% more than the fatigue life of R-MSEDC-0. This is
because of that FRP material near bottom surface makes more contribution to restricting crack opening than that near top surface. Liu et al. also concluded similar result. They found that increasing thickness of the composite patch beyond a certain minimum value dose not result in any significant increase in fatigue life (LIU et al. 2012).

Values of SIF are graphed in Figure 8, where we can find that two curves coincide with each other. From this point of view, strengthening effect of FRP-1 plate is equivalent to that of FRP-2. However, thinner FRP plate caused more element numbers and longer computing time. Therefore the other steel panels were all patched with prestressed FRP-1 plates.

![Figure 7 Fatigue cycles vs. crack length S](image1)

![Figure 8 Crack length S vs. values of SIF](image2)

**EFFECTS OF PRESTRESSED FRP PLATES ON STEEL PANELS FATIGUE BEHAVIOR**

Values of SIF during the crack propagation of U-MSEDC, R-MSEDC-0, R-MSEDC-5, R-MSEDC-10 and R-MSEDC-15 are shown in Figure 9. It indicates that patching FRP plate can decrease $K_I$ dramatically. The values of $K_I$ will become smaller as prestress level increases. When the crack of steel panel, patched with prestressed FRP, keeps open during fatigue loading, the positive part of $\Delta K_I$ will not be changed with prestress. In this case, prestress will not enlarge the fatigue life of steel panel with Paris law and Tanaka formula. From Figure 9(b), we can find that when fatigue load decreases to 17 MPa, the values of $K_I$ are still positive. So, fatigue life of R-MSEDC-5 is not much different from that of R-MSEDC-0.

![Figure 9 Effect of prestressed FRP plates on SIF](image3)

![Figure 10 Fatigue cycles vs. crack length S](image4)
Figure 11 Fatigue life contributed by different part of model

Curves between crack length and fatigue cycles of these models are compared in Figure 10. Both patching and prestressing can improve fatigue performance of steel panels with inclined crack. Figure 11 shows the fatigue life contributed by FRP and prestress. The fatigue life of R-MSEDC-0 and R-MSEDC-5 are 166674 and 168787. Deviation between them is 1.25%. Fatigue life of R-MSEDC-0 has a 51% increase versus that of U-MSEDC. Fatigue life of R-MSEDC-10 and R-MSEDC-15 have 23.3% and 62.8% increase versus that of R-MSEDC-0. So we can conclude that the prestress increase will accelerate fatigue performance improvement. High prestressed FRP plate is recommended to repair cracked steel panel.

CONCLUSIONS

In this paper, crack propagation in steel panels patched with prestressed and non-prestressed FRP plates is simulated by BEM. From the results, we can conclude that:

1. When mode I crack plays a dominant role during crack growth, there will not be much difference between MSEDC and MCSC.

2. The value of positive part of $\Delta K_I$ is diminished after repairing with FRP plate. So that a longer fatigue life can be achieved.

3. Fatigue life of steel panel patched with non-prestressed FRP plate has a 51% increase versus that of unrepaired steel panel. Whereas, there is little difference between steel panels patched with non-prestressed and 5% prestressed FRP plate.

4. Fatigue life improvement can be increased quickly with increment of prestress. Therefore, high prestressed FRP plate is suggested.

DURABILITY OF STEEL BEAMS STRENGTHENED WITH CFRP PLATE

J. Deng and Y. Xie
School of the Civil Engineering and Transportation, Guangdong University of Technology, China

ABSTRACT

CFRP external bonding is an innovative technique to repair or strengthen steel beams. The weakest link of the retrofitted beams is the adhesive bonding, and plate peeling is the most important failure mode due to the high stress concentration at the discontinuous sections. Adhesive bonding subjected to fatigue loading and hygrothermal environment may have a significant adverse effect. This paper presents a study on the durability of the steel beams strengthened with CFRP plate. Firstly, a fatigue test programme of the retrofitted steel beams was conducted. An $S-N$ curve was proposed to predict the crack-free fatigue life of the retrofitted beams. An equation to predict the crack-propagation fatigue life had also been developed. Secondly, the behaviour of overloading damage steel beams strengthened with CFRP plate exposed to hygrothermal environment was investigated. The accelerated ageing experiments were carried out for 3 months and 6 months by exposing specimens to cyclic wetting in salt water and drying in hot air. The specimens were tested to failure under four-point bending. The results show that the hygrothermal environment weakened the bonding behaviour of the adhesive.

KEYWORDS

CFRP, steel beams, strengthening, durability.

INTRODUCTION

Highway bridges are designed for lives of more than 100 years. Depending on the type of highway, components in decks can experience up to a hundred million stress cycles over their design lives (May and Tilly, 1982, Moses et al., 1987). Consequently, fatigue damage is one of the main problems that occur in old metallic bridges. Hollaway and Cadei (2002) pointed out that the adhesive bonding between the CFRP plate and the metallic substrate is the weakest link and its fatigue performance is of particular importance. The stress concentrations conduct fatigue interfacial failure at the plate ends (Deng and Lee, 2007a) or at the crack locations (Colombi and Fava, 2015). Colombi and Fava (2015) indicated that reinforcement debonding has a detrimental effect on the reinforcement effectiveness and it lessens the fatigue life. Moreover, it is critical to understand the influence of the environmental conditions on the behaviour of the adhesive bonding. Kim et al. (2012) found an increase in the load carrying capacity of steel-CFRP joints after wet/dry cycles and freeze/thaw cycles. However, Nguyen et al. (2012) observed about 10% reduction in the bond strength after exposed to thermal cycling. Agarwal et al. (2014) present that the bond strength of steel-CFRP joint reduced 28% after freeze/thaw cycles. In this paper, a study on the durability of the steel beams strengthened with CFRP plate was conducted. Fatigue life of the retrofitted steel beams and the effects of overloading damage and hygrothermal environmental exposure were investigated.

Figure 1 Details of retrofitted beam
THEORETICAL STUDY

The details of the retrofitted beams were shown in Figure 1. The maximum interfacial stresses of the steel beams strengthened with CFRP plate are given in this section. An empirical equation to predict fatigue life during the crack propagation is developed based on Paris Law as well.

Maximum interfacial stresses

At the boundaries, the maximum shear stress \( \tau_{\text{max}} \) can be written as:

\[
\tau_{\text{max}} = \frac{1}{b} \lambda c - \frac{Z_s}{bf} E I V(0)
\]  

(1)

where

\[
\lambda = \sqrt{\frac{f_s}{f_t}}
\]  

(2)

\[
f_t = \frac{t_a}{Gb}
\]  

(3)

\[
f_s = \frac{(Z_s + Z_f)Z_t}{E f I_t} + \frac{1}{E_s A_s} + \frac{1}{E_f A_f}
\]  

(4)

\[
c = N_{f0} - \frac{\Delta \varepsilon_{sf}}{f_s}
\]  

(5)

\[
\Delta \varepsilon_{sf} = (\alpha_f - \alpha_s) \Delta T \frac{M_s Z_s + F_p}{E_s A_s} + \frac{M_f Z_f}{E_f I_f}
\]  

(6)

\( \Delta \varepsilon_{sf} \) is the relative deformation between the bottom of the steel beam and the top of CFRP plate when the adhesive layer is ignored, including the relative deformations caused by temperature change, load-release jacking, prestressing force and applied moment. The subscripts \( s, f \) and \( a \) denote steel beam, CFRP plate and adhesive, respectively. \( Z_s, Z_t, b \) and \( t_a \) the distance from the neutral axis to the bottom of the steel beam, the distance from the neutral axis to the top of the CFRP plate, the plate width and the adhesive thickness. \( E, I \) and \( A \) are the elastic modulus, the second moment of area and the area, respectively. \( M_s, V(0) \) and \( N_{f0} \) are the applied bending moment, the applied shear force and the longitudinal force at the boundaries, respectively. \( \alpha \) and \( \Delta T \) are the thermal expansion coefficient and the temperature change, respectively. \( M_p \) is the bending moment applied on the steel beam by load-release jacking. \( F_p \) is the prestressing force applied on the CFRP.

At the boundaries, normal stress \( \sigma_{\text{max}} \) can be written as:

\[
\sigma_{\text{max}} = \left( \beta - \frac{\lambda}{2} \right) \frac{t_a}{b} c - \frac{\beta f_s Z_s}{bf} E I V(0)
\]  

(7)

where

\[
\beta = \sqrt{\frac{f_s}{4 f_s}}
\]  

(8)

\[
f_s = \frac{t_a}{E_f b}
\]  

(9)

\[
f_s = \frac{1}{E_f I_f} + \frac{1}{E_s I_s}
\]  

(10)

Combining the maximum shear and normal stresses, the maximum tensile principal stress \( \sigma_{1\text{max}} \) can be written as:

\[
\sigma_{1\text{max}} = \frac{\sigma_{\text{max}}}{2} + \sqrt{\left( \frac{\sigma_{\text{max}}}{2} \right)^2 + \tau_{\text{max}}^2}
\]  

(11)

Fatigue life prediction

The fatigue life includes crack-free life and crack-propagation life. Crack-free life can be obtained from the S-N Curve. In accordance with the FE analysis (Deng and Lee, 2008), the crack will initiate in the adhesive from the end of the plate and propagate along the interface between the steel beam and adhesive. In accordance with Paris Law, the relationship between the crack propagation rate \( da/dN \) and the energy release rate \( G \) can be expressed as:
\[
\frac{da}{dN} = D(G_{\text{max}})^n
\]

where \(G_{\text{max}}\) is the maximum energy release rate during one fatigue cycle, \(D\) and \(n\) the empirical coefficients, which can be determined by experimental data. Guidance CIRIA C595 (Cadei et al., 2004) provides an equation to calculate the energy release rate \(G\) of strengthened beams:

\[
G = \frac{M^2}{2b} \left[ \frac{1}{(EI)_b} - \frac{1}{(EI)_s} \right]
\]

where \(M\) is the applied bending moment on the beam at the plate end or the crack front, \((EI)_b\) and \((EI)_s\) the section bending stiffness of beam strengthened with the FRP plate and the plain beam, respectively.

The crack propagation life \(N\) of the retrofitted beams can be obtained as:

\[
N = \frac{(-2n+1)^{-1}(l_0 + a)^{-2n+1} + C}{D\left[ \frac{1}{4} P^2 \left( \frac{1}{(EI)_b} - \frac{1}{(EI)_s} \right) \right]}
\]

where

\[
C = (-2n + 1)^{-1}(l_0 + a_0)^{-2n+1}
\]

\[
a_0 = \frac{E_G}{\pi \sigma_n^2}
\]

EXPERIMENTAL STUDY

To investigate the durability of the retrofitted steel beams, a fatigue experiment study was conducted to obtain the \(S-N\) curve and \(a-N\) curve. Moreover, an experimental study on overloading damaged retrofitted steel beams subjected to wet-dry environmental exposure was conducted.

Fatigue tests

A minimum load of 5 kN was applied to all the fatigue tested beams so as to ensure firm contact between the beam and the supports. The maximum loads are from 40 kN to 125 kN. Loading was applied sinusoidally, with a frequency of 1 to 2 Hz. During the fatigue cyclic loading, the test was stopped at regular intervals, or when cracking was detected, and the specimen was then subjected to three cycles of loading and unloading between 0 kN and the maximum applied load at a rate of 2 kN/second. This was done in order to measure the loads, the strain values at the CFRP plate ends and the deflections during the load cycle, since these data cannot be recorded accurately during the fatigue load cycles.

Overloading damaged tests

The specimens were damaged under overloading fatigue loading. Loading was applied sinusoidally, with a frequency of 0.1 Hz. The minimum and maximum cycle loads are 0.1\(P_c\) and 0.5\(P_c\), where \(P_c\) is the loading when crack initiates in the bonding layer. From the Miner’s rule and the overloading spectrum (Wang et al., 2014), the fatigue damage accumulation index for the retrofitted steel beams per year is \(28.5 \times 10^4\) and thereby the number of cycles in the tests is 400.

Wet-dry environmental exposure

The wet-dry environment was produced by placing specimens into salt water under wetting/drying cycles. The wetting/drying environmental chamber with a length of 3 m, a width of 2 m and a depth of 1.5 m can automatically adjust the water content. The temperature control accuracy is \(\pm 1^\circ\)C. Each wetting/drying cycle was 24 h. The specimens were immersed in a 3.5% NaCl solution for 10 h, following by drying at 40 \(^\circ\)C for 14 h. The specimens were exposed for 3 months and 6 months, respectively.

Static tests

The tests were carried out in a servo-hydraulic SDS500 test machine with a maximum capacity of 500 kN, subjected to a four-point bending set up, as shown in Figure 2. The specimens were tested under static load, by displacement control at a rate of 0.05 mm/sec. Loading of the specimen continued even after the CFRP plate peeling, which occurred in all retrofitted specimens. Loading was stopped when local post-yield buckling appeared in the control specimen or when the notched specimens fractured with the notch propagation.
RESULTS AND DISCUSSIONS

S-N curve and crack-free life

The maximum principal interfacial stresses ($\sigma_{\text{1max}}$) of all specimens are calculated by Eq. (11). The curves for $\sigma_{\text{1max}}$ versus the log of the crack free life $N_1$ is presented in Figure 4. $\sigma_{\text{1max}}$ (80.4 MPa) is the maximum principal interfacial stresses of specimen with a maximum applied load of 135 kN. The relationship is approximately linear and regression analyses produce the following best-fit equation (with a correlation coefficient, $R^2 = 0.96$):

$$\sigma_{\text{1max}} = -4.19Ln(N_1) + 78.62$$  \hspace{1cm} (17)

It has been established by the authors that the bonded strength of retrofitted metallic beams is not influenced by the size and material properties of the metallic beams or the CFRP plates (Deng and Lee, 2007b). Therefore, this S-N curve can be applied generally as long as the same adhesive is used. The fatigue threshold for the tested beams is 40 kN, with a corresponding threshold stress 23.8 MPa for the adhesive. This threshold limit is about 30% of the ultimate failure stress 80.4 MPa under static loading.

Crack propagation life

The crack initiation and propagation in all the specimens were similar. For all the plates that had debonded, cracking started from the middle of the spew fillet and then propagated to the interface between the steel beam and the adhesive at an angle of 45 degrees. Then the crack grew along the interface and stopped eventually. There was always a short length of adhesive remaining uncracked that bonded the plate to the beam. The curves for the log of the crack propagation rate $da/dN$ versus the log of the energy release rate $G$ is presented in Figure 5. The
relationship is approximately linear and regression analyses produce the following best-fit equation (with a correlation coefficient, $R^2 = 0.7896$):

$$\log(da/dN) = 2.753\log(G_{\text{max}}) - 11.718$$

Therefore, the empirical coefficients $D$ and $n$ in Eq (12) are $10^{-1.7}$ and 2.75, respectively.

**Strength of the specimens after environmental exposure**

The load versus displacement plots of the specimens are shown in Figure 6. Two aspects are noted from Figure 6. Firstly, the stiffness and strength of the reference beam AR is higher than the beams ARFH which were overloading damaged and subjected to dry-wet cycles. Secondly, the stiffness and strength of the specimen ARFH-90 subjected 90 days dry-wet cycles are higher than ARFH-180, which indicates that the retrofitted steel beams deteriorated with the period of the dry-wet cycles.

The debonding loads of all specimens were compared in Figure 7. It showed that the beams subjected to overloading fatigue tests have lower debonding loads than others. The debonding loads of the specimens reduced with the days of the dry-wet environmental exposure.

**Failure modes of the specimens after environmental exposure**

The failure modes of the strengthened notched beams were the CFRP plate peeling but part of it remained attached to the beam. The typical failed specimen was showed in Figure 3. Figure 8 shows the bonded surfaces of the CFRP plate and steel beams of the failed specimens which the CFRP plates were detached totally from the steel beam by hand. The figure shows that debonding in specimens AR and ARFH developed from the notch in the steel beams along the interface between the CFRP plate and the adhesive. In specimen ARH1-180 subjected to the dry-wet cycles, however, the corrosion of the steel caused the debonding initiated along the interface between the steel beam and the adhesive. In specimen ARFH-180, the debonding still initiated along the interface between the CFRP plate and the adhesive, which indicates that the overloading fatigue damaged this interface where the steel corrosion stain can be observed.
CONCLUSIONS

This paper presents a study on the durability of the steel beams strengthened with CFRP plate. Fatigue life of the retrofitted steel beams and the effects of overloading damage and hygrothermal environment exposure were investigated. The accelerated ageing experiments were carried out for 3 months and 6 months by exposing specimens to cyclic wetting in salt water and drying in hot air. From the fatigue tests results, an S-N curve is proposed to predict the crack-free fatigue life of the retrofitted beam. An equation to predict the crack-propagation fatigue life has also been developed. The test results show that overloading fatigue damage reduced the debonding loads of the retrofitted beams subjected to the environmental exposure. Moreover, the debonding loads of the specimens reduced with the days of the dry-wet environmental exposure.

ABSTRACT
In this paper, an experimental study was conducted to investigate the bonding behaviors of engineering cementitious composite (ECC)-to-concrete interface. Considering the construction method of ECC and cured interface, a total of 18 specimens were prepared. All specimens were prism with the dimension of 40mm (width) × 80mm (depth) × 160mm (length) and consisted of two parts: ECC layer with an approximately thickness of 40 mm on the top and the concrete substrate at the bottom. The bonding area for all specimens was about 40mm (width) × 160mm (length). Three types of interfaces were obtained by cured the top surface of concrete substrate: type A was simply only removing the cement paste attached to the concrete substrate and then cleaning the surface of bond substrate; type B was spreading immediately 0.5mm-1.75mm fine aggregate followed by a 2mm thickness epoxy resin layer brushed and type C was similar with type B additionally applying 2.5mm-5mm coarse aggregate. After the concrete substrates were cured 28 day, the casting ECC and spraying ECC were placed directly against this to form the bonding interface. The pull-out force acted on the bonding interface was implemented by a universal tensile machine. The test results showed that the interfacial full debonding occurred for specimens with type A and B interfaces, while the fracture failure was observed in the ECC layer for specimens with type C interface. The roughness degree induced by different type of interface had a significant influence on the bond strength of ECC-to-concrete interface and coarser interface can cause higher interfacial bond strength. Meanwhile, the interfacial bond strength was decreased by application of the sprayed ECC for all three types of interface. It is concluded that the interfacial bond performance can be improved effectively by treating the bond interface.

KEYWORDS
Engineered cementitious composites (ECC), concrete, interface, bond strength.

INTRODUCTION
The engineered cementitious composites (ECC) has many advantages, such as ultra high toughness (Ahmed et al. 2009; Kim et al. 2011), multiple micro-cracking behaviors (Wang et al. 2016), self-healing characterization (Suryanto et al. 2015), better fatigue resistance (Leung et al. 2007; Qian et al. 2013) and good durability (Yildirim et al. 2015). One of important application for ECC is repairing or rehabilitating the damage structures, such as bridge decks, main girders and tunnel linings (Zheng et al. 2016). Therefore, the interfacial properties between ECC and old concrete are the most critical and then it need to be studied deeply (Wang et al. 2016).

As so far, very limited research work has been conducted to investigate the influences of concrete and ECC strengths (Bu et al. 2012), roughness degree of concrete substrate (Bu et al. 2012; Carbonell et al. 2013), fiber types (Kamal et al. 2014) and curing time of interface (Carbonell et al. 2013) on the bonding behaviors of ECC-to-concrete interface and the fatigue performance of the ECC-to-concrete interface (Zhang and Li 2002; Liu et al. 2013). Usually, the casting ECC was used in their researches and then the influence of construction method for this material on the interfacial behaviors was not considered. Theretorefore, the casting and spraying ECC were both applied in this paper to investigate the effect of contortion method on the bonding behaviors of ECC-to-concrete interface. Moreover, different cured interface between the concrete and ECC was also included.
EXPERIMENTAL STUDY

Description of specimens

A total of 18 specimens were prepared to investigate the bonding behaviors of ECC-to-concrete interface. All specimens have a prism shape with the designed geometric dimensions of 160mm in length, 80mm in depth and 40mm in width. The ECC layer with an approximately thickness of 40 mm on the top and the concrete substrate at the bottom were bond together by a 40mm × 160mm bond interface, as shown in Figure 1.

All specimens are divided into three groups and each group has three identical coupons according to the construction method of ECC and type of interface. Specimen designation is as follows and is described in Table 1. The initial letter (N or S) indicates the construction method of ECC (e.g. N is casting ECC and S is spraying ECC). The second letter (A, B or C) represents the interface type. Type A is simply only removing the cement paste attached to the concrete substrate and then cleaning the surface of bond substrate. Type B is spreading immediately 0.5mm-1.75mm fine aggregate followed by a 2mm thickness epoxy resin layer brushed and finally Type C is similar with type B additionally applying 2.5mm-5mm coarse aggregate, as shown in Figure 2.

Before manufacturing the specimens, a steel mould was manufactured. The steel mould was consisted of two-compartment, one for the concrete substrate and another for ECC. To enhance the interfacial bonding performance, two steel rivets were welded on one steel plate and pre-embedded into the concrete and ECC. Moreover, a steel rebar was welded on another face of that steel plate so that it can be clamped by the chucks of tensile machine, as shown in Figure 1.

The process of making specimens are as follows: 1) casting concrete into one steel compartment to form the substrate; 2) removing the surface cement paste at the substrate concrete interface after the substrate concrete was cured 28 day; 3) treating the interface according to interfacial type as mentioned above; 4) casting or spraying ECC into another steel compartment against the cured interface directly to form the specimen, as shown in Figure 1. All the specimens were tested after 28 days curing of the ECC under the temperature of 20±2°C and relative humidity of 95%.

Materials

The ECC mixtures were consisted of cement, fly ash, silica fume, water, water-reducing agent, accelerating agent, silica sand and polyvinyl alcohol (PVA) fibers. Ordinary Portland cement was applied. The sizes of silica sand were from 0.15mm to 0.32 mm. The 39 μm diameter and 12 mm length PVA fibers manufactured by Kuraray Corporation of Japanese were selected to reinforce the cement base. The PVA fibers added to the matrix were 2% of total material volume. The measured 28-day compressive strengths of ECC and concrete substrate were 32.3 MPa, and 43.2 MPa, respectively. The detailed mixture proportions of concrete and ECC are shown in Table 2.

Test setup

The uniaxial pull-out force acted on the bonding interface was implemented by a universal tensile machine, as shown in Figure 3. The whole loading process was controlled by displacement and the speed of displacement was 0.2 mm/min. Displacement and loads were real-time collected by an automatic data acquisition system.

![Figure 3 Test setup.](image-url)
RESULTS AND DISCUSSION

Failure modes

Two failure modes were observed in the test. For specimens with Type A and B interfaces, the interfacial full debonding was observed, as shown in Figure 4. For specimens with Type C interface, ECC fracture along the bond interface occurred, as shown in Figure 5. Although the construction method of ECC is different for specimens in Group N and Group S, the failure mode has not changed for different type of interface. It can be concluded that the roughness degree of concrete substrates has a significant influence on the failure mode, while the casting method of ECC almost has no obvious influence on the failure mode.

The load-displacement curves of one selected specimen from the corresponding group under the uniaxial pull-out load are shown in Figure 6. It can be seen form Figure 6, the load-displacement responses exhibit nearly a linear relationship before the applied loads reach to the maximum values. When applied load beyond the peak values, the curves drop straightly until the specimens failed.

The experimental results were summarized in Table 1. Compared with the type A interface specimens in Group N-A, the interfacial debonding strength of specimens with types B and C of interfaces are increased significantly. Similar situation can be also seen in groups S-A, S-B and S-C using the spraying ECC. For example, the mean values of interfacial debonding strength are only 0.29 MPa for specimens in group N-A, but a higher value (i.e. 0.49 MPa for group N-B and 0.69 MPa for group N-C) can be obtained by using the coarse interface. Therefore, the roughness degree of concrete substrates had a significant influence on the interfacial debonding strength between ECC and concrete. In addition, it can also found that the nominal interfacial debonding strength for the spraying ECC were all smaller than that for the casting ECC no matter what types of interface are applied, which indicates the influence of construction method of ECC was obvious on the interfacial debonding strength.

\[
\tau = \frac{F_{\text{max}}}{A}
\]

where \(\tau\) is nominal interfacial debonding strength, MPa; \(F_{\text{max}}\) is maximum pull-out load, kN; \(A\) is interfacial area, mm\(^2\).

Nominal interfacial debonding strength
CONCLUSIONS

The effect of contortion methods of ECC and interface types on the bond behaviors of ECC-to-concrete interface were experimentally investigated in this paper. Two failure modes were observed during the test, which were the interface debonding for specimens with type A and B interfaces and ECC fracture for specimens with type C interface. The cured interface had a significant influence on the failure mode and the debonding strength of interface and coarser interface can cause higher interfaceal bond strength, while the construction methods of ECC only affect the interfacial bond strength. Relatively low bond strength was obtained for specimens manufactured with spraying ECC no matter what types of interfaces was applied in the test specimens. It is concluded that the influence of construction method of ECC was obvious on the interfacial debonding strength.

ABSTRACT

Combining Al (namely, aluminum alloy) and CFRP (carbon-fiber-reinforced polymer) jackets to form hybrid columns can yield many advantages. For stub ones, bearing capacity can be improved significantly. For long ones, hybrid columns have improved buckling behaviors compared with traditional pure Al columns. Firstly, the elastic buckling bearing capacity based on the margin yield criterion of Al will increase. Secondly, the maximum buckling bearing capacity based on maximum strength criterion will also increase. Thirdly, the deformation capacity will improve. In this paper, for stub specimens, a systematic study of CFRP-Al hybrid columns is conducted including experiments, theoretical analysis and finite element analysis (FEA). Specially, for long specimens, due to the fact that current theoretical model is not suitable for hybrid specimens, FEA is used to get the maximum buckling bearing capacity of them. Besides, typical column curves for long hybrid specimens are obtained by FEA based on maximum strength criterion for design.

INTRODUCTION

A combination of composites with other structural materials, such as steel (Feng et al. 2013), concrete (Feng et al. 2015), and natural materials (Feng et al. 2012), can be created to yield favorable structural behaviors. Instead of simply replacing other materials, this method enables the direct and efficient use of composites in construction. Many studies have focused on FRP columns and FRP-metal hybrid columns (Guades et al. 2013; Han et al. 2007; Jiao et al. 2004), which have identified new possibilities for combining FRPs and metals for structures in construction and have demonstrated improved properties compared to traditional structures. Al and FRP have many similar advantages like low weight, good corrosion resistance, free maintenance, no ferromagnetic properties and flexible manufacturing procedures (Ye and Feng 2006; Zhao and Zhang 2007). CFRP-Al hybrid components retain these advantages and also compensate for some of their disadvantages. Previous studies have demonstrated considerable interest in reinforcing Al structures with FRPs (Kim 1998; Lee et al. 2004; Zhang et al. 2014). This paper presents experimental and theoretical investigations of the compressive capacities and buckling behaviors of stub and long CFRP-Al hybrid columns.

EXPERIMENT

The mechanical properties of the Al materials and CFRP and the specimen number are the same as those in the previous paper (Feng et al. 2016). The section configurations are shown in Figure 1.
The test results of short specimens are shown in the previous paper (Feng et al. 2016). For long specimens, due to the fact that the CFRP jacket will not yield, the hybrid long specimens have the following global buckling behaviors. Figure 2 shows the typical force-lateral displacement curves of long specimens, which indicates the tendency. Firstly, the elastic buckling bearing capacity \( F_A \) based on the margin yield criterion of Al will increase. Secondly, the maximum buckling bearing capacity \( F_B \) based on maximum strength criterion will also increase. Thirdly, the index of judging deformation capacity can be defined as the lateral displacement when the load decreases to 85% of its maximum load (Feng et al. 2013). \( \Delta_{\text{hybird}} \) and \( \Delta_{\text{Al}} \) represent the lateral displacement of hybrid columns and Al pure columns, respectively. It is obvious that \( \Delta_{\text{hybird}} \) is much larger than \( \Delta_{\text{Al}} \). Thus, it is seen that the deformation capacity after bucking will also improve.

\[
\begin{align*}
\Delta_{\text{hybird}} & > \Delta_{\text{Al}} \\
\text{Thus, it is seen that} \quad \text{the deformation capacity after bucking will also improve.}
\end{align*}
\]

DISCUSSION OF THEORETICAL MODEL FOR \( F_B \)

For stub columns, local buckling or strength failure may happen. Based on calculation method proposed by Feng et al. (Feng et al. 2016), \( F_B \) can be obtained accurately.

For long columns, global buckling happened. In order to get \( F_B \), the stability coefficient \( \varphi \) should be obtained. Based on the margin yield criterion, Eq. 1 gives the way to calculate \( \varphi \), which can also be called Perry-Robertson formula.

\[
\varphi = \frac{1}{2 \lambda^2} \left[ (1 + \epsilon_0 + \lambda^2) - \sqrt{(1 + \epsilon_0 + \lambda^2)^2 - 4 \lambda^2} \right] 
\]  
(1)

In the “Technical code of cold-formed thin-wall steel structures” (GB50018-2002), Eq. 1 has also been adopted to obtain \( \varphi \). Specifically, the equivalent relative initial bending \( \epsilon_0 \) can be obtained by the following equations, where \( \lambda \) is the regularized slenderness ratio:

\[
\begin{align*}
\bar{\lambda} \leq 0.5, \quad \epsilon_0 &= 0.25 \bar{\lambda} \\
0.5 < \bar{\lambda} \leq 1.0, \quad \epsilon_0 &= 0.05 + 0.15 \bar{\lambda} \\
\bar{\lambda} \geq 1.0, \quad \epsilon_0 &= 0.05 + 0.15 \bar{\lambda}^2
\end{align*}
\]  
(2-4)

However, the mechanism of hybrid long columns is different from pure ones. Figure 3 shows the change of the stress distribution of the hybrid columns during loading. Due to the high strength of CFRP, the margin will not

\[
\begin{align*}
\Delta_{\text{hybird}} & > \Delta_{\text{Al}} \\
\text{Thus, it is seen that} \quad \text{the deformation capacity after bucking will also improve.}
\end{align*}
\]
yield. Thus, the Perry-Robertson formula is only available for pure columns. Besides, a simple theoretical way is hard to get $F_B$. Therefore, FEA is used in the following analysis to get $F_B$.

**Figure 3** Change of the stress distribution of long hybrid columns during loading

**FEA**

FE modeling was performed by using ANSYS software (Díaz C et al. 2011; Yang et al. 2013); the Al was meshed by using the 3-D structural solid element SOLID45, and the CFRP jacket was meshed by using the layered 3-D structural solid element SOLID46.

**Stub columns**

The arc length method was applied to solve nonlinear problems. The values of the compressive bearing capacity are in good agreement of experimental results (Feng et al. 2016).

**Long columns**

No debonding was observed in the long columns; thus, the nodes that were shared by the CFRP jacket and the Al were coupled. The FEA was conducted as the followings: eigenvalue buckling analysis was conducted thus the first-order buckling mode was obtained. Then non-linear buckling analysis was conducted. The good results are shown in Figure 4, where $\phi_{FEM}$ and $\phi_E$ are stability coefficients from FEM and experiment, respectively.

**Figure 4** Comparison of stability coefficient $\phi$ from experiment and FEM
Based on the reliable FE modeling, the column curves can be obtained. Figure 5 shows the relationship of $\varphi$ and $\lambda$. It is obvious that long hybrid columns can be divided into two categories: $\lambda \geq 1.25$ and $\lambda < 1.25$.

**Column curve of Specimens of $\lambda \geq 1.25$**

$\xi$ is defined as the ratio of the bending stiffness that is provided by the CFRP jacket to that of the entire specimen, as shown in Eq. 5:

$$\xi = \frac{(\sum E_{L,C} I_{C})}{(\sum E_{L,C} I_{C} + E_{A} I_{A})}$$  \hspace{1cm} (5)

Based on Eqs 2 to 4, the value of $\omega_0$ is influenced by $\xi$ and $\lambda$. The values of $a_1$ and $a_2$ are defined as initial imperfection factors based on $\xi$. The values of $a_1$ and $a_2$ could be obtained from the relationship of $\varphi$ and $\lambda$ by Eq. 7 at different $\xi$. The least square method was used to get the relationship of $a_1$ and $\xi$, $a_2$ and $\xi$. The results are shown in Eqs 8 and 9.

$$e_\varphi(\xi, \lambda) = a_1(\xi) + a_2(\xi) \times \lambda^2$$  \hspace{1cm} (6)

$$\varphi = \frac{1}{2 \lambda^2} \left[ (a_1 + 1) + (a_2 + 1) \lambda^2 \right] - \sqrt{\left[(a_1 + 1) + (a_2 + 1) \lambda^2 \right]^2 - 4 \lambda^2}$$  \hspace{1cm} (7)

$$a_1 = -0.2\xi^2 + 0.06\xi + 0.10$$  \hspace{1cm} (8)

$$a_2 = 0.09\xi^2 - 0.03\xi + 0.05$$  \hspace{1cm} (9)

**Column curve of Specimens of $\lambda < 1.25$**

Linear functions are chosen as primary function for the least square method, as shown in Eq. 10. Similarly, the results of $b_1$ and $b_2$ are shown in Eqs 11 and 12.

$$\varphi = b_1 \lambda + b_2$$  \hspace{1cm} (10)

$$b_1 = -0.28\xi^2 - 0.54\xi - 0.48$$  \hspace{1cm} (11)

$$b_2 = 0.37\xi^2 + 0.66\xi + 1.13$$  \hspace{1cm} (12)

Taking Eqs 11 and 12 into Eq. 10, $\varphi$ of specimens of $\lambda < 1.25$ can be obtained:

$$\varphi = \min \left\{(-0.28\xi^2 - 0.54\xi - 0.48) \lambda + 0.37\xi^2 + 0.66\xi + 1.13, 1 \right\}$$  \hspace{1cm} (13)

The overall results are compared with the experimental results with relatively good agreement, as shown in Figure 6, where $\varphi_\lambda$ and $\varphi_\text{ex}$ are stability coefficients from column curves and experiment, respectively.
CONCLUSION

Stub and long CFRP-Al hybrid columns exhibited higher compressive bearing capacities and higher buckling loads compared to Al columns, respectively. Specially, for the long one, the loads did not decline suddenly after buckling occurred due to the use of the CFRP jacket. Besides, it was found that the buckling mechanism of long hybrid columns was different from that of pure columns due to the elastic CFRP jacket cannot yield. Thus, based on the Perry-Robertson formulation and the related coefficients determined by the FEM results, column curves of long hybrid columns were proposed, which shows good agreements with experimental results.

ABSTRACT

Carbon fibre reinforced polymer (CFRP) materials have been proven effective in strengthening steel structures. Extensive studies were conducted to investigate the fatigue behaviour of CFRP retrofitted steel plates while research on repaired steel beams was less reported. This study tested seven cracked beams under cyclic loading, among which, six were strengthened by different materials and patch systems. These materials included normal modulus CFRP laminate, high strength steel (HSS) plate, SafStrip (SAF) plate, and two types of epoxies. The effect of adhesive bonding and mechanical anchorage was discussed. It was found these high strength materials considerably retarded the crack propagation and extended the fatigue life of the test specimens. In some cases, the crack growth rate decreased as the crack length increased. Besides, the crack mouth opening displacement (CMOD) was also significantly reduced after retrofitting. Comparing the fatigue life when the crack propagated to half height of the steel beam, CFRP laminate with structural adhesive Araldite 420 appeared to be the most effective among these retrofitting schemes.

KEYWORDS

Fatigue test, high strength material, steel beam, strengthening.

INTRODUCTION

Fatigue damage is a major concern for many steel structures since fatigue cracks may emanate at areas where stress concentrates. Therefore, it is of great importance to retrofit the deficient members in a cost-effective way. In recent years, externally bonded carbon fibre reinforced polymer (CFRP) was considered as an alternative in comparison with traditional techniques (e.g. Zhao and Zhang 2007; Teng et al. 2012). Research on CFRP application to cracked steel plates has demonstrated the great potential of this approach in fatigue crack repair. Extensive experimental results showed that the overlays could significantly retard crack propagation and extend fatigue life of steel plates (e.g. Täljsten et al. 2009; Liu et al. 2009a; Yu et al. 2013; Colombi et al. 2014) and numerical simulation was performed to investigate the effect of repair schemes, such as bond length, bond width, bond location and number of bond layer on the strengthening efficiency (e.g. Kaddouri et al. 2008; Liu et al. 2009b; Wang et al. 2013; Yu et al. 2014).

However, research work on fatigue strengthening of cracked steel beams is comparatively less performed. Jiao et al. (2012) tested 21 initially cracked steel beams under fatigue loading and three different retrofitting methods were considered, i.e., welding, welding and bonding with CFRP plate or CFRP woven. The experimental results showed that in comparison with solely welding, one layer of CFRP plate and four layers of CFRP woven sheets extended the fatigue life of the steel beams about seven times and three times, respectively. In Wu et al. (2012), the retrofitting efficiency of more strengthening materials was compared, including high-modulus CFRP plate (HM-CFRP), high-strength CFRP plate (HS-CFRP), steel-wire basalt-fibre-reinforced polymer plate (SW-BFRP) and welded steel plate. It was concluded from the current results that the best fatigue performance was achieved by HM-CFRP. Since adhesive is the weakest link in the bonding system of CFRP to steel, the bond behaviour plays an important role which is directly related to the success of the strengthening scheme. Kim and Harries (2011)
presented an experimental and numerical study on the flexural behaviour of damaged steel beams strengthened by CFRP strip. In particular, an empirical model was proposed to estimate the fatigue response of CFRP-steel interface. More recently, Colomi and Fave (2015) also focused on the interfacial behaviour. It was revealed that a debonded area did exist around the crack front. With consideration of the complex issues of adhesive bonding, Ghafouri et al. (2012a,b) developed a prestressed unbonded reinforcement system and derived the required prestressing level to arrest the crack propagation.

In this study, seven defected steel beams strengthened by different high strength materials were tested under fatigue loading, including normal modulus CFRP laminate, high strength steel (HSS) plate and SafStrip (SAF) plate. Both adhesive bonding and mechanical anchorage were adopted based on the properties of these patches. The crack propagation and crack mouth opening displacement (CMOD) with fatigue cycles were recorded during the experimental programme. Test results showed that in comparison with the control specimen, the fatigue behaviour of the steel beams was significantly improved with different high strength materials and repair configurations.

**DESCRIPTION OF TEST SPECIMENS**

**Configuration of Test Specimens**

Specimens were I-shaped steel beams (HM 150 × 75 × 5 × 7) with an overall width of 75 mm and a height of 150 mm. The specimen was machined with a notch to simulate the initial damage. The artificial slot, which was 15 mm long and 0.3 mm wide, went through the tension flange and a portion of the web, as shown in Figure 1.

A total of seven specimens were designed, of which one was tested as the control specimen and the other six were strengthened on the tension flange by using different materials and patch systems (Figure 2). CFRP laminate, HSS plate, and SAF plate all have high strength-to-weight ratio and their nominal thickness were 1.4 mm, 1 mm and 3.2 mm, respectively. Different from conventional CFRP materials, the SAF plate is a combination of unidirectional carbon and E-glass fibers and E-glass continuous strand mats, leading to a high bearing strength. Their mechanical properties are listed in Table 1.

**Material Properties**

The steel beams used in the tests were Q345b (according to Chinese Standard GB 50017-2003). Coupon specimens were manufactured from the web and flange and the results are listed in Table 1. CFRP laminate, HSS plate and SAF plate all have high strength-to-weight ratio and their nominal thicknesses were 1.4 mm, 1 mm and 3.2 mm, respectively. Different from conventional CFRP materials, the SAF plate is a combination of unidirectional carbon and E-glass fibers and E-glass continuous strand mats, leading to a high bearing strength. Their mechanical
properties were also obtained through coupon tests. Regarding to the cases strengthened by adhesive bonding, two types of epoxies, Araldite 420 and Sikadur 30, were selected to bond the CFRP to the steel substrate. The technical data provided by the manufacturer is given in Table 1.

**Specimen Preparation**

The tension flange was first sandblasted and then cleaned with high-pressure air and acetone. For adhesive bonded specimens, CFRP laminates were glued to the steel surface and the specimens were cured for two weeks at room temperature. The adhesive layer thickness was controlled to be around 0.5 mm. For mechanical anchored specimens, the screws were driven in by a torque wrench with a torque moment of 56 kN·m.

**FATIGUE TESTING**

**Loading Procedure**

Four-point bending tests were performed on all the specimens as shown in Figure 1. Cyclic compressive loading \( P \) from 3.5 to 35 kN with a frequency of 6 Hz was selected. The loading applied by the actuator of the MTS servo hydraulic testing machine was evenly distributed between the two loading points through a spreader beam \( (P/2) \). The maximum load of the spectrum was about 63% of the calculated yield load of the unstrengthened beam, based on the mid-span notched cross-section. In order to prevent out-of-plane displacement of the specimen under cyclic loading, two stoppers were installed on both ends of the bending rig (Figure 3).

Besides fatigue loading, the specimens were also loaded statically to the maximum load of the fatigue loading spectrum at the very beginning and after a certain cycle numbers to detect the CMOD variation. The fatigue test was stopped when the crack broke through the beam web or two million cycles were achieved.

**Data Acquisition**

It is important to monitor the crack propagation with fatigue cycles. Though uncovered, the accurate position of the crack front in the beam web was difficult to identify as a result of the constraint effect of strengthening materials on the crack opening. Therefore, strain gauges at a certain interval were attached to characterize the crack growth. Sudden change of the strain reading indicated that the strain gauge was damaged due to the crack propagation to the corresponding position. During the static test, two clip-shape displacement transducers with a gage length of 2 to 7 mm were installed at both ends of the initial cut on the tension soffit to record the CMOD.

**EXPERIMENTAL RESULTS AND DISCUSSIONS**

A total of seven specimens were tested. The detailed experimental programme and the results are listed in Table 2.
Failure Modes

As the cycle number increased, the crack of Beam 1 propagated towards the compression flange and finally went through the beam web (Figure 4). With respect to the specimens with retrofitting, Beams 2 and 5 survived after two million cycles and different failure modes were observed for the other specimens, as depicted in Figure 5.

![Failure of Beam 1 without retrofitting](image1)

Beams 2 and 3 having the CFRP laminates bonded by Araldite 420 and Sikadur 30, respectively. Beam 2 did not fracture after two million cycles and it was found that the crack had already gone throughout the beam web at about 1.07 million cycles. Afterwards, no further crack propagation was observed and the interfacial debonding zone around the initial notch spread towards the ends of the laminate. Similar phenomenon occurred to Beam 3 that interfacial debonding progressed as the fatigue cycle number increased as a result of stress concentration. The debonding progression along the bond length was not exactly symmetrical with respect to the mid-span. When the crack reached a certain length, it suddenly went through the beam web accompanied with cohesive failure.

Beams 4 to 7 were strengthened by mechanical anchorages. In Beams 4 and 5, the CFRP laminates were attached through frictional force. One bolt of Beam 4 fractured, and afterwards, the crack broke through the beam web. Different areas on the fracture surface of the bolt as shown in Figure 5(b) implied that it may fail by fatigue. Beam 5 survived when two million cycles were applied and the crack had not reached 128 mm where a strain gauge was attached, which demonstrated that Anchor B was more effective in retarding crack propagation in comparison with Anchor A. For Beams 6 and 7, which were repaired by HSS and SAF directly anchored to the tensile flange, respectively, the strengthening materials finally fractured. It is found in Figures 5(c) and 5(d) that the HSS plate fractured at the middle cross section whereas the SAF plate fractured at the place of anchor. It was due to the material properties of these two kinds of materials that the HSS plate was a uniform material while the SAF plate was composed of fibres. Though drillable, the holes cut fibres of the SAF plate, resulting in a detrimental effect and consequently a local failure at the anchorage.

![Failure of the steel beams with retrofitting](image2)

Fatigue Crack Propagation and Opening

Figure 6 plots the crack propagation with fatigue cycle numbers of all the specimens. It should be pointed out that, beams 2 and 5 did not fracture during the experimental programme. The crack length was measured from the tension soffit to the crack front, including the dimension of the initial slot. In comparison with the unstrengthened specimen, the crack propagation was significantly retarded in the strengthened specimens. It was noticed that for
Beams 2 and 5 survived after two million cycles, their $N-a$ curves were upper convex, which indicated that the crack propagation rate decreased with crack length.

The average CMOD value recorded by the two displacement transducers versus fatigue cycles is depicted in Figure 7. The results shown here are the values at the peak load of 35 kN during every static loading process. For Beam 1, the vertical slope indicated that the CMOD developed very quickly. With the presence of strengthening materials, the CMOD was considerably decreased, which implied that these overlay patches could offer a constraint effect on the crack opening. Similar to Figure 6, different shapes of CMOD versus cycle number curve were observed that a better performance was achieved in Beams 2 and 5 where the CMOD development was obviously slowed down with fatigue cycles.

![Fatigue Life Crack length versus fatigue cycles](image1)
![Fatigue Life CMOD versus fatigue cycles](image2)

**Fatigue Life**

Table 2 lists the fatigue life and fatigue life extension ratio of all the specimens. The fatigue life extension ratio is defined as the fatigue life of a strengthened specimen to that of the bare specimen. Besides Beams 2 and 5, which didn’t fail at two million cycles, the fatigue life of the strengthened specimens was extended from 4.2 to 15.8 times. Beams 2 and 3 were both retrofitted with adhesive bonding and the test results clearly showed the difference between retrofitting with structural adhesives of Araldite 420 and Sikadur 30. Araldite 420 was more efficient in this strengthening scheme which was mainly attributed to its higher interfacial fracture energy in comparison with Sikadur 30 (Fernando 2010). Beam 4 had its fatigue life prolonged to 15.8 times, which was almost twice that of Beam 3. It was therefore confirmed the flexibility of mechanical anchorage applied in fatigue strengthening. Anchor B showed an apparent superiority to Anchor A, which was because the number of bolts in Anchor B was twice as many as Anchor A, leading to a larger pressure force and consequently frictional force. The fatigue life ratios of Beams 6 and 7 were 7.7 and 4.2 times, respectively, although the nominal tensile stiffness of HSS and SAF was approximately the same. It was mainly due to the detrimental effect of hole drilling to the SAF plate as aforementioned, and as a result, the fatigue life of Beam 7 was relatively shorter.

When the crack reached half height of the beam, the specimen was considered as severely damaged. If we compare the fatigue life at the crack length of 75 mm as shown in Figure 6, it was found that the best performance was achieved by using CFRP laminate with Araldite 420.

**CONCLUSIONS**

This paper presented an experimental study on the fatigue behaviour of defected steel beams strengthened with different high strength materials. The following is concluded.

Based on the experimental investigations, the fatigue life of the strengthened specimens was considerably extended in comparison with the bare steel beam and two specimens survived after two million cycles. The retrofitting technique not only retarded the crack propagation but also reduced the CMOD. In some cases, the development rate of crack length and CMOD decreased with crack length. Considering the fatigue life when the crack reached half height of the specimen, Beam 5 with CFRP bonded by Araldite 420 led to the best performance.

Different failure modes were observed in the experimental programme. The CFRP attached specimens fractured due to cohesive failure or anchor failure while the HSS/SAF attached specimens fractured resulted from the rupture of the strengthening materials. The fatigue behaviour improvement of CFRP retrofitting with mechanical anchorage was comparable to that with adhesive bonding. In comparison with CFRP materials, the strengthening efficiency by using HSS plate and SAF plate was relatively weaker. However, they were thought to be feasible for temporary retrofitting attributed to the ease of installation.
Significant difference in fatigue life was observed for beams retrofitted with Araldite 420 and Sikadur 30. It was concluded based on the current test results that, Araldite 420 was more useful in this strengthening system.

MODE-I FATIGUE CRACK ARREST IN METALLIC GIRDERS USING PRE-STRESSED UN-BONDED CFRP PLATES

Elyas Ghafoori and Masoud Motavalli
Empa, Swiss Federal Laboratories for Materials Science and Technology, Structural Engineering Research Laboratory, Duebendorf, Switzerland. E-mail: elyas.ghafoori@empa.ch

ABSTRACT

Although there exists many studies that have shown that CFRP-strengthening of cracked steel elements can extend the fatigue life substantially, there is not many researches on the design criterion that can guarantee a complete fatigue crack arrest in steel. This paper aims to give a better understanding about the design of CFRP retrofit solutions that can assure a fatigue crack arrest in damaged steel members subjected to cyclic loads. The concepts of crack closure, fatigue thresholds and effective stress intensity factor (SIF) are briefly explained. A fracture-based analytical solution is used to estimate the overall SIF of a cracked steel beam retrofitted by pre-stressed CFRP plate. In order to verify the accuracy of the proposed retrofit concept, three steel beams were strengthened by pre-stressed un-bonded CFRP plates. Before strengthening, all beams were notched, and subsequently were subjected to pre-cycling to create sharp cracks with different sizes of 3 mm, 20 mm and 40 mm. The specimens were then strengthened with different CFRP pre-stress levels of 10%, 20% and 30%. Finally, the specimens were subjected to cyclic loading. It has been shown that as long as the overall SIF at the crack tip is zero (or negative), the crack does not propagate, and a complete fatigue crack arrest can be achieved.

KEYWORDS

Carbon fibre-reinforced polymer (CFRP), steel strengthening, bridge metallic girders, fatigue crack arrest.

INTRODUCTION

Civil infrastructures are ageing worldwide and require constant inspections and repairs. In some cases the damage is so critical that the whole structures need to be replaced. Especially in the case of bridges, this often requires a huge financial investment and can also lead to traffic congestions for an extended period of time during the demolition of the old structure and construction of a new one. Therefore, there is a need to develop new retrofit techniques and concepts. Carbon fibre-reinforced polymer (CFRP) has been proven to be effective in strengthening of steel plates (e.g., Colombi et al. 2003, Dawood et al. 2007, Schnerch et al. 2006, Teng 2012, Zhao 2013) and steel beams (e.g., Ghafoori 2013, Ghafoori and Motavalli 2013, Ghafoori and Motavalli 2015b, Ghafoori and Motavalli 2015c, Ghafoori and Motavalli 2015a).

In general, fatigue strengthening of steel members can be done for members with or without cracks. In the latter case, strengthening is done to prevent fatigue crack initiation (e.g., Ghafoori et al. 2015a, Ghafoori et al. 2015b, Ghafoori et al. 2015c, Ghafoori et al. 2014), and in the former case, to reduce or completely arrest fatigue crack growth (FCG) of an existing crack (e.g., Aljabar et al. 2016, Ghafoori and Motavalli 2011, Ghafoori et al. 2012a, Ghafoori et al. 2012b). This paper focuses on the former case (i.e., strengthening of metallic elements with existing crack). Although many studies have shown that CFRP strengthening can extend the fatigue life of the steel elements considerably (e.g., Colombi et al. 2014, Colombi et al. 2015, Dawood et al. 2007, Wu et al. 2012, Wu et al. 2013), there are not many studies on the conditions of a complete arrest of FCG. Therefore, this study aims to give a better understanding about the criterion that results in a complete fatigue crack arrest in cracked steel members.

BASICS OF FATIGUE AND FRACTURE MECHANICS

As this paper aims to present a CFRP strengthening approach for fatigue crack arrest in cracked steel members, there is a need to have a basic knowledge about some key concepts in fracture mechanics such as crack closure phenomena and fatigue threshold, which are briefly explained in this section.
Crack Closure Effect (CCE)

The crack closure concept implies that the elastic compliance of cracked specimen at low loads remains identical to the compliance of un-cracked specimen because the crack faces are still in contact. The most common five mechanisms that lead to crack closure effect (CCE) are plasticity-induced, roughness-induced, oxide-induced, induced by viscous fluids and transformation-induced crack closure. The CCE results in a certain tensile load before the crack starts to open (K_{op}). In this paper, K is the stress intensity factor (SIF). The effective SIF range is then defined as (Elber 1970)

\[ \Delta K_{eff} = K_{max} - K_{op} \]  

which results in the modified Paris law

\[ \frac{da}{dN} = C \cdot \Delta K_{eff}^m \]  

where a and N are the crack length and number of cycles, respectively, and C and m are material constants. This phenomenon is illustrated in Figures 1.a and 1.b. The crack opening SIF, K_{op}, can either be determined directly by measuring the displacement at the crack mouth or from the compliance of the whole specimen. In that case, K_{op} (see Figure 1.a) is defined at the intersection between the un-cracked and cracked stiffness (see Figure 1.b). Nevertheless, the transition from fully closed to fully open happens over a certain load range, as shown in Figure 1.b. Depending on the crack size, it is also possible that the crack tip remains open while the crack faces are partially closed. For a partially open crack with a fully closed crack tip as well as for a fully closed crack, it can be assumed that the SIF is zero (Ghafoori et al. 2012a, Beghini and Bertini 1990).

Fatigue Threshold Concept

The ASTM Standard E647−13a 2014 defines the fatigue threshold as the ΔK-value linearly extrapolated for fatigue growth rate of 10^{-10} m/cycles. The crack propagation rate in steel is depended on the stress ratio (R) (see Figure 2), which is generally believed to be due to the CCE. The effect disappears when the values for low R ratios are corrected for ΔK_{eff} and in that case all data converges to the same value of ΔK_{th}, as can be seen in Figure 2 (Tanaka 1989).

For the case of a CFRP-strengthened steel beam, as shown in Figure 3, the crack remains closed due to the compression from the pre-stressed CFRP plate up to a certain amount of the external load. Only the load range between the crack opening load and the upper load limit is effective. Therefore, the concept of ΔK_{eff} is used in this paper to calculate the SIF of the cracked members.

FRACTURE ANALYSIS OF CFRP-STRENGTHENED STEEL BEAMS

Crack Closure Phenomena Triggered by Pre-stressed CFRP Plate

From Figure 3, the pre-stressed CFRP plate that is attached to the beam bottom flange applies a compressive force to the cracked section. The pre-stressing load also results in an additional bending moment due to the eccentricity of the CFRP plate from the beam neutral axis. Hence, the acting forces on the steel beam have three components: I) a bending moment due to the external load, II) a compressive axial force due to the pre-stressed CFRP plate, and, III) a negative bending moment due to the eccentricity of the CFRP plate. The fracture effect of these three force components on the crack in the steel beam can be summed up using superposition rule, which is valid in the linear elastic fracture mechanics (LEFM). Note that the force components II and III, due using the CFRP plate, are acting against the force component I. Depending on the magnitude of the external load and the CFRP pre-stressing force, the stress distribution at the cracked-section changes, as shown in Table 1. In the absence of the external bending moment, the existing crack is completely under compression due to the compressive stress from the pre-
stressed CFRP plate. With a slight increase of the external load, the compressive stress at the crack is reduced until the crack-opening moment \( M_{co} \) is reached, implying that the very bottom part of the crack is stress free. If the external load is further increased, the crack will be in the semi-active state which means that part of the crack is under compression. The crack becomes active only when that the crack tip is no longer under compression, and, therefore, the crack-activation moment \( M_{ca} \) is reached. This also represents the instant when the mode-I stress intensity factor \( K_I \) is exactly zero. For external bending moments larger than \( M_{ca} \), stresses at the crack tip increase and the resultant \( K_I \) becomes larger.

Figure 2 \( \Delta K_{th} \) for mild steel (Tanaka 1989).

Note that in some literature and especially in many numerical simulations, a crack under compression is related to a negative stress intensity factor. Although a negative value for the SIF does not have a physical meaning, it implies that the crack tip is under compression (e.g., Ghafoori et al. 2012a, Ghafoori et al. 2012b).

**SIF of Steel I-Beams Strengthened with Pre-stressed CFRP Plates**

An analytical model for the SIF of cracked I-beams under axial load \( (N) \) and bending moment \( (M) \) has been developed based on the energy release rate by Ghafoori and Motavalli 2011

\[
K_I = \left[ -\frac{N^2}{A} \cdot \frac{(M - Y_c N)^2}{I} + N^2 \cdot (\lambda_1 + \lambda_2) + M^2 \cdot (\eta_1 + \eta_2) \right] \frac{\pi}{t_{ef}(1 - \nu^2)} \]  

(3)

where \( Y_c \) is the position of the neutral axis of the cracked and un-cracked cross section. \( \lambda_i \) and \( \eta_i \) are parameters based on the geometry of the cross-section and the crack length. The subscript \( c \) denotes to the cracked cross section. Ghafoori et al. 2012a have extended their analytical method for calculation of the overall SIF of the CFRP-
strengthened beams by superpositioning the SIFs related to the different load components. Assuming that the LEFM conditions are fulfilled, the overall SIF of the CFRP-strengthened beams is given by

$$K_{overall} = K_{external\ load} + K_{CFRP} = K_1^{external\ load} + K_1^{max} + K_2^{max}$$  \hspace{1cm} (4)

Hence, the overall SIF as a function of the geometry, the external bending moment and the pre-stressing level is given by (Ghafoori et al. 2012a)

$$K_1^{overall} = \frac{M - P_l(t_f + \frac{h}{2})}{\pi t_w(1 - \nu^2)} \left[ \left( \frac{1}{l} + (\eta_1 + \eta_2) \right) \frac{\pi}{t_w(1 - \nu^2)} \right]^{\frac{1}{2}} - \frac{P_l}{A} \frac{(1 + \lambda_1 + \lambda_2) + Y_e(\eta_1 + \eta_2)}{t_w(1 - \nu^2)}$$

where $P_l$ is the current axial force in the CFRP under the external bending moment $M$. More details about the analytical solution can be found in Ghafoori et al. 2012a.

**EXPERIMENTAL PROGRAM**

Materials and Specimens

The CFRP plates were provided by the S&P Clever Reinforcement Company AG, Switzerland. The plates had a width of 50 mm and a thickness of 1.2 mm. The mechanical properties of the CFRP, based on the production data sheet, are listed in Table 2. In this paper, all pre-stressing levels are expressed as a percentage of the tensile strength of the CFRP ($f_{t, CFRP} = 2704$ MPa). The IPE 120 steel beams were provided by Briner AG, Switzerland. The mechanical properties of the steel profiles, based on the production data sheet, are listed in Table 3. Three steel beams were strengthened using unbonded CFRP plates. The procedure of strengthening is similar to what has been explained by Ghafoori et al. 2012a. The tests on the beams were performed using the four-point bending test set-up, shown in Figure 3.

In order to create a starting point for the crack to grow, an initial damage in the form of a notch was created in the mid-section of the beam. Therefore, the bottom flange of each beam was cut at the mid-span and a 1.5 mm wide and 6 mm long notch was cut into the web, as can be seen in Figure 4. The geometry of notch size was identical for all specimens. Each specimen, however, was subjected to a pre-cycling loading regime so that the crack length is increased to a desired length according to ASTM Standard E647–13a 2014. Details about pre-cycling will be given later in this paper. Finally, three beams with the crack lengths of 3 mm, 20 mm and 40 mm were prepared, as shown in Table 4. Each specimen has been retrofitted by one CFRP plate with a particular pre-stress level, as indicated in Table 4. In this paper, due to the limitation of paper size, only details about preparation and test results of specimen Beam 1 is provided and more details about the whole experimental, numerical and analytical research program will be published later in a journal paper.

**Pre-cycling**

The crack in all three specimens was grown by applying pre-cyclic loading according to ASTM Standard E647–13a 2014, as summarized in Table 4. According to the ASTM Standard, the crack propagation rate was kept below $10^{-3}$ m/cycles. The size of the plastic zone was estimated to be small enough to guarantee that the condition for LEFM is fulfilled. The length of fatigue crack after pre-cycling for Beam 1, Beam 2 and Beam 3 were 3 mm, 20 mm and 40 mm, respectively. A strain gauge was glued near to the crack tip (see Figures 4 and 5) to estimate the stress level near the crack tip. After applying the pre-cycling, the specimens were strengthened with the pre-stressed CFRP plates (see Table 4).
Figure 4 A strain gauge attached at the vicinity of the crack tip in a) Beam 1 and b) Beam 3.

Figure 5 Strain at the crack tip for Beam 1 during cyclic loading as function of a) external load, and b) time.

Figure 6 Visual inspection of the crack before and after the fatigue loading as well as after the increased load.

**Cyclic Loading**

For strengthening Beam 1, the CFRP was first pre-stressed up to 264.9 MPa (9.8% of the failure stress) before the beam is placed on the CFRP and the clamps are tightened. After the release of the actuator load, the stress in the CFRP is reduced to 239.1 MPa (i.e., about 10% decrease). For fatigue test, the upper and the lower loads were set...
to 6.0 kN and 0.6 kN, respectively. This results in a stress ratio of $R=0.1$. The upper load level was chosen in a way that results in a zero strain at the crack tip (i.e., onset of crack activation, $M_0$). The magnitude of the stress at the crack tip was read by the applied strain gauge, as shown in Figure 4. 1’000’000 fatigue cycles with a loading frequency of 4.35 Hz were applied. Figures 5.a and 5.b show the strain at the crack tip during cyclic loading as function of force in cylinder and time, respectively.

No fatigue crack growth was observed after 1’000’000 cycles. This observation acknowledges that fact that the crack does not grow as long as the crack tip is not in active mode (see Table 1). Note that the SIF of the retrofitted beam according to Eq. (5) is zero. Furthermore, Figures 6.a show the visual inspection of the crack after pre-cycling, while Figure 6.b depicts the state of crack after strengthening and application of 1’000’000 cycles, which indicates a complete fatigue crack arrest.

### Increased Cyclic Load Level

After 1’000’000 cyclic loads without any crack propagation in the steel, the load was increased just above the fatigue threshold for additional 200’000 cycles. The threshold value of SIF (i.e., $\Delta K_{th}$) for mild steel based on Figure 2 is about 2.8 MPa$\sqrt{m}$, which is equal to 88.3 MPa$\sqrt{mm}$. As the strengthening with the pre-stressed CFRP results in a crack closure due to the compressive force, it is appropriate to use the data points for $\Delta K_{eff}$ in Figure 2. The increased load level was aimed to create a FCG rate of $10^{-5}$ mm/cycle (i.e., a crack growth of 2 mm in 200’000 cycles). As it is shown in Figure 2 by two dashed red lines, this FCG rate corresponds to a $\Delta K_{eff}$ of 9 MPa$\sqrt{m}$, which is equivalent to 284.6 MPa$\sqrt{mm}$. The analytical formulation in Eq. (5) was used to calculate the load corresponding to $\Delta K_{eff}=284.6$ MPa$\sqrt{mm}$, which resulted in an upper and lower load levels of 7.8 kN and 0.8 kN. The beam was then subjected to this cyclic load range and the crack propagated about 1.7 mm with an average crack propagation rate of $8.5 \times 10^{-6}$ mm/cycle. Figures 7.a and 7.b show the strain at the crack tip for Beam 1 after increased load level as a function of external load and time, respectively. It can be seen that the crack tip is under tension, which implies an active crack mode. Furthermore, Figure 6.c clearly shows that the crack length was increased for about 1.7 mm after applying 200’000 cycles with increased load.

![Figure 7](image-url)

Figure 7. Strain at the crack tip for Beam 1 after increased load level as function of a) external load, and b) time.

Similar test procedure has been repeated for Beam 2 with medium crack length and Beam 3 with long crack length. The results of the other two tests were similar to the results of Beam 1.

### CONCLUSIONS

Basic concepts of fracture mechanics such as the crack closure effect, the fatigue threshold, and the effective SIF have been briefly explained. For the case of the CFRP-strengthened cracked steel elements, different fracture modes of passive, semi-active and active crack modes have been explained. It has been shown that the CFRP pre-stress can act as a source for the crack closure.

Three steel beams were notched and then subjected to pre-cycle loading regime to create sharp cracks from the notches with different sizes of 3 mm, 20 mm and 40 mm. The specimens were strengthened with different CFRP pre-stress levels of 10%, 20% and 30%. The specimens were then subjected to cyclic loading that would result in a zero SIF at the crack tip (i.e., onset of crack activation). It has been shown that once the overall SIF at the crack tip is zero (or negative), the crack does propagate. In other words, when the CFRP pre-stress level is high enough.
to apply a compressive stress to the crack tip, the crack remains passive and the FCG is arrested. In order to further verify this conclusion, the cyclic loading level were slightly increased such that the resulting SIF became positive (i.e., crack tip under tension). The latter resulted in an active crack mode, therefore, fatigue crack propagated though the web. The main finding of this research is to show that it is possible to design a CFRP retrofit solution for cracked steel members such that the fatigue crack propagation is arrested.

COMPARISON AND ANALYSIS OF THE EFFECT OF STRENGTHENING STEEL PLATE WITH VOLUME TYPE DEFECTS BY CFRP ON ONE SIDE

Zheng Xue, Bin Jia, Xiao Liu and Jianwei Yu
Southwest University of Science and Technology, Mianyang 621010, China

ABSTRACT

CFRP strengthening effect of steel structure is affected by defect types, pasting location of CFRP and other factors. It is analyzed that the effect regularity of defect size and depth of the defects to bearing capacity of CFRP reinforcing steel, and the influence of relationship between CFRP and defect position on strengthening effect in this paper based on the tensile test of the volume defects of steel plate specimens strengthened by CFRP.

KEYWORDS:
Reinforcement in defect surface, reinforcement in non defect surface, reinforcement effect, defect types.

INTRODUCTION

Steel structure is widely used in civil engineering field because of its high strength, light weight, high rigidity and so on. However, the metal material is easy to be destroyed by chemical reaction with the surrounding environment. But, the corrosion of steel is not uniform. This is easy to cause surface corrosion of the steel structures and stress concentration to affect the safety of steel structure[2-5]. Technology of steel structure strengthened with FRP has the advantages of no secondary stress and defects, good durability, convenient construction, low maintenance costs and has attracted much attention in the field of Engineering[6-13]. However, the effects of FRP strengthening the steel structure with defects are affected by many factors. Hongbo Liu[14] proved that the width, length and thickness of CFRP affected the bearing capacity of steel plate by testing. Ma Jianxun et al.[15] found that the larger bonding area of CFRP is, the more the residual bearing capacity of the steel plate is increased. Lu Yiyun[16] discussed the effects of CFRP bonding width, length and number of layers on the bearing capacity of the specimens.

For FRP strengthening steel structure with defects, we can directly paste the FRP in the surface of defect to complete the reinforcement. If you can not or inconvenience in the defect surface to complete the FRP paste, then you can paste it in the back side of the surface of defect. However, the reinforcement effect of the two methods remains to be seen whether the reinforcement effect is consistent or not. This paper makes a further validation analysis.

EXPERIMENTAL DESIGN

This test specimen is 5mm thick Q235 steel plate. CFRP cloth is UT70-30 unidirectional carbon fiber cloth produced by Sichuan aerospace Tuoxin basalt Industrial Co.Ltd.. Mechanical properties are shown in Table 1. Resin binder is CH-1A impregnated adhesive produced by Longchang Sichuan Chengu Rubber Industry Co. Ltd..

The shape of steel corrosion defects is much more variable and irregular. According to the size of the defect area, it is divided into two types: large area corrosion and small area of pitting corrosion. As shown in Figure 1 and Figure 2, the test set with large area defects of steel specimens and small area defects of steel specimens. Among
them, the steel plate specimens with large area defect are non-penetrating oval pit defects, the maximum defect depth is 2mm, and the corrosion area $A_0$ is the percentage of steel plate area. The steel plate specimens with small area defect are non-penetrating conical pit defects which has 10mm long axis and 8mm short axis. The design condition of the specimens is shown in Table 2 and Table 3.

THE LOADING PROCESS AND PHENOMENON

Using 300kN microcomputer control electron universal testing machines (max test force 300kN) to carry out tensile test which loading rate is 0.1kN/s. The experiments are carried out in order to test the tensile test of each specimen.

The phenomenon occurred in the whole test process of the large area defect specimen after the front reinforcement and the back reinforcement: The CFRP cloth and the steel plate did not stripping in the initial stage of loading. When the tensile load is close to the yield load of the non-reinforced steel plate, the tensile test piece begin to give off a faint sound. When the tensile load is more than 85kN, CFRP cloth first stripped in the middle of the paste. Along with the increase of the load, the peeling is gradually developed to the end anchorage zone. When the load is close to 90kN, one side of the anchorage began to slip. The deformation of steel plate increases quickly when the end anchorage has a large slip. The middle part of the plate appears necking, then it quickly tensile failure from the defect of the deepest necking position. The angle between the fracture direction and the axis is less than 45 degrees. In this process, CFRP cloth has not been torn or broken. The failure process of the specimen is shown in Figure 3.

The phenomenon occurred in the whole test process of the small area defect specimen after the front reinforcement and the back reinforcement: In addition to the next few points, it is consistent with the loading process of large area corrosion defect specimens. When the tensile load is close to 95kN, the tensile test piece began to give off a faint sound. When the tensile load is more than 110kN, CFRP cloth first stripped in the middle of the paste. The cracking deformation of steel plate is obvious. The angle between the fracture direction and the axis is less than 90 degrees. In this process, CFRP cloth has not been torn or broken. The failure process of the specimen is shown in Figure 4.

Analysis of experimental phenomena: Prior to the yield of the steel plate, the deformation of the CFRP cloth and the steel plate was almost the same, and there was no relative slip, so it can work together well. CFRP cloth share a part of the load, the yield of the steel plate is delayed, and the yield bearing capacity of the member is improved. The end anchoring of CFRP cloth can improve the bonding ability of the end, and delayed stripping of the end of the CFRP cloth, and the tensile load of the component is further improved. After steel plate yield, because the steel plate in the yield stage will have a larger elongation, and the elongation of CFRP cloth still keeps the linear growth. At the same time, the shear strength of the bonding layer can not contentment the bond, so they began to appear relative slip. They can not work together. The plate is tensile failure, because the load quickly transferred to the steel plate. Due to the tensile strength of CFRP cloth is much higher than that of steel, so the CFRP cloth is not broken. When the load continues to increase, the end of the CFRP cloth appears to slip, so it can not further improve the ultimate bearing capacity of the specimen. Because the CFRP cloth is not yielding stage, the test curve showing the strength performance of CFRP cloth. As a result, there is no obvious phenomenon in the yield stage when loading the specimen. The end anchoring of CFRP cloth can improve the bonding ability of the end, and the end of stripping is delayed, and the tensile load of the component is further improved. The test finally end up as the steel plate tensile failure after bonding failure of CFRP cloth and steel plate. If we can increase the bonding strength is a great help to improve the bearing capacity of the specimen.
EXPERIMENT RESULTS AND ANALYSIS

Strengthening specimen with large area defect by CFRP

Load-displacement curve

The load-displacement curve of different defect area is shown in Figure 5. Figure 5 shows that with the increase of the corrosion area, the bearing capacity of all specimens are reduced. Because the maximum defect depth of the test plate is consistent, with the increase of the defect area, the effective section of the steel plate becomes smaller, so the residual capacity is reduced.

![Figure 5](image1)

**Figure 5** The load-displacement curve of specimens with large area defect

Comparative analysis

In Figure 6, the comparative of the load-displacement curves of the corrosion area of 20%, 40% and 60% are given respectively. From the figure shows that the bearing capacity of the reinforcement specimens are all increased. The degree of improvement of yield load of the two types of reinforcement is higher than that of the ultimate load. The yield load mostly increased by 33.2%, The ultimate load mostly increased by 2.55%. For large area defect steel plate, reinforced in the defect surface or non defect surface both can achieve good results. Prior to the yield of the steel plate, the deformation of the CFRP cloth and the steel plate was almost the same, and there was no relative slip, so it can work together well. CFRP cloth share a part of the load, the yield of the steel plate is delayed, and the yield bearing capacity of the member is improved. When the steel plate to the yield stage, the deformation of the steel plate was significantly greater than the deformation CFRP cloth, then they began to appear relative slip, and CFRP cloth is in a state of detachment. The load that CFRP cloth shared quickly transferred to the steel plate. Lead the steel plate enters the yield stage, and its strain increases rapidly. But the deformation of CFRP cloth is very small. So they can not work together well when the steel plate is subjected to a continuous increase of load. Under the effect of super large load, The connection force between steel plate and CFRP cloth is only provided by the end anchorage. So the stripping is also rapidly from the middle to both ends. Because CFRP cloth is slip in the end anchorage zone, the steel plate lost constraint. After that, the deformation of plate increases quickly. Therefore, the ultimate bearing capacity of steel plate is not much improved.

![Figure 6](image2)

**Figure 6** The load-displacement curve of the specimens with large defects which reinforcement and non-reinforcement

The test data of the specimens with large area corrosion defects are remitted to Table 4. Table 4 data show that, compared with the specimens that reinforced on the back, under different corrosion area, the yield load of the specimens that reinforced in the front is respectively increased by 0.95%, 2.17%, 2.92%. The ultimate load is respectively increased by 0.84%, 0.83% and 0.90%. The yield load is increased by approximately 1%-3%. The ultimate load is increased by about 1%. For large area defect of the specimen, the effect of reinforcement in the front is better than...
the effect of reinforcement on the back. Because when the CFRP cloth is directly stuck on the defect surface, the confinement effect of the steel plate is more obvious. This can effectively reduce the stress concentration at the steel plate defects. When the CFRP cloth is far away from the defect surface, the limiting effect is weakened. Therefore, the improvement of the bearing capacity of the composite member is relatively low. But the enhancing effect is very small. So in the future reinforcement, we should firstly consider strengthening in defect surface. If the reinforcement is not achieved in the defect surface, the effect of reinforcement on the back is also very outstanding.

Table 4 Test Result

</table>

From the test data in Table 4, When the corrosion area is 20%, 40% and 60%, the yield load of the specimens which reinforced on the back is respectively increased by 17.5%, 23.5% and 29.4%. The yield load of the specimens which reinforced in the front is respectively increased by 18.7%, 26.2% and 33.2%. The larger the corrosion area, the better the reinforcement effect. Because when the corrosion depth is certain, the defect area is bigger, the stress concentration is more relaxed, so the strengthening effect is more obvious.

Strengthening specimen with small area defect by CFRP

Load-displacement curve

The load-displacement curve of different defect depth is shown in Figure 7. From the Figure 7 shows that with the increase of the corrosion depth, the bearing capacity of all specimens are reduced. Because the maximum defect area of the test plate is consistent, with the increase of the defect depth, the effective section of the steel plate becomes smaller, so the residual capacity is reduced.

Comparative analysis

In Figure 8, the comparative of the load-displacement curves of the corrosion depth of 1.5mm, 2.5mm and 3.5mm are given respectively. From the figure shows that the bearing capacity of the reinforcement specimens are all increased. But from the whole experiment, the increase of yield load and ultimate load is not large. The yield load mostly increased by 7.1%, The ultimate load mostly increased by 8.1%. Prior to the yield of the steel plate, the deformation of the CFRP cloth and the steel plate was almost the same, and there was no relative slip, so it can work together well. CFRP cloth share a part of the load. However, although the tensile strength of CFRP is very high, the bond strength of the resin adhesive is very low. So the interface between the steel plate and the resin adhesive is still the weak part of the whole specimen. In addition, from the size of the defect, the steel plate specimens are relatively complete. Therefore, it is impossible to greatly improve the bearing capacity of the specimens under the condition that the shear strength of the resin adhesive is not high.
The test data of the specimens with large small corrosion defects are remitted to Table 5. Table 4 data show that, compared with the specimens that reinforced on the back, under different corrosion depth, the yield load of the specimens that reinforced in the front is respectively increased by 2.37%, 1.70%, 3.50%. The ultimate load is respectively increased by 1.40%, 0.70% and 0.28%. For small area defect of the specimen, the effect of reinforcement in the front is also better than the effect of reinforcement on the back. On the whole, this is not particularly significant to improve the bearing capacity of the bearing capacity of specimens by paste a layer of CFRP cloth. At the same time, it also shows that the relative position of the carbon fiber cloth and the defect is directly related to the improvement of bearing capacity. Because when the CFRP cloth is directly stuck on the defect surface, the confinement effect of the steel plate is more obvious. This can effectively reduce the stress concentration at the steel plate defects. When the CFRP cloth is far away from the defect surface, the limiting effect is weakened. Therefore, the improvement of the bearing capacity of the composite member is relatively low.

</table>

From the test data in Table 5. When the corrosion depth is 1.5mm, 2.5mm and 3.5mm, the yield load of the specimens which reinforced on the back is respectively increased by 3.7%, 4.8% and 3.5%. Their ultimate load is respectively increased by 3.0%, 6.7% and 7.8%. The yield load of the specimens which reinforced in the front is respectively increased by 6.1%, 6.6% and 7.1%. Their ultimate load is respectively increased by 4.5%, 7.4% and 8.1%. The deeper the corrosion area, the better the reinforcement effect. Because when the corrosion area is certain, the defect depth is bigger, the stress concentration is more relaxed, so the strengthening effect is more obvious.

**CONCLUSIONS**

1. Whether it is a large area of defect specimen or a small-area defect specimen, the stress level of the defect can be reduced and the bearing capacity of the specimen can be improved by using the back of the reinforcement and positive reinforcement. Though positive reinforcement effect is superior to the back of the reinforcement, the effects are very limited. Relative to the back of the strengthening, the specimens yield load of positive reinforcement is increased up to 3.5% and the ultimate load is increased up to 2.2%. Therefore, it is proposed that the key application technology of CFRP single side reinforced defect plate: In the practical engineering application, you should first consider the use of positive reinforcement. If positive reinforcement is not possible, you could also consider using the back of the reinforcement.

2. The reinforcement effect is affected by the defect size and depth. The larger the defect area is, the more relaxed the degree of stress concentration of the defect has and the more obvious the effect of front and back reinforcement
is. The deeper the depth of the defect is, the more reduced the level of stress concentration of the defect has and the more obvious strengthening effect is.

ABSTRACT

Numerous research studies are available in the literature on strengthening of steel members using carbon fiber reinforced polymer (CFRP) composites. Although it is clear that strengthening using prestressed CFRP plates has several advantages over non-prestressed reinforcements, less attention has been paid in the literature to develop theoretical formulations. Consequently, in this paper, unbonded and bonded prestressed CFRP-strengthened steel plates are analyzed and stresses in CFRP and steel substrate are analytically formulated. Furthermore, the effect of single-side retrofit, which is usually neglected in stress calculations, has been studied. Analytical formulations were then verified by the results of static tests on CFRP-strengthened steel plates under tensile loading. The primary results show that prestressing could considerably reduce the tensile stresses in steel. Consequently, strengthening with prestressed CFRP laminates could be used as an efficient technique for strengthening of steel members, especially those prone to fatigue. However, the available capacity of the prestressed bonded reinforcements before debonding is much less than the developed mechanically anchored, prestressed unbonded reinforcements. Moreover, analytical modeling and experimental results of the current study show that neglecting the eccentricity in single-side CFRP-strengthened steel plates could result in an unsafe stress prediction in steel substrate.

KEYWORDS

Steel member, strengthening, prestressed CFRP, unbonded reinforcement, analytical solution.

INTRODUCTION

Nowadays, a large number of metallic structures are aging worldwide and some of them such as road and railway bridges, offshore structures and communication towers need to be strengthened to carry higher service loads or be safe enough for everyday use due to the fatigue problem. Conventional method of strengthening aging metallic structures, i.e. installing external steel plates to the tension face of the member using bolts or welding, is time-consuming, costly and not so efficient since the external strengthening steel plates are usually bulky, heavy, difficult to fix and prone to fatigue and corrosion of their own (Zhao 2014). On the other hand, unique advantages of carbon fiber reinforced polymer (CFRP) composites such as high corrosion resistance, light weight, high strength, elastic modulus, and fatigue life, made CFRP composites a well-accepted material for static and fatigue strengthening of such structures.

A considerable number of research studies can be found in the literature dealing with strengthening of steel members using CFRP composites (see Zhao and Zhang 2007). Although it is evident that utilizing prestressed CFRP composites has several advantages over non-prestressed reinforcements especially due to a certain decrease in existing stresses in the member, less attention has been paid to model and use prestressed CFRP reinforcements for strengthening of existing steel structures. This might be explained due to the fact that high prestressing levels cannot be reached in bonded CFRP reinforcements. However, this issue can be solved using mechanically anchored, unbonded reinforcements as recently shown by Ghafoori and Motavalli 2015a,b.

The current study presents an analytical solution for stress analysis in unbonded and bonded prestressed CFRP-strengthened steel plates under external tensile loading. To anchor high prestressing forces from CFRP plates to steel substrate a novel prestressed unbonded retrofit (PUR) system has been developed and tested. Afterwards, a set of experiments was performed to evaluate the capability of the analytical model in predicting the stresses in
steel and CFRP as well as the interfacial shear stresses in bonded joints. Note that the limited results, provided in this paper, are part of a large research program on mixed-mode fatigue strengthening of metallic members using CFRP composites at the Swiss Federal Laboratories for Materials Science and Technology (Empa) in collaboration with the Swiss Federal Institute of Technology Lausanne (EPFL) and Monash University in Melbourne.

**ANALYTICAL SOLUTION**

**Unbonded Reinforcements**

In case of utilizing mechanical end anchorages to transfer stresses from CFRP laminates to a steel plate (see schematic configuration in Figure 1a) it is possible to formulate axial stresses in steel and CFRP reinforcements using equilibrium equation as follows:

\[
\sigma_s = T_s - T_{pre} \frac{A_t}{A_s} \left( \frac{1}{E_s} + \frac{1}{E_f} \right) \frac{(\alpha_f - \alpha_s) \Delta T}{A_s}
\]

(1)

\[
\sigma_f = n T_f - \frac{T_{pre} - T_{release}}{A_f} \frac{1}{2A_s} \left( \frac{1}{E_s} + \frac{1}{E_f} \right) \frac{(\alpha_f - \alpha_s) \Delta T}{A_s}
\]

(2)

where \( T_{pre} \) is the initial prestressing force in CFRP laminates, and \( T_{release} \) is the released force which can be calculated as (please refer to the nomenclature for the notations):

\[
T_{release} = \frac{T_{pre}}{1 + \frac{E_s A_f}{E_f A_s}}
\]

(3)

Furthermore, \( n = \frac{E_f}{E_s} \), and \( A_t \) is the transformed cross sectional area of the joint calculated as:

\[
A_t = A_s + 2nA_f
\]

(4)

**Bonded Reinforcements**

**Double-side retrofit**

In case of utilizing CFRP laminates adhesively bonded to a steel plate (Figure 1b), the governing equilibrium equations and boundary conditions can be derived using the free body diagram of an infinitesimal element of the joint depicted in Figure 2 in conjunction with the chosen coordinate systems as shown in Figure 1b. The two differential equations for the horizontal force equilibrium can be expressed as (Täljsten et al. 2009; Albat and Romilly 1999):

\[
\frac{dT_s(y)}{dy} - b_f \tau_s(y) = 0
\]

(5)

\[
\frac{dT_f(y)}{dy} + 2b_f \tau_s(y) = 0
\]

(6)

where \( T_s \) and \( T_f \) are axial forces in CFRP and steel, respectively,

\[
T_s(y) = \sigma_s(y)A_s
\]

\[
T_f(y) = \sigma_f(y)A_f
\]

(7)
The compatibility equations for the CFRP plate, steel, and adhesive can be expressed as:

\[
\frac{d\epsilon_r(y)}{dy} = \frac{T_r(y)}{E_r A_r} - \epsilon_{pre} + \alpha_r \Delta T
\]

\[
\epsilon_r(y) = \frac{dv_r(y)}{dy} = \frac{T_r(y)}{E_r A_r} + \alpha_r \Delta T
\]

\[
\tau_r(y) = G_s \frac{dv_r(y)}{dy} = G_s \tan \left( \frac{v_r(y) - v_s(y)}{t_s} \right) = \frac{G_s}{t_s} (v_r(y) - v_s(y)) + \alpha_r \Delta T
\]

Note that \( b_f \) and \( A_f \) are the summation of widths and cross sectional areas of all individual plates bonded on one side of the steel plate. Differentiating Eq. (10) and substituting Eqs. (8) and (9) gives:

\[
\frac{d\tau_r(y)}{dy} = \frac{G_s}{E_s A_s} \left( \frac{T_r(y)}{E_r A_r} - \epsilon_{pre} + (\alpha_f - \alpha_s) \Delta T \right)
\]

Finally by differentiation of Eq. (11) and substituting of equilibrium equations (i.e., Eqs. (5) and (6)) a second-order ordinary differential equation in terms of interfacial shear stress distribution can be derived as:

\[
\frac{d^2\tau_r(y)}{dy^2} + \lambda \frac{d\tau_r(y)}{dy} = 0
\]

where

\[
\lambda = \frac{G_s}{t_s} \left( \frac{1}{E_s A_s} + \frac{2}{E_f A_f} \right)
\]

Considering the boundary conditions, Eq. (12) leads to the interfacial shear stress as well as axial stresses in the adherents, formulated as follows:

\[
\tau_r(y) = \frac{G_s}{A_r} \left( (\alpha_f - \alpha_s) \Delta T - \epsilon_{pre} - \frac{T}{E_r A_r} \right) \sinh (\lambda y)
\]

\[
\sigma_r(y) = \frac{G_s}{A_f} \lambda \frac{T}{E_f A_f} \left( (\alpha_f - \alpha_s) \Delta T - \epsilon_{pre} - \frac{T}{E_r A_r} \right) \left( \frac{\cosh (\lambda y)}{\cosh (\lambda l)} - 1 \right)
\]

\[
\sigma_s(y) = \frac{T}{A_s} \frac{2G_s}{\lambda^2 A_f} \left( (\alpha_f - \alpha_s) \Delta T - \epsilon_{pre} - \frac{T}{E_r A_r} \right) \left( \frac{\cosh (\lambda y)}{\cosh (\lambda l)} - 1 \right)
\]

where \(-l \leq y \leq l\).

**Single-side retrofit**

In the most practical cases, both sides of the considered steel plate (which is assumed to be a part of a steel structure) are not accessible. As a consequence, it is instructive to derive the governing equations for single-side CFRP-strengthened steel plates. In this case the steel plate undergoes a bending moment due to the eccentricity of the system. Furthermore, it is obvious that in this case the solution is dependent on the general boundary condition of the steel plate. Through the following solution, it is assumed that the whole system is simply supported. The two differential equations for the horizontal force equilibrium can be expressed as:

\[
\frac{dT_r(y)}{dy} - b_f \tau_r(y) = 0
\]

\[
\frac{dT_r(y)}{dy} + b_f \tau_r(y) = 0
\]

where \( T_r \) and \( T_s \) are axial forces in CFRP and steel, respectively (see Eq. (7)). The compatibility equations for the CFRP, steel, and adhesive can be expressed as:

\[
\epsilon_r(y) = \frac{dv_r(y)}{dy} = \frac{T_r(y)}{E_r A_r} - \epsilon_{pre} + \alpha_r \Delta T
\]

\[
\epsilon_s(y) = \frac{dv_s(y)}{dy} = \frac{T_s(y)}{E_s A_s} + \frac{M_s(y) t_s}{2E_s I_s} + \alpha_s \Delta T
\]

\[
\tau_s(y) = G_s \frac{dv_s(y)}{dy} = G_s \tan \left( \frac{v_s(y) - v_f(y)}{t_s} \right) = \frac{G_s}{t_s} (v_s(y) - v_f(y))
\]

Differentiating Eq. (21) and substituting Eqs. (19) and (20) gives:
Differentiation of Eq. (22) yields:

$$\frac{d^2\tau_s(y)}{dy^2} = \frac{G_b}{t_s} \left[ \frac{dT_f(y)}{dy} - \frac{dT_f(y)}{dy} - \frac{dM_s(y)}{dy} - \frac{M_s(y)}{2E_sI_s} \right]$$

The moment equilibrium of the differential segment of the steel plate gives:

$$\frac{dM_s(y)}{dy} + \frac{b_t}{2} \tau_s(y) = 0$$

Finally the differential equation governing the interfacial shear stress distribution can be derived by substituting of force equilibrium equations (Eqs. (17) and (18)) as well as the moment equilibrium equation (Eq. (24)) in Eq. (23) as:

$$\frac{d^2\tau_s(y)}{dy^2} - \lambda^2 \tau_s(y) = 0$$

where

$$\lambda^2 = \frac{G_b \left( \frac{1}{E_sA_t} + \frac{1}{E_sA_t} + \frac{t_s^2}{4E_sI_s} \right)}{t_s}$$

Solving the differential equation given in Eq. (25) and applying the boundary conditions leads to the interfacial shear stress as well as axial stresses in the adherents, formulated as follows:

$$\tau_s(y) = \frac{G_b}{2t_s} \left( (\sigma_s - \sigma_a)\Delta T - \sigma_{pre} - \frac{T}{E_sA_t} \right) \left( \sinh (\lambda y) \right) \cosh (\lambda l)$$

$$\sigma_s(y) = \frac{G_b}{\lambda^2 I_s} \left( (\sigma_s - \sigma_a)\Delta T - \sigma_{pre} - \frac{T}{E_sA_t} \right) \left( \cosh (\lambda y) \right) \cosh (\lambda l) - 1$$

$$\sigma_a(y) = \frac{T}{A_t} b \frac{G_b}{\lambda^2 I_s} \left( (\sigma_s - \sigma_a)\Delta T - \sigma_{pre} - \frac{T}{E_sA_t} \right) \left( \cosh (\lambda y) \right) \cosh (\lambda l) - 1$$

where \(-l \leq y \leq l\).

### EXPERIMENTAL PROGRAM

### Test Layout and Material Properties

In order to evaluate the performance of the developed analytical model in predicting CFRP and steel contributions in a CFRP-strengthened steel plate under uniaxial tensile loading, a set of experiments on steel plate specimens with dimensions of 1100×150×10 mm (length×width×thickness) was planned. The test layout and specimens’ description are provided in Table 1. The utilized steel was of type S355J2+C with nominal yield strength of 355 MPa. The Young’s modulus of the steel was determined equal to 200.9 GPa. Furthermore, normal modulus unidirectional CFRP plates of type S&P 150/200 with cross sectional dimensions of 50×1.4 mm (width×thickness) was used. The elastic modulus and ultimate strength of the laminates were measured as 156 GPa and 2905 MPa, respectively.

Table 1 Specimens’ description and test results
In those specimens strengthened using adhesively-bonded CFRPs, a two component epoxy adhesive of type Araldite 420 was used. The thickness of adhesive was measured after curing process using a micrometer and the average values for each of the specimens are provided in Table 1. The ultimate tensile strength of the adhesive was determined equal to 26.0 MPa obtained from three 6-day samples (see Michels et al. 2016 for further info on the test process). No auxiliary test was performed to determine shear modulus of the adhesive, $G_s$, as part of the current study; however, $G_s=730$ MPa was used in the analytical model based on the manufacturer’s catalogue.

**Strengthening Procedure**

In order to strengthen steel plate specimens using bonded CFRP plates, first the bond area was sand-blasted and carefully cleaned with acetone. Two 520-mm-long CFRP plates were glued to one side of the specimen No. 2, while in specimen No. 3, one CFRP strip was used on each side. The specimens were cured in the room temperature for 6 days before testing. On the other hand, strengthening of the steel plates using mechanical unbonded clamps was much faster since the clamps work based on friction and no surface preparation for steel plate neither curing for adhesive is required. Each set of the designed clamps consists of a hard plate which is in contact with the CFRP plate, pressing it to the steel substrate using the prestressing force generated in M12 bolts (grade 12.9). In total 8 bolts were used in each of the clamps, tightened with a torque of 160 N.m, generating 72 kN prestressing force per bolt. As the whole system works based on friction, diamond friction foils (see 3M technical catalogue) was used between the CFRP and steel. Specimen No. 4 was easily prepared by putting different parts of the mechanical clamps together and tightening the M12 bolts of each clamps, which tied the CFRP plates to the steel substrate. It should be mentioned here that due to the lack of space, no detailed info regarding the design of mechanical clamps could be provided as part of this paper.

To strengthen steel plate specimens No. 5 and 6, an especial prestressing setup was designed to simultaneously prestress two parallel CFRP laminates (Figure 3). The distance between the two CFRPs was accurately kept equal to 10.40 mm using high strength steel cubes in the prestressing grips. The laminates were prestressed up to a load level of 120 kN (approx. 30 % tensile capacity of the laminates) using a hydraulic jack, while the load and strain in CFRPs were monitored using a 300 kN load cell and strain gauges applied on the CFRPs, respectively. After prestressing the laminates, epoxy adhesive was applied on the prepared surfaces of specimen No. 5 and the specimen was put in between the strips. The prestressing force was kept constant for 6 days, and afterwards released to zero. On the other hand, specimen No. 6 was prepared almost in 1 hour due to the fact that after prestressing, CFRP laminates were immediately clamped to the specimen using mechanical anchorages (Figure 3). After releasing the prestressing force, CFRP laminates were cut from both sides of the prestressing grips and the strengthened specimens were carried to the testing machine.

**Test Setup**

All the specimens were equipped with conventional foil strain gauges on steel and CFRPs, as well as magnetic strain gauges on steel. The specimens were tested under displacement-controlled condition with a speed of 1 mm/min using a 1000 kN static-fatigue servo-hydraulic Schenck machine with an Instron controller. Test setup and the typical bonded and unbonded CFRP-strengthened specimens are shown in Figure 4.
RESULTS AND DISCUSSIONS

As it was mentioned before, fatigue strengthening of metallic members is the main focus of the current ongoing research project. Consequently, all the reference/strengthened specimens were subjected to uniaxial tension up to a load level equal to 300 kN, which corresponds to approximately 50% of yield strength of the bare steel. Except test No. 5 in which both of the CFRP plates were debonded from the steel plate at load levels of 50 and 153 kN, respectively, neither any interface failure in bonded reinforcements nor any slip between CFRP and steel in unbonded reinforcements occurred in all other specimens. Load vs. strain in the middle part of the steel specimens were plotted in Figure 5, while the ultimate strain values in steel are also provided in Table 1 for comparison. As expected, strengthening of steel plates using bonded/unbonded CFRP reinforcements increases the stiffness of the member while stiffness of the single-side retrofit is relatively lower than that of double-side strengthening due to the eccentricity of the system. Furthermore, Figure 5 clearly shows the advantage of prestressing in reducing the strains in the steel substrate. However, as it was previously mentioned, in test specimen No. 5 the prestressed CFRP plates were debonded from the steel plate in low load levels, while the mechanical clamps could carry the prestressing force up to the end of loading procedure. It is worth mentioning here that specimen No. 6 was loaded up to 800 kN to further investigate the performance of the designed PUR system. It was observed that no slip between the prestressed CFRP plates and steel substrate occurred even at a load level of 800 kN, which proves the high performance of the designed PUR system.
Load-strain behavior of strengthened specimens was predicted by the proposed analytical formulations and the predictions are also plotted in Figure 5 for comparison purposes. It can be concluded from Figure 5 that the analytical model is capable of accurately predicting the behavior of non-prestressed and prestressed CFRP-strengthened steel plates. It is obvious that linear elastic behavior of all the individual elements of the joint (i.e. steel, CFRP, and adhesive) is a pre-assumption of the developed analytical model, which is also the case in fatigue problem. It means that the model is only applicable up to the end of the elastic regime in steel.

In specimen No. 3, seven strain gauges were mounted on half-length of the CFRP plate at distances of 10, 30, 50, 70, 90, 175, and 260 mm from the CFRP end (see Figure 4a). Utilizing the set of strain gauges, the evolution of interfacial shear stresses in the CFRP-to-steel bonded joint was determined and the results were used to construct the data points presented in Figure 6 (please refer to Hosseini and Mostofinejad 2013 for the calculation of interfacial shear stresses based on the CFRP strain measurements). Moreover, distribution of the interfacial shear stresses along the bond length, predicted by Eq. (14) was also plotted for different load levels in Figure 6. Comparing the experimental data points with the proposed analytical solution shows the high capability of the model in predicting interfacial shear stress distribution along the bond length. Numerous research studies on bond behavior of CFRP composites to concrete/steel substrate proved the fact that not the whole bond length contributes in load bearing, and there exists an effective bond length, which the interfacial shear stresses are transferred to the substrate through this zone (Yu et al. 2012; Fernando 2010; Hosseini and Mostofinejad 2014). Experimental results, presented in Figure 6, reveal that the effective bond length of the utilized bonded joint was about 40 mm. The distribution of interfacial shear stresses, obtained from the analytical model, shows that in the middle 440 mm of the bond length (220 mm from the centerline on each side) there is almost no interfacial shear stress. Consequently, the model can be also used to have an approximation regarding the effective bond length of adhesively bonded CFRP reinforcements.

CONCLUSIONS

Based on the analytical modeling and experimental tests done in the current study, the following concluding remarks can be drawn:

- A very good correlation was observed between the results of the developed analytical model and experiments performed on CFRP-strengthened steel plates under uniaxial tension. The model can be used to accurately estimate stresses in CFRP and steel substrate both in case of non-prestressed and prestressed CFRP laminates bonded or mechanically anchored to the steel substrate in the elastic regime. Interfacial shear stresses, and subsequently, the effective bond length of CFRP-to-steel can be estimated using the developed analytical model.
- Experimental results of the current study showed that even though adhesively bonded CFRPs can transfer prestressing loads to the steel substrate, the available capacity of the prestressed bonded laminates would be very low for carrying external loads, and the CFRP plate would be debonded from the steel substrate in low load levels.
- A mechanical anchorage system is developed to transfer high prestressing forces to the steel substrate via friction. Experimental tests on steel plates strengthened with unbonded CFRP laminates using the aforementioned system revealed the high capacity of the system, since no slip/failure was occurred in those specimens. Furthermore, despite in bonded joints, no special surface preparation neither curing is required.
when mechanical clamps are used. Consequently, strengthening steel members using prestressed unbonded CFRPs can be a very efficient technique, especially in cases that a reduction in existing stresses is needed such as in fatigue strengthening of steel bridges.

- Both results of the analytical modeling and experimental tests revealed that neglecting the eccentricity in single-side CFRP-reinforced steel members, might lead to an unsafe prediction of stress level in steel, especially when the steel member is relatively thick.

ABSTRACT

This study addresses behavior of bond between fiber reinforced polymer (FRP) and steel plate. A total of 48 FRP-steel double-lap bond specimens, subjected to elevated temperature ranging from room temperature to 120 °C, were tested to investigate the performance of the bond between FRP and steel. The experimental results showed that the failure mode of test specimens was altered from steel-adhesive debonding to FRP-adhesive debonding. The load carrying capacity decreased significantly at temperatures approaching or exceeding the glass transition temperature ($T_g$) of adhesive. Based on the experimental results, a model is proposed to analyze the FRP-steel interface at elevated temperature.

KEYWORDS

Bond, FRP, steel plate, elevated temperature, ultimate load.

INTRODUCTION

Fiber-reinforced polymer (FRP) has been widespread implemented in upgrading structures due to its preferable mechanical properties, including high strength, light weight, good fatigue resistance and flexibility in shape. In the repair of steel structures with FRP method, the FRP is bonded to the steel surface using epoxy adhesives. Both the flexural and the shear strength of steel structure can be significantly increased, and adequate overall ductility can be obtained. As the load is transferred to the FRP material by epoxy adhesives, the durability of its bond with steel is critically important for the safety of the repaired structure.

Although a few researches have been conducted to better understand the bonding performance of FRP-steel interface at ambient temperature (Fawzia et al. 2006, 2010), very few studies have been performed to evaluate the bond behavior between FRP and steel plate subjected to temperature, which is particularly important for building applications where hot climate or fire is of high concern. Most epoxy polymers are vulnerable to high temperatures and their mechanical properties will decrease rapidly when the temperature exceeds $T_g$, at which they transform from glassy state to rubbery state. The behavior could lead to the reduction in mechanical properties of both adhesive and FRP composite, weaken the stress transfer, resulting in failure in adhesively-bonded joints. This study investigates the characteristics of FRP-steel bond under temperature.

EXPERIMENTAL PROGRAM

Test Specimens

A total of 48 double-lap shear bond specimens, divided into 16 groups of three identical samples, were tested. The experimental parameters selected were FRP type (CFRP and GFRP) and the temperature ($T$ = 27, 40, 50, 60, 70, 80, 100, 120 °C) respectively. The detail of specimens is shown in Figure 1. Two FRP sheets were bonded
symmetrically to the 3mm-thickness steel plate surface over a length of 150 mm. A two-part epoxy adhesive with the \( T_g \) being 50 °C was applied for all test specimens. The mechanical properties of adherends and adhesive are listed in Table 1.

**Test Setup and Instrumentation**

For control specimens, nine strain gauges were attached on the top of the FRP sheet spacing at 20 mm. For specimens at elevated temperatures, strain gauging with adhesively bonded strain gauges is difficult due to the susceptibility of the adhesive to heat. The displacements calculated from strain readings basically agree well with the LVDT readings reported by Yu et al. (2012). Therefore, two L-shaped cooper plates, which had a low coefficient of thermal expansion \( (1.65 \times 10^{-5}/°C) \) were attached symmetrically for measuring displacement at the loaded end. Specimens were preheated for 20 minutes in a device and kept inside throughout the testing process. The tests were conducted using a universal testing machine with a capacity of 100 kN. The schematic view of test setup is shown in Figure 2.

![Figure 2 Sketch of test setup](image)

**EXPERIMENTAL RESULTS AND DISCUSSION**

**Failure mode**

A shift on the failure mode from steel-adhesive debonding to FRP-adhesive debonding was observed. Both CFRP series and GFRP series showed similar failure modes, and thus only one set of images was provided in Figure 3. In the range of 27-50 °C, specimens displayed a steel-adhesive debonding failure. The debonding initiated from the loaded end and then heading to the free end along the steel surface. The results suggest that, at temperatures below the \( T_g \), the adhesive used is brittle, glassy and has microcracking propensity, flaws and imperfections. This in turn will weaken the interfacial adhesive layer, lead to the debonding failure between steel and adhesive (Al-Shawaf et al. 2009). In the range of 60-120 °C, the debonding failure occurred along the interface between FRP and adhesive, with a few of adhesive left on the steel plate. In addition, with the increase of temperature, more residual epoxy was attached on the surface of steel plate. This failure shift could be attributed to the degradation of bond-strength in adhesion at elevated temperature.

![Figure 3 Failure modes of specimens](image)

**Analytical Modeling**

For specimens at ambient temperature, based on the bilinear model proposed by Dai et al. (2005), a model adaptive to predict the relationship of shear stress and interfacial slip is developed.
As shown in Figure 4, the equation of equilibrium for the FRP sheet can be written as:

\[
\frac{d\sigma_f(x)}{dx} - \frac{\tau(x)}{t_f} = 0
\]  

(1)

The relationship of the FRP strain and interfacial slip should be known to obtain the \( \tau-s \) curve. According to the current literature review (Yuan et al. 2004; Xia and Teng 2005; Dai et al. 2006; Yu et al. 2012; Dai et al. 2014), the bond-slip curves for FRP-to-steel bonded joint are similar to those for FRP-to-concrete bonded joint, both have a bi-linear shape. And their development of shear stress are the same. Moreover, the strain-slip curves at the loaded end derived from the load-slip relationship for FRP-to-steel bonded joints are similar to those for FRP-to-concrete bonded joints. Therefore, a unique expression linked to an exponential term is proposed according to reference (Dai et al. 2006, 2014):

\[
\varepsilon(x) = f(s(x)) = \alpha (1 - e^{-\beta s})
\]  

(2)

where \( \alpha \) and \( \beta \) are regression parameters.

Combining Eqs 1 and 2, and neglecting the strain of steel plate, the bond stress versus interfacial slip can be expressed as:

\[
\tau = t_f \frac{d\sigma_f(x)}{dx} = E_f t_f \frac{d\varepsilon(x)}{dx} = E_f t_f \frac{df(s(x))}{ds(x)} \frac{ds(x)}{dx} = \alpha^2 \beta E_f t_f e^{-\beta s} (1 - e^{-\beta s})
\]  

(3)

where \( E_f \) and \( t_f \) are the tensile modulus and the thickness of FRP sheet respectively.

Therefore, the maximum load, \( P_{\text{max}} \), transmitted to the FRP sheet can be expressed as:

\[
P_{\text{max}} = \varepsilon_{\text{max}} b_f t_f E_f = \lim_{s \to \infty} \alpha (1 - e^{-\beta s}) b_f t_f E_f = \alpha b_f t_f E_f
\]  

(4)

For specimen at elevated temperature, the effect of elevated temperature is to degrade the mechanical properties of epoxy-impregnated FRP composite, especially when the temperature exceeds the glass transmission temperature (\( T_g \)). According to the degradation model by Mouritz and Gibson (2006), the relationship of FRP tensile modulus and temperature can be written as:

\[
E_f(T) = \frac{E_U + E_R}{2} - \frac{E_U - E_R}{2} \tanh[k(T - T_g)]
\]  

(5)

in which, \( E_U \) and \( E_R \) are the unrelaxed (low temperature) and relaxed modulus (high temperature) respectively; \( k \) is a constant; \( T_g \) is the temperature when a 50% reduction in property value is observed.

And the ultimate load at the loaded end with enough bonded length can be written as:

\[
P_{\text{max}} = E_f(T) t_f b_f \left[ \alpha - (\alpha_f - \alpha_s)\Delta T \right]
\]  

(6)

where \( \alpha_f \) and \( \alpha_s \) are the linear coefficients of thermal expansion for FRP and steel respectively, \( \Delta T \) is the service temperature variation (thermal loading).
Figure 5 reports the comparison of experimental results and predictions using the proposed model. It should be noted that a few ultimate loads were not recorded due to the premature failure of specimens at high temperature. As can be seen, good agreement between predicted and experimental values are observed in all specimens regardless of FRP type. In the range of 27-50 °C, the average strengths of specimens showed a progressive decrease as the temperature increased, and the average ratios of predictions to experimental data are 1.019 and 1.012, with the coefficients of variation (COV) being 0.022 and 0.069 respectively. When the temperature exceeds 50 °C, a significant reduction of ultimate load was observed, and a few specimens exhibit lower bond strength than the prediction. The reason for this phenomenon was that probably the internal stress created within the interface due to the volatilization of decomposition as a result of adhesive volume decrease, together with the thermal stress caused by differences of the coefficients of linear thermal expansion of the adhesive and the adherends, would increase the porosity and flaws within the adhesive which, in turn, have a detrimental effect on adhesive-joint capacity.

CONCLUSIONS

The failure mode of specimen was affected by the experimental temperature. It was likely to change from steel-adhesive debonding to FRP-adhesive debonding. The load carrying capacity of specimens degraded with the increase of temperature. This degradation was pronounced at temperatures above $T_{c}$. Based on the results, a model is proposed for analyzing the bond behavior between FRP and steel at elevated temperature.

TEST ON FLEXURAL PERFORMANCE OF RC BEAMS STRENGTHENED WITH PRESTRESSED HB-CFRP SYSTEM

Feng Zhang, Lei Gao and Wanzhi Zhang
Geotechnical and Structural Engineering Research Center of Shandong University, Jinan 250061

ABSTRACT

By comparing and analyzing the flexural performance of reinforced concrete (RC) beams strengthened with HB-CFRP system and prestressed HB-CFRP system, the influence of prestress on the flexural performance of the RC beams was investigated and the flexural capacity, CFRP strain, mid-span deflection and the utilization of the CFRP material strength were investigated. The test results showed that this strengthening technique which RC beams are strengthened with using prestressed HB-CFRP system can restrain effectively the formation and development of cracks, improve the stiffness of the beam. Compared with non prestressed method of HB-CFRP system, the cracking load of the beam is increased by 71% and the flexural capacity is increased by 67%. The strengthening technique can also restrain the concrete stripping, avoid the debonding failure of CFRP and improve the utilization of the CFRP material strength.

INTRODUCTION

Fiber Reinforced Polymer (FRP) is widely used to the reinforcement of Reinforced Concrete (RC) structures and other structures (Ying-ming LI et al. 2009; Wang Sheng-yi 2005). Especially, external bonding of FRP plates (EB-FRP) has became as a simple, popular and flexible method for the reinforcement of RC beams (Lawrence Cbank et al. 2007; Li Song-hui et al. 2005; Nanni A 1997). However, the strengthening method of EB-FRP system has obvious defect that is the premature debonding of the composite laminates (Teng et al. 2005; Yang Yong-xin et al. 2004). So the utilization of FRP material strength is only 15% ~ 35% (Yan Jun-hui 2009). Besides, the failure mode of the EB-FRP system tends to be brittle failure (Guo Zhang-gen et al. 2007). As a result, City University of Hong Kong develops a kind of strengthening technique of RC beams with hybrid bonded FRP. The combination of EB-FRP and mechanical anchorage improves the bonding performance between FRP and concrete. The experimental study in the paper (Wu Yu-fei et al. 2008) shows that the interfacial bond strength of HB-FRP system is 7.5 times higher than that of EB-FRP system.

However, the HB-FRP system without using prestress still has obvious shortcomings. It is observed that the FRP does not work until the reinforced structure is loaded again. The efficiency of the strengthening method using HB-FRP system is too low. This method is not able to adjust the internal force of structure; it also has little effect on modifying the mechanical performance of reinforced structure (Ti An-guo 2006). Compared with the non prestressed HB-FRP system, the prestressed HB-FRP system can improve the utilization of the CFRP material strength, save the 30% ~ 50% FRP material usage and avoid the deboning of the FRP plates (Wang Xing-guo et al. 2005; Lin Yu-dong et al. 2013). Further more, the prestressed HB-FRP system can restrain the formation and development of cracks. Therefore, more and more people are interested in studying the prestressed HB-FRP system, so the corresponding experimental and theoretical study of RC beams are carried out. Abroad, Deuring (Deuring M 1993) carried out the experimental study on flexural behaviour of large proportion of the T Beams strengthened with non prestressed or prestressed FRP plates. Garden, Quantrill R J, Dong-Suk Yang, Abhijit Mukherjee et al. (Garden H N et al. 1998; Quantrill R J et al. 1998; Dong-Suk Yang et al. 2009; Abhijit Mukherjee et al. 2009; Hajishahemi A et al. 2011) carried out the experimental study on flexural behavior of the corresponding model and the prototype beams. In China, Tian An-guo, Wang Xing-guo, Lin Yu-dong et al. (Tian An-guo 2006; Wang Xing-guo et al. 2005; Lin Yu-dong et al. 2013) also carried out the experimental and theoretical study of RC beams strengthened with the prestressed FRP and obtained some research results.
In addition, He Xue-jun, Zhou Chao-yang et al. (He Xue-jun et al. 2008) carried out experimental study on the flexural behavior of RC beams strengthened with near-surface mounted CFRP laminates. The near-surface mounted CFRP laminates can prevent the FRP from peeling off more effectively and has more flexural capacity than the externally bonded CFRP-strengthening beams. Based on the concept of failure mechanics and considering interfacial shear stress transfer, effective stress transfer length and no interfacial debonding failure, Niu He-Dong et al. (Niu He-dong et al. 2002) carried out the theoretical derivation of the maximum possible prestress on bonding reinforcement technique of prestressed FRP laminates.

The focus of this paper is to study the flexural performance of RC beams strengthened with prestressed CFRP plates and mechanical anchorage. Two beams including HB-CFRP system reinforced beam and prestressed HB-CFRP (PHB-CFRP) system reinforced beam were subjected to flexural test. Compared with HB-CFRP reinforced beam, the flexural capacity, failure mode and load-deflection behavior of PHB-CFRP reinforced beam were taken as the main research parameters.

EXPERIMENTAL PROGRAM FOR RC BEAMS STRENGTHENED WITH PHB-CFRP SYSTEM

Beam specimen Design

In order to explore the flexural behavior of RC beams strengthened with PHB-CFRP system, two beams are subjected to flexural test. Flexural test was conducted on a control beam strengthened with HB-CFRP system, on a beam strengthened with PHB-CFRP system. The main experimental parameter is whether or not the prestress is applied. RC beams were cast with dimensions of 3300mm (l)×240 mm (b)×350 mm (h). Specifications of steel include longitudinal reinforcement (4φ20) and stirrup (φ8@150). The characteristics of all the beams, as well as their steel reinforcement details, are shown in Figure 1 and Table 1. Concrete compressive strength is 30MPa. The width and thickness of CFRP plate is 50mm and 3mm respectively. The ultimate strength of CFRP plate is 2.8GPa. The construction method of prestressing CFRP beam uses similar post-tensioning method. In the test, the special anchorage and clamp (Figure 2) were applied to anchoring the end of CFRP plate. In addition, the steel plate and chemical bolts were used to anchor the CFRP at the bottom of the beams. The size of the steel plate is 120mm×60mm. The chemical bolt is a kind of expansion bolt. The diameter of the chemical bolt is 10mm, the length is 57mm, and the anchorage depth is 50mm (Figure 3).

HB-CFRP beam specimen detail

HB-CFRP test beam uses wet bonding method for the FRP plate and the steel plates - expansion bolts for reinforcement. First of all, the surface of the beam was cleaned which the loose concrete was removed by using the grinding machine, so the solid concrete aggregate was exposed. The area of concrete which is used to bond CFRP plate should be chiseled. Then the epoxy adhesives was put on that the place of the beam. Second the dipping adhesive was applied to bond the surface of the concrete and the corresponding surface of the CFRP plate. The dipping adhesive was uniformly distributed. Then put the CFRP plate on the surface of the concrete and used the special rubber roller to uniformly roll the composite material, squeezed the bubble, so that the surface between concrete and CFRP could be completely bonded. Finally the positions of the reserved holes of the steel fasteners were needed to setting out. Meantime we used drilling rig to drill holes and used a high pressure air gun to clean up. Then the expansion bolts were put into the reserved holes, the mechanical anchoring steel plates were installed, and the nuts should be tightened by use of the torque wrench (Figure 4). The contact surfaces between the mechanical anchoring steel plates and the CFRP plates were needed to apply epoxy adhesives to reinforce. After the reinforced system was completed, the RC beam could be tested. The beam specimen strengthened with HB-CFRP plates is shown in Figure 5.

PHB-CFRP beam specimen detail

The manufacturing process of the PHB-CFRP beam includes the manufacturing process of HB-CFRP beam as well as the application of prestress. Before pouring concrete, the bolts of the pedestal should be embedded. Firstly, the CFRP plate was bonded on the surface of the concrete liking traditional EB-FRP system. Then the fixed end anchor and the tensioning end anchor were located in the beam and the counterforce screws were gone through the tensioning end anchor, stretching tighten the lock nuts. Secondly the jack was applied to give the force, and the pressure sensor was used to measure the reaction force. When the loading force reached the required value, the anchor nuts were tightened. Finally, the CFRP plate was strengthened through the anchorage system consisting of the steel plate and the chemical bolts. After the structural adhesive was fully solidified, the loading device could be removed to carry out the flexural test. The loading device of prestress is shown in Figure 6 and the anchorage system of the CFRP plate is shown in Figure 7.

Experimental Design

The test beams are simply supported at both ends. The tests are based on mid-span static loading and are carried out on the 100t counterforce frame. The loading system is shown in Figure 8.
Experimental parameters include the load size, deflection, strain of CFRP. The size of the load was controlled by the pressure sensor during the test. Arrangement of the strain measuring points and the deflection measuring points of the two beams was same. The strain measuring points were arranged in the longitudinal 2m range of the FRP plates and at the bottom of the concrete beams. The deflection measuring points were arranged in the bottom of support, 1/4 span and 1/2 span. During the loading process, high precision electronic dial gauges were used to measure the deformation of the beams. The strain and deflection measuring points are shown in Figure 9.

EXPERIMENTAL PHENOMENON

The concrete in the place of loading point is crushed. In the tests, it didn’t occur CFRP tensile failure. During the process of loading, the interface between CFRP and concrete came out "crackling" sounds. It was observed that the bonding interface began to occur debonding. When the load could no longer continue to increase, the debonding failure length and distribution of the CFRP plate of the PHB-CFRP beam was found to be smaller than that of the HB-CFRP beam. In addition, the cracking load size of the PHB-CFRP beam was much greater than that of the HB-CFRP beam. Due to the existence of prestress, the formation and development of the cracks of the RC beam are effectively restrained and crack spacing and crack length distribution become smaller. The cracks of the HB-CFRP beam and the PHB-CFRP beam are extended to the top of the beams. The longitudinal cracks distribution of the HB-CFRP beam are uniform and the mostly cracks are vertical. Compared with this phenomenon, the PHB-CFRP beam has a large number of oblique cracks. In the end, there are two of the "eight" - shaped oblique cracks (Figure 10) which are from the bottom of the beam to the loading point, so that the load size can not continue to rise.
RESULTS AND DISCUSSION
Fracture characteristics and Load-carrying capacities

In the experiment, the formation and development of the cracks were continuously observed. When the HB-CFRP beam was loaded to the 35.2kN, the first vertical crack occurred in the mid-span section, and the corresponding cracking load of the PHB-CFRP beam was raised to 60.1kN. Compared with the former, the cracking load was increased by about 71%. Test results show that the PHB-CFRP reinforcement can effectively restrain the appearance of cracks and increase the stiffness of the RC beam. When the load size is loaded to 70kN, the distribution of cracks (Figure 11) of the two beams are observed and recorded. It is found that the extended height and longitudinal range of the cracks of the PHB-CFRP beam are smaller. As a result, it shows that the beam strengthened with PHB-CFRP system can effectively restrain the expansion and extension of cracks. When loading to the failure of the beams (Figure 12), the flexural capacity of HB-CFRP beam is about 120kN and that of PHB-CFRP beam is about 200kN. Obviously, the flexural capacity of the PHB-CFRP beam is increased by about 67%.

FRP strain distribution

In the experiment, the strain distribution of CFRP at the bottom of the testing beams is shown in Figure 13 and Figure 14. It can be seen that the CFRP strain distribution is approximately symmetrical, which the maximum value is in mid-span section, and minimum value is at the end of beam. When the load size is small, the FRP strain increases uniformly with the increase of the load size. When the load is up to 130kN, the strain in the 1.4 m length range from the left end to the right section of HB-CFRP beam bottom decreases suddenly. This is because the left end of CFRP plate occurs debonding. The 0.4m length range of the right section of the CFRP plate does not occur debonding, so that the strain changes a little compared with the former stage. The ultimate strain value of CFRP plate is 17500με. The maximum strain value of HB-CFRP beam is 2580με, the material strength utilization is 14.7%. The PHB-CFRP beam’s initial strain value is 2080με. While the PHB-CFRP beam is loaded to failure, the maximum strain value of CFRP plate is 5406με, so the material strength utilization is 30.9%. The experiment shows that the utilization of CFRP material strength can be improved obviously by using prestress.

Load-deflection curves

The load-deflection curves in mid-span section of the test beams are shown in Figure 15, and that of the left and right 1/4 section are shown in Figure 16. The load-deflection curves are the shape of two sections, the maximum deflection value is in mid-span, and the two sides of the deflection distribution of the beam is approximately symmetrical. When the load size is increased to A point, the load increment size begins to decrease and the deflection size increase rapidly. In the initial stage, the load-deflection curves of HB-CFRP beam increase uniformly. When the load size is increased to 110kN, the bottom of CFRP plate occurs debonding, the interfacial
bonding stress between FRP and concrete disappears, and the cracks expand rapidly. The deflection size in the mid-span rapidly increase, accompanied with the increase of the load size. In particular, the variation of the deflection is small as well as the load size continuously increases in the initial stage of loading. And the whole loading process, the deflection size of the PHB-CFRP beam at each corresponding stage of loading is less than that of the HB-CFRP beam. The stiffness of PHB-CFRP beam is significantly improved than that of HB-CFRP beam.

When the size of the load is 64kN, the HB-CFRP beam comes out a slight "bang" sound. As the load value is up to 110kN, there is a loud "bang" sound. It is observed that the CFRP plate occurs debonding, not long off, only the left section. While the PHB-CFRP beam has a slight "bang" sound under loading to 140kN. During the process of loading to 200kN, the beam continuously comes out the sound. Finally, when the load value is up to 200kN, there is a loud "bang" sound. It is observed that the CFRP plate occurs debonding (Figure 17) in the symmetrical area near the mid-span. The length and distribution of the debonding of the PHB-CFRP beam are found to be smaller than that of the HB-CFRP beam.

Comparison of the debonding of the anchor section and the non-anchor section of the beams under the condition of high load, it is found that the experimental results are different. The anchor section of the beam does not occur debonding owing to the vertical pressure of the anchorage system, while the non-anchor section obviously occurs debonding. The experimental phenomenon is shown in Figure 18.

In addition, there are two obvious oblique cracks between the load point and the support, and the concrete is crushed under the loading point. The final failure mode belongs to the shear compression failure of the inclined section, which not only is the flexural failure of the normal section, but also is the debonding failure of the interface between concrete and the CFRP plate. Obviously, the strengthening method of PHB-CFRP system can be used to restrain the occurrence of debonding failure, but the shear capacity of the inclined section is insufficient. Otherwise, RC beam strengthened with PHB-CFRP system should have greater flexural load-bearing capacity.
CONCLUSIONS

(1) Comparison and analysis of the flexural performance of the two testing beams, it is concluded that the strengthening method of PHB-CFRP system can obviously improve the flexural capacity of RC beam.
(2) The strengthening method of PHB-CFRP system can restrain the occurrence of cracks, reduce the longitudinal cracking range, and improve the stiffness of RC beam.
(3) The anchorage system improves the cohesive strength of the concrete interface. This strengthening method can effectively restrain the occurrence of interfacial debonding and improve the utilization of CFRP material strength.
(4) For the purpose to improve the flexural performance of RC beam, the shear capacity should be also taken into consideration. So that it can guaranteed that the flexural failure of RC beam is prior to the shear failure.

ABSTRACT

One of the goals of sustainable development applied to bridge infrastructure is to provide bridge owners with strengthening solutions that may lead to an increase of existing structures service life. In the case of steel bridges, the assessment of the remaining service life is most often linked to the determination of the structural deterioration caused by corrosion and fatigue. Damage caused by fatigue is very difficult to assess before crack initiation, and is more bound to occur in old structures, for which the phenomenon was not taken into account in design before 1970. In addition, old steel materials present a more brittle behavior. The FASSTbridge project, financed through European Infravation call, is aimed at developing a pre-cracking fatigue assessment and strengthening methodology for steel bridges, based on the technology of adhesively bonded composite. The methodology will include an assessment method of remaining fatigue life of existing structures, the design and on-site application of a strengthening system, and the environmental and economical appraisal of the solution. A new strengthening technique based on CFRP plates will be developed. This technique will include the formulation and production of a specific adhesive, specifications for using commercial CFRP plates, and the definition of instrumentation plans to monitor the performance of the strengthening system. Finally an on-site application in an actual steel bridge will be carried out, to verify the quality of the proposed solution.

KEYWORDS

CFRP, Adhesively bonded reinforcement, Steel structures, Fatigue.

INTRODUCTION

Steel bridges serve as vital components in the transportation infrastructure. Bridges are a frequent cause of the major negative impact in densely populated areas with regard to both users’ convenience (such as service disturbances, disruptions, accessibility problems, delays, traffic jams) and welfare (such as obstacles to safety and security, nuisance from noise, vibration dust, and air pollution). Moreover, problems derived from their improper functionality are also cause of important impacts in the economic activities of the affected area (transportation, job accessibility, development strategies). In Europe 15% of the 300 000 bridges are made of steel or they have concrete-steel composite structures (Ye et al. 2014). Of this number, it is considered that approximately 68% need structural interventions. In the USA, 34% of the 599 000 bridges are made of steel. Of this number, approximately 9% are classified as structurally deficient, 15% are functionally obsolete and 9.5% are both structurally deficient and functionally obsolete (Lee 2012). Many of these bridges were constructed using old standards and for a design service life of 50 years, which is coming to its end or has already been exceeded.

Fatigue is the second main cause of damage after corrosion for steel bridges, limiting their load-carrying capacity and residual life, and is one of the main causes involved in fatal mechanical failure of this kind of asset. The increase of traffic flows and loads in the last decades has a direct influence on this issue, especially on structures designed and erected many years ago for which fatigue was not taken into account during design (Palmer 2014). Fatigue is a progressive and local weakening process in which structural damage is accumulated due to the continuous and repetitive application of external loads (vehicles and trucks in the case of steel bridges). The process of fatigue consists of three steps: crack initiation, crack propagation and failure. This phenomenon is extraordinarily dangerous and difficult to identify with a conventional structural stress analysis, which might lead
to a misleading result of safety. In addition, there is no mean to measure fatigue damage on site before crack initiation. Damage can only be assessed using either fatigue design loading from the standards, or long-term on-site strain measurement (Kühn et al. 2008). The corresponding methods, that allow the determination of the remaining service life, can be based on the characteristics of the studied asset (deterministic methods) or in existing statistics (probabilistic). The latter require a considerable amount of data, which is still scarce. Therefore, deterministic methods are commonly used.

Currently, the mainstream strategy concerning fatigue has been a reactive strategy. Maintenance or repair indeed has mainly occurred after the appearance of cracks in the structure. With a bridge stock that is inevitably ageing, it is necessary to widely adopt a preventive strategy to enable road administrations to enlarge the service life of steel and composite steel bridges in a cost-effective and sustainable manner to avoid the high economic and environmental costs of following the current strategy in the years to come. The prevention of fatigue is thus a high priority. To provide such a strategy, it is essential to seek an easy-to-apply solution which includes an engineering analysis methodology for assessing the fatigue damage status and the application of fast, cost-effective and sustainable retrofitting strengthening techniques that enable the wide adoption of the preventive approach, avoiding difficult, resource-consuming and costly retrofitting and repair interventions and demolitions of the steel and composite steel bridges stock.

Once fatigue damage has been identified, normally by visual inspection for crack detection, various methods are frequently used to strengthen steel bridges. The most popular among engineers is the attachment of steel plates to the tension flange of the girders (FHWA 2013) (Figure 1). However, this method has several disadvantages: plates are usually bulky, heavy, difficult to fix and prone to corrosion and fatigue. In general, conventional strengthening techniques are labor-intensive and disruptive to traffic flows, thus limiting their application in the wide network of European and American steel bridges. Carbon Fibre Reinforced Polymers (CFRP) composites, although more expensive than steel plates in terms of price per unit/m², have several and relevant advantages that make them suitable and cost effective for steel bridges retrofitting: their application is less time consuming than traditional solutions (i.e. from one month to a few days, therefore less traffic disruptive), have a high strength-to-weight ratio, excellent fatigue properties, low space disruption, high durability and versatility, and are easy to transport, handle and apply (without heavy equipment) (Tavakkolizadeh et al. 2003; Bocciarelli 2009; Deng 2011) (Figure 1). Despite their wide application on indoor concrete structures, where CFRP is progressively replacing the traditional techniques, CFRP has not been broadly used for steel structures yet, especially in bridges. The main technical barrier for the adoption of CFPR is the durability of existing commercial adhesives in outdoor environments, which is still limited for this kind of interventions, where high functional periods with minimum maintenance are expected. When exposed to outdoor environments and fatigue conditions, in order to ensure cost-effective and durable strengthening interventions, high quality adhesives are necessary (Zhao 2014).

These different statements motivated the proposal to the ERA-Net European Research call Infravation of the project called FASSTbridge (FASSt and effective solution for STEel bridges life-time extension). The project is coordinated by the Spanish research centre Tecnalia, and implies the contribution of two expertise and research organisms (IFSTTAR from France, and MPA Stuttgart from Germany), one Italian company specialized in polymer formulation and production Collanti, two engineering offices (LAP-Consult from Germany and Altavista from United States), the Spanish international building company Dragados SA and a public owner: the Community of
Madrid. The project started on November 2015 and has duration of 24 months. This paper will describe the objectives and implementation plan of the project.

OBJECTIVES OF FASSTBRIDGE PROJECT

FASSTbridge aims at drastically reduce the economic and environmental costs of ownership of the steel bridges stock in Europe and the USA by providing a reliable preventive, cost-effective and sustainable solution for steel bridges life-time extension. The preventive nature of the solution is the key to cost-effectiveness and sustainability, since it will allow the timely design and implementation of innovative, competitive CFRP-based strengthening actions that will reduce the overall costs and environmental impact of life-time extension.

This solution will stand on two pillars. The first will be dedicated to the proposal of a FASSTbridge methodology to prevent the evolution of irreversible fatigue derived problems at a pre-cracking scenario. The second will concern the development of a FASSTbridge strengthening system to preventively extend life-time of steel bridges.

**FASSTbridge methodology**

The methodology will address the development and validation of a preventive and easy-to-apply procedure to assess the remaining life of steel bridges. Such a procedure should be in agreement with existing methods presented in (AASHTO 2012; Kühn et al. 2008), and should propose a clear strategy between the classical nominal stress method and the local stress approach. It should also be supported by indicators from non-destructive or monitoring methods.

If insufficient remaining service life is determined, a proposal will then be made regarding the design and the application of adhesively bonded composite reinforcement for fatigue strengthening operations. This will be based on existing guidelines and previous investigations (CNR 2007; DNV 2012; Schnerch et al. 2007; Cadei et al. 2004).

The methodology will also include a strategy regarding the maintenance of the strengthening, and the monitoring to verify the efficiency of the structural reinforcement and to contribute to databases for the assessment of steel bridges in fatigue.

**FASSTbridge strengthening system**

The proposed strengthening system will rely on the development of a specific adhesive for the considered application. The adhesive should be durable and allow a correct force transfer between CFRP plate and steel adherend. It should also have good rheological performance before curing to allow an easy on site application. The obtained mechanical properties of the cured adhesive should be durable and in agreement with existing standards. Associated to this adhesive, a commercial CFRP plate will be chosen according to the requested technical and economical properties needed for the project.

The compatibility of both parts (adhesive and CFRP plate) will be verified through different tests on the assembly and under different environmental conditions relevant with the design codes recommendations (AASHTO 1989; EN1990 2002; EN 1991 2003). The experiments will also check the compatibility of different monitoring devices with the assembly. The led experimental investigations will be followed by the definition of a pre-certification plan for the studied system.

**FASSTbridge solution**

In addition to the assessment tools and strengthening system, the FASSTbridge solution will be completed with a method to evaluate the effectiveness and efficiency of the interventions based on cost-benefit analysis and life cycle analysis.

An on-site application will be carried out at the end of the project to demonstrate the applicability of the complete solution. This will be done on a composite steel/concrete bridge from the community of Madrid. It will include the application of complete methodology (determination of the remaining life-time, design of the reinforcement, cost-benefit and life-cycle analyses, application of the reinforcement and monitoring on site) (Figure 2).
IMPLEMENTATION

To ensure the achievement of the stated objectives a work plan, including 6 work packages, has been defined for the project (Figure 3). The first package is dedicated to the overall management and coordination of the project. The last package aims at ensuring good dissemination of the results. The other four packages are the technical ones and will be thus more deeply described in the following paragraphs.

**WP2: Life-time expectancy for existing steel bridges**

The work package 2 will be dedicated to design the FASSTbridge methodology regarding the assessment of the remaining fatigue life of the structures, the design of the reinforcement and its maintenance. A review of existing methods regarding fatigue will be carried out for both US and European cases (Figure 4). This should lead to a proposal of an assessment method placed between the classical nominal stress method and the local stress approach (Kim et al. 2015). If the assessment proves one or more detail to be prone to fatigue damage, inspection should be carried out to check the existence of cracks.

In the case of existing cracks, calculation methods based on fracture mechanics will be recommended. Adhesively bonded CFRP may be used to slow crack propagation in such a case (Bassetti et al. 2000; Liu et al. 2009; Lepretre...
et al. 2016), which will not be included in the project since the aim of FASSTbridge is to define a preventive solution.

In the case where no cracking occurred, the second part of WP2 will be dedicated to the definition of the design of strengthening, using adhesively bonded CFRP plates and based on existing recommendations (CNR 2007; DNV 2012; Schnurch et al. 2007; Cadei et al. 2004). This will also include a specific review on the topic of monitoring and the definition of a specific strategy for the studied case.

Figure 4 Fatigue classes according to AASHTO on the left and Eurocode on the right

**WP3: Development and selection of the strengthening components**

Work package 3 aims at defining the FASSTbridge reinforcement system, i.e. developing the adhesive, choosing the CFRP plate and assessing their compatibility. The adhesive will be developed by Collanti according to the specifications of the adhesive defined at the beginning of the project and dedicated to obtain durable and reliable performance. The rheological behavior of the adhesive will be assessed as in (Benzarti et al. 2011; Houhou et al. 2014) to check that the developed adhesive meets the requirements in terms of ease of application, mechanical properties, thermal properties (glass transition temperature) and durability.

The technical and economical properties of the requested CFRP plate will then be determined and a commercial product chosen. Its compatibility with the developed adhesive will be assessed using first prototype testing on the assembly.

Figure 5 Experimental results (glass transition temperature and mechanical tensile behavior) regarding the influence of hydrothermal ageing on two commercial epoxy resins (Benzarti et al. 2011)

**WP4: Strengthening system process qualification**

This work package is entitled to validate the adopted strengthening system through an extensive experimental campaign, designed according to the requirements of the system from the literature (Zhao et al. 2007; Linghoff et al. 2009; Dawood et al. 2010; Deng 2011; Kim et al. 2011; Ghafoori et al. 2015; Hesmati et al. 2015). The influence of the execution process and the temperature will be investigated by static tests as the one defined in (Chataigner et al. 2011). Additionally, specific campaigns dedicated to the study of the durability of the
reinforcement process, will also be carried out similarly to campaigns done in (Chataigner et al. 2012) (Figure 6). The experimental campaign will also be designed to assess the possibility to integrate sensing capabilities to the reinforcement in agreement with the defined methodology.

Work package 4 will also lead to the definition of the cost-benefit and the life-cycle analyses. It will describe the proposed adopted methodology for both cases and the requested information, so that both may be carried out.

![Figure 6 Failure modes in shear of a CFRP to steel bonded assembly before and after hydrothermal ageing](Chataigner et al. 2012)

WP5: Real case demonstration of the solution

The last technical package aims to demonstrate the applicability of the whole proposed solution on a real bridge. For this purpose, the community of Madrid has proposed to analyze one of the bridges within their area of responsibility (Figure 7). The chosen bridge is a composite bridge erected in the 1960s. It has suffered a considerable increase of traffic flow that was not considered during design, but does not present damages.

![Figure 7 Photos of the bridge in Madrid for the on-site application](Chataigner et al. 2012)

The FASSTbridge methodology will be applied on this bridge to assess its remaining fatigue life. A design of an adhesively bonded CFRP reinforcement will then be done for the most critical details. This will allow to carry out both cost-benefit and life cycle analyses of the solution in that particular case and to apply the designed reinforcement system and the chosen monitoring strategy on site.

CONCLUSIONS

The FASSTbridge project aims at developing a fast and effective solution for steel bridges fatigue life-time extension (fasstbridge.eu). The project intends to propose:

- a methodology of structural assessment of remaining service life regarding fatigue, and design of a reinforcement based on adhesively bonded CFRP with additional monitoring,
- in addition to a reinforcement process that will be developed. This one should combine a specifically designed adhesive with a chosen commercial CFRP product.

The overall proposed solution will be completed with cost-benefit and life-cycle assessment tools so that the advantage of the proposed procedure may be evaluated. The project includes a specific work package dedicated to
the application of the whole solution on site on a composite steel-concrete bridge in Madrid. To achieve the comprehensive and extensive work proposed in this project, the consortium of the project is composed by public and private research and expertise organisms, consulting engineering firms, a construction company, a public structure owner, an adhesive production company.

ABSTRACT

In the present paper, a total of 10 RC beams strengthened with prestressed and non-prestressed NSM CFRP strips were subjected to static and fatigue loading tests and the monotonic behavior and failure modes of these RC beams with different pre-stress levels were investigated. The influence of various factors, including the CFRP prestress level, CFRP bond length, protection of concrete cover, and the fatigue load levels on the fatigue performance of specimens were analyzed. Test results showed that a high prestress level leads to the cover separation at the end of CFRP prematurely and thus reduces the load carrying capacity of the strengthened beam. However, the failure caused by cover separation at CFRP end can be prevented or delayed by increasing the bond length, wrapping the beam at CFRP end with U-shaped CFRP sheets, and decreasing the prestress level. Additionally, the transformation of failure mode generally leads to great change of fatigue life.

KEYWORDS

Near-surface mounted, CFRP strips, prestress, fatigue performance, cover separation; bond length

INTRODUCTION

Carbon fiber reinforced polymers (CFRP) have been widely used for the strengthening of engineering structures, especially RC bridges. However, by using externally bonded (EB) FRPs, the full strength of FRP can not be utilized (e.g. Masoud et al. 2011) and concrete structures are inclined to fail due to the debonding of EB FRP-concrete interface. Conversely, with the technique of strengthening concrete structures with near surface mounted FRP (NSM FRP), the bonding area between FRPs and concrete is increased. Thus, the debonding of FRP-concrete interface is restrained and the bond capacity of FRP-concrete interface is improved. However, the high strength of FRP is still not fully utilized by the technique of NSM FRPs. On this account, recently researchers have begun to investigate the technique of strengthening structures with prestressed NSM FRPs. It was found that, with regard to this technique, the strength of FRP can be fully utilized, the load carrying capacity of structures significantly improved, and the excellent bond between NSM FRP and concrete can provide anchorage for prestressed FRP (e.g. GUO et al. 2011), and thus the cost of mechanical anchorage required by the strengthening technique with prestressed FRP can be saved. Hence, the technique of strengthening RC structures with prestressed NSM FRP has attracted the most attention from researchers both at home and abroad and a number of investigations in this regard have been conducted. Oudah et al. (e.g. Oudah et al,2012a,2012b ).Tested RC beams strengthening with NSM-CFRP strips prestressed to 0, 20, 40, and 60% of the CFRP ultimate tensile strength. The stress range induced in the tension steel is 125 MPa. All beams were subjected to fatigue loading for 3 million cycles and did not fail. Their experimental test results showed that bond degradation was observed in strengthened beams using NSM-CFRP strips prestressed to 0 and 20%, whereas no signs of bond degradation were observed in beams strengthened using NSM-CFRP strips prestressed to 40, and 60%. They thus concluded that prestressing the CFRP strips enhances the bond between NSM FRP and concrete. (e.g. Fernandes et al. 2012) Tested concrete elements strengthened with NSM FRP laminate strips under fatigue loading and found that all specimens did not fail after 2 million cycles. Besides, according to (e.g. Wahab et al,2012a,2012b) concrete beams strengthened with NSM prestressed CFRP rods exhibited two failure modes: Fracture of steel reinforcement under a low fatigue load and debonding of FRP-concrete interface under a high fatigue load (debonding began at the support and then developed toward the loaded point). In contrast, domestic research on the NSM FRP system (prestressed or non-prestressed) under fatigue loading is scarce and knowledge about the fatigue performance and failure modes of concrete elements is much more limited. Yet, the limited existing research has already proved the complexity of the bond behavior of structures strengthened with NSM FRP.
In view of this, the present study studied the bond behavior of 10 specimens strengthened with prestressed NSM FRP under static and fatigue loading and primarily investigated the effect of various factors (such as CFRP pre-stress level, CFRP bond length, protection of the concrete cover at the end of CFRP, and fatigue load level etc.) on the fatigue behavior of these specimens, aiming at providing theoretical foundation for the application of the technique of strengthening concrete elements with NSM FRP.

TEST PROGRAM

In the experimental study, a total of 10 RC beams strengthened with NSM CFRP were tested, which are with a full length of 3500mm, an effective span of 3300mm, and a sectional dimension of 60mm×350mm. Two reinforcing steel bars with a diameter of 16 mm were used in both the tension zone and the compression zone. Steel stirrups of 8-mm nominal diameter were arranged at a 100 mm interval along the whole length of beams. The design strength of the concrete is C40, and both the pure bending section and the shear bending section are 1100mm long. For detailed dimension and steel reinforcement arrangement, please refer to Figure 1. The bond length of CFRP strips varies from 2900mm to 3300mm, with CFRP strips arranged symmetrically. CFRP strips are Aslan 500 series, with a nominal tensile strength of 2068MPa, an elastic modulus of 131Gpa, and a sectional dimension of 16mm×2.0mm. Epoxy resin is Sikadur®-30 resin from Sika Co. Ltd. Loading was applied by pulse fatigue loading machine with a frequency of 2Hz.

![Figure 1 Specimen Dimension and Steel reinforcement Arrangement (Strips)](image)

Two of the ten specimens were strengthened with prestressed CFRP and subjected to static loading, and one was strengthened with non-prestressed CFRP and tested under fatigue loading. The other 7 specimens were strengthened with prestressed CFRP and to fatigue loading. Test parameters include: CFRP pre-stress level, fatigue loading level, anchorage at the end of CFRP, CFRP bond length. For details, please refer to Table 1.

Note: In specimen IDs, “N” stands for NSM double-groove strengthening, “L” and the number after it for bond length (in cm; the bond length is of 290cm if not specifically given), “P” and the number after it for pre-stress level, “S” for static loading, “F” for fatigue loading and the numbers before and after it for the lower and upper fatigue limits (kN), and “AN” for U-shaped carbon fibre anchorage for the concrete cover at the end of CFRP.
TEST PROCESS AND PHENOMENA

As mentioned above, the present study subjected 10 RC specimens strengthened with NSM FRP strips to static or fatigue loading tests. Detailed testing process and phenomena of each specimen are described as follows:

Specimen NP720-S was strengthened with NSM-CFRP strips prestressed to 720Mpa and subjected to monotonic static test, with a cracking load of 43.2kN. At a load level of 115kN, diagonal cracks were found at the end of FRP, and at 127kN, horizontal branches of these diagonal cracks were observed. At 148kN, the yielding of longitudinal steel reinforcements occurred, at 190kN, the midspan deflection reached 42.9mm, and the concrete cover at the end of CFRP delaminated, the main bar was exposed, and crushed concrete was seen peeling off, making the FRP strip exposed to the air. The whole process is very quick, as shown in Figure 2.

Specimen NP720-19F112 was subjected to fatigue test, with the upper and lower fatigue limits being 60% and 10% of the ultimate load of Specimen NP720-S (112kN and 19kN respectively). When the initial static load was increased to the upper fatigue limit, diagonal cracks of 45° were found in the concrete at the end of FRP, extending to the top of the beam. With the increase in fatigue load, horizontal branches of these diagonal cracks were quickly formed at the steel reinforcement-concrete interface, in very quick growth and forming a typical separation of concrete cover. The fatigue life is only 900 cycles, as shown in Figure 3.

Specimen NP1000-S was strengthened with NSM-CFRP strips prestressed to 1000MPa and subjected to monotonic static test, with a cracking load of only 36.4kN. At a load level of 109kN, diagonal cracks were observed at the end of CFRP, and at 125kN, horizontal branches of these diagonal cracks were found. With the increase in the load, more and more horizontal cracks were seen continuously propagating toward the midspan. At 157kN, horizontal cracks become confluent with one other, resulting in the debonding of the bottom CFRP together with 2cm-thick concrete along the concrete cover at the bottom of the precut groove. Yet, the bond between the debonded concrete and epoxy resin (CFRP strip) was intact. The failure mode of the specimen is as shown in Figure 4.

Specimen NP1000-16F80 was subjected to fatigue test, with the lower and upper fatigue limits being 10% and 50% of the ultimate load of Specimen NP1000-S (16kN and 80kN respectively). The cracking load of the specimen is 43kN. When the initial static load was increased to 79kN, a 6cm-long diagonal crack was found at the end of FRP. After 2200 cycles, horizontal branches of the diagonal crack were seen gradually widening and propagating toward the midspan. After 4000 cycles, horizontal cracks began to decrease in height (2cm down into the groove) and propagated backward to the cracked end of FRP. After 5500 cycles, the backward horizontal cracks resulted in the complete separation of the 2cm-thick concrete cover from the end of CFRP to a place below the loaded point. The failure mode is as shown in Figure 5.

Specimen NP1000-16F64 differs from Specimen NP1000-16F80 only in that the upper fatigue limit was decreased to 40% of the ultimate load of Specimen NP1000-S (64kN). The cracking load of the specimen is 39kN. After static loading, no diagonal cracks were found at the end of FRP. Under fatigue loading conditions, though diagonal cracks were observed at the end of FRP after 6,000 cycles, horizontal branches of these diagonal cracks initiated...
only after 62,000 cycles, propagated into 20cm-30cm long cracks after 140,000 cycles, and stabilized for the rest of 1 million cycles, indicating good fatigue properties of the specimen, as shown in Figure 6. After 1 million cycles, the specimen was subjected to static loading test so as to study its post-fatigue monotonic behavior. At a load level of 128kN, two new horizontal cracks were found below the old horizontal cracks and were seen gradually widening and propagating both forward and backward and finally confluent with each other, resulting in the complete separation of the 2cm-thick concrete cover from the end of CFRP to the mid span. Still, the bond between the separated concrete and epoxy resin was intact. The failure load is 146kN, while the deflection is only 13.4mm. Compared with the specimen subjected to static test, the debonding of the specimen subjected to fatigue test is comparatively slow.

The bond length of Specimen NL310P1000-16F80 was set to be 310cm. Under fatigue loading conditions, diagonal cracks were found at the four ends of the two FRP strips after 16,000 cycles, with the angle varying from 55° to 75°. After 21,300 and 22,900 cycles, horizontal branches of the diagonal cracks initiated in planes A and B respectively and were seen growing at nearly the same speed into 36cm-long and 5-7cm-high cracks after 32700 cycles. After that, the cracks propagated forward and backward: on the one hand, the cracks continued to propagate forward to the midspan and became confluent with the diagonal cracks; on the other hand, the cracks gradually decreased in height and propagated backward to the end of CFRP after 37,700 cycles, resulting in the separation of 2cm-5cm thick concrete cover toward the midspan. The length is about 160cm. Failure mode of the specimen is as shown in Figure 7.

Specimen NP480-16F80 differs from Specimen NP1000-16F8 only in that the prestress was decreased to 480MPa. The cracking load of the specimen was up to 43kN. During the whole process of the fatigue test, no diagonal or horizontal cracks were found at the end of FRP, exhibiting fatigue properties of common RC. After 167,000 cycles, it became impossible to increase or decrease the load, crack width nearby the loaded point increased and specimen deformation got worse. Open the crack, and fatigue failure in longitudinal steel reinforcement was found at the loaded point.

The present study designed Specimen N-10F48 (non-prestressed) as such that the upper and lower fatigue limits were set to be 48kN and 10kN respectively (so as to make the initial strain in the midspan CFRP under static
loading be the same as that of Specimen NP1000-16F80). The cracking load of the specimen is only 28kN. During the whole process of the fatigue test, no cracks were found at the end of FRP and no obvious degradation at other locations. After 796,000 cycles, it suddenly became impossible to increase or decrease the load, main crack width increased, separation of concrete cover occurred, and fatigue failure in steel reinforcement was found.

Specimen NL330P1000-16F80 has a bond length extending to the full effective span (330cm), with other parameters being the same as those of Specimen NP1000-16F80. During the whole process of the fatigue test, no diagonal or horizontal cracks were found in concrete at the end of FRP. After 315,000 cycles, it became impossible to increase or decrease the load, crack width at one side of the loaded point increased abruptly. After 345,000 cycles, crack width at the other side of the loaded point also increased greatly. Open the concrete cover by the method of chiseling, two steel reinforcements in this section were found to have failed due to fatigue loading.

**TEST RESULTS AND DISCUSSION**

**Monotonic behavior of strengthened specimens**

Both specimens submitted to static loading used a 290 cm CFRP bond length. Monotonic behavior of specimens with different CFRP pre-stress levels was investigated. Test results are as shown in Table 2.

<table>

</tbody>
</table>

Analyses of midspan strain and deflection showed that: compared with non-prestressed Specimen N-10F48, the deflection of prestressed Specimens NP720-S and NP1000-S decreased by 12% and 37%, steel reinforcement strain decreased by 45% and 50%, cracking load increased by 54% and 30% respectively, indicating that the technique of prestressing resulted in improvement of flexural rigidity and performance of specimens.

Test results also showed that, with a smaller prestress, the specimen failed due to separation of concrete cover at the end of CFRP at the steel reinforcement-concrete interface; with a higher prestress, Specimen NP1000-S failed due to the separation of concrete cover at the interface of groove bottom before the yielding of steel reinforcement. Besides, the ultimate load of Specimen NP1000-S decreases by 18% compared with Specimen NP720-S. Possible reasons are that a higher prestress induced a greater interface shear stress in the groove wall and bottom at the end of FRP, and the combination of load shear stress, flexural rigidity of FRP and debonding stress caused by flexural deformation resulted in the premature debonding of groove bottom interface. These results indicate that prestressed NSM FRP improved the load carrying capacity of specimens. Yet with a higher prestress, specimens may fail due to premature separation of concrete cover at the end of FRP or a thin concrete layer. A even higher prestress may cause the interface debonding at the groove bottom of FRP system.

**EFFECT OF BOND LENGTH ON FATIGUE PERFORMANCE**

Bond length is a crucial factor affecting the load carrying capacity of the concrete at the end of FRP and thus is probably responsible for the separation of the concrete. Additionally, the actual bond length is dependent on the strengthening conditions. Therefore, it is of vital importance to investigate the effect of bond length on the behavior of concrete cover at the end of FRP. Taking 1000MPa as the reference prestress level, the present study investigated the fatigue properties of specimens with 290, 310 and 330cm bond length. Table 3 summarizes the test results.

As can be seen from failure modes listed in Table 3, specimens with 290 and 310 cm bond length failed due to the separation of concrete cover at the end of FRP, exhibiting nearly identical crack propagation and concrete cover declamation. The only difference was that the specimen with a longer bond length (310) degraded at a lower speed and has a longer fatigue life. Still the failure of Specimen with 330 bond length was not due to the debonding at the end of FRP but due to the fracture of steel reinforcement, with no diagonal or horizontal cracks found at the end of FRP or nearby during the fatigue test. From the above analyses, it can be concluded that lengthening the bond length improves the load carrying capacity of the concrete cover at the end of FRP, delays or in some cases
prevents the separation of the concrete cover. The failure mode of the specimen transforms from separation of concrete cover to fatigue failure of steel reinforcement.

### EFFECT OF LOAD LEVEL ON FATIGUE PERFORMANCE

The fatigue behavior of specimens greatly differs from their monotonic behavior. And the failure mode may vary from specimen to specimen subjected to different load levels. The present study explored the effect of load level on fatigue properties of specimens. Table 4 represents the detailed test results.

### Table 4 Fatigue Properties of Specimens Subjected to Different Load Levels

<table>
<thead>
<tr>

<td>80</td>
<td>0.55</td>
<td>Separation of concrete cover at the end of CFRP</td>
</tr>
</tbody>
</table>

Table 4 showed that, at a load level of 80kN (the upper fatigue limit), Specimen NP1000-16F80 failed due to separation of concrete cover at the end of CFRP (short fatigue life); yet when the upper fatigue limit decreased to 64kN, Specimen NP1000-16F64 did not fail even after 1 million cycles and only a little damage was done to the concrete cover and no further damage was observed after 297,000 cycles (as shown by Figure 6). It can be seen that the fatigue load level has a noticeable effect on damage to the end of CFRP, for the decrease in the load level will lead to a great decrease in the shear stress, and thus greatly delay or prevent the propagation of horizontal cracks in the concrete cover at the end of CFRP. Though the specimen, in the subsequent static loading test, failed due to separation of concrete cover at the end of FRP, the failure load (146kN) was comparatively low compared with that of Specimen NP1000-S (157kN), indicating that the damage to the concrete cover was not significant after 1 million cycles. Since horizontal cracks in the concrete cover stopped growing after 297,000 cycles and the strain in the steel reinforcement remained to be 500με after 100,000 cycles, the specimen may not fail due to fatigue failure or fracture of steel reinforcement (long fatigue life). Conversely, Specimen N-10F48 failed due to fracture of steel reinforcement after 796,000 cycles, with the strain in the steel reinforcement being around 775με. Therefore, it can be concluded that Specimen NP1000-16F64 is more likely to fail due to fatigue failure of steel reinforcement if the fatigue loading test continues, supporting the existing claim that varying the fatigue load level may result in different failure modes of specimens.

### EFFECT OF PRE-STRESS LEVEL ON FATIGUE PERFORMANCE OF STRENGTHENED BEAMS

As previously analyzed, pre-stress level is another important factor affecting the load carrying capacity of the end FRP. The present study subjected specimens with different prestress levels (yet with the same bond length of 290cm) to fatigue loading tests. To be specific, pre-stress levels were set to be 0MPa, 480MPa, and 1000MPa. Table 5 includes the detailed test results.

As to Group I specimens strengthened with non-prestressed and prestressed FRP strips (prestress level of 1000MPa), the initial strain in the midspan steel reinforcements was set to be the same and specimens were subjected to fatigue loading tests. Test results showed that Specimen N-10F48 differs from Specimen NP1000-16F80 in terms of failure development and the final failure mode. Specimen N-10F48 failed due to steel reinforcement fracture, but with the concrete cover at the end of FRP remained intact and free of cracks all the
time. Conversely, Specimen NP1000-16F80 failed due to the quick separation of the concrete cover. As to Group II specimens with different prestress levels but with the same fatigue load level, Specimen NP480-16F80 failed due to steel reinforcement fracture, while Specimen NP1000-16F80 failed due to separation of concrete cover at the end of FRP caused by horizontal cracks. These phenomena proves that prestress level has a significant influence on the failure mode of specimen. Increasing the prestress level leads to the transformation of failure mode from steel reinforcement fracture to separation of the concrete cover at the end of FRP. It can be concluded that the setting of pre-stress level directly determines the shear stress in the concrete cover at the end of FRP and the fatigue stress in the steel reinforcement at the midspan. Altering prestress level directly results in the transfer of the weakest part, the transformation of the failure mode, and the great change in the fatigue life of the specimen. Therefore, there should be one pre-stress limit which can make the specimen not fail due to separation of concrete cover and improve the flexural properties of the specimen to the greatest extent.

CONCLUSIONS
This paper presents an experimental study on mechanical behavior of 10 RC specimens strengthened with prestressed NSM FRP under static and fatigue loading conditions. The following conclusions can be highlighted:
1. Under static loading, increasing the prestress level leads to an improvement of the load carrying capacity of specimens strengthened with NSM CFRP strips. But a very high prestress may cause the earlier separation of the concrete cover at the end of FRP and the decrease of the ultimate load. Specimens with different prestress levels exhibit different failure modes: specimens with a lower prestress level fail due to separation of the concrete cover at the end of FRP, while those with a higher prestress level fail due to separation of bottom concrete cover at the end of FRP. This may be attributed to the fact that a higher prestress level results in a greater stress in the groove wall.
2. The main failure mode observed in all RC beams strengthened with prestressed NSM FRP strips under static and fatigue loading is the separation of concrete cover at the end of FRP. Using U-shaped carbon fiber sheets can effectively constrain the deformation and separation of concrete and thus prevent concrete separation from happening. Decreasing load amplitude can significantly check the propagation of cracks in concrete cover at the end of FRP. Besides, for specimens with an upper load limit of 40%, the cracks at the end of FRP stop growing after 297,000 cycles.
3. Altering the prestress level has a significant effect on the fatigue properties of specimens. With a higher prestress level, the failure mode transforms from steel reinforcement fracture to separation of concrete at the end of FRP and the fatigue life of specimens decreases greatly. This is because, at the same load level, a higher prestress level induces a smaller stress in steel reinforcement yet a greater the stress in the concrete at the end of FRP. Hence, the setting of prestress level directly determines the shear stress in the concrete cover at the end of FRP and the fatigue stress in steel reinforcement. Altering prestress level directly results in the transfer of the weakest part of the specimen.
4. A longer bond length provides a gradual decrease in the stress in concrete at the end of FRP and thus a longer fatigue life of the concrete. After the bond length has been increased to a certain value, the failure mode of the specimen transforms from separation of the concrete cover at the end of FRP to fatigue failure in steel reinforcement, which in turn greatly improves the fatigue life of the specimen.

ABSTRACT

The fiber reinforced polymers (FRP) have features such as high tensile strength, light weight, high corrosion resistance, and high fatigue resistance. Therefore, they can be used for construction of short span bridges. It was found that the resin matrix contained in the FRP materials becomes soften at the glass transition temperature ($T_g$), so that, their mechanical properties will be deteriorated at $T_g$. The $T_g$ of some commercially available FRP materials is around 60°C and 82°C and hence, the flexural behavior of the bridges constructed using the FRP can be affected by hot environmental temperature. In this study, the influence of elevated temperature on the flexural behavior of composite beams consisting of glass FRP (GFRP) and ultra-high strength fiber reinforced concrete (UFC) was investigated. Large-scale beam bending tests were conducted at temperatures between 20°C and 90°C. The experiment results revealed that the flexural capacity and stiffness of the GFRP I-beams are highly influenced by the glass transition temperature of the vinylester resin matrix. It was found that the use of UFC segments significantly improves both the flexural capacity and stiffness of the GFRP I-beams at temperatures between 20°C and 90°C. This is because of the elimination of premature delamination or kink failure of the GFRP I-beam’s compression flange by the UFC slab. The experiment results were compared with fiber model analysis results and both the results were agreed up to the occurrence of UFC segment slip in the GFRP and UFC composite beams.

KEYWORDS

GFRP, ultra-high strength fiber reinforced concrete, composite beam, glass transition temperature, flexural behavior, fiber model analysis.

INTRODUCTION

The fiber reinforced polymers (FRP) are being used for construction of short span bridges because of their advantages compared to the conventional construction materials, such as high corrosion resistance, high tensile strength, lightweight, and high fatigue resistance. Hai et al., 2010 reported that the superior tensile properties of FRP I-beams cannot be effectively utilized because of the premature delamination failure of the compression flange. This problem was overcome by strengthening the compression flange using ultra-high strength fiber reinforced concrete (UFC) slab (Wijayawardane et al., 2014). Use of the UFC slabs has advantages over reinforced concrete slabs such as high durability, high compressive and tensile strength, and lightweight. The UFC slab consists of precast segments and those segments were connected to the glass FRP (GFRP) I-beam top flange using FRP bolts and epoxy adhesive.

Foster and Bisby (2008) reported that the material properties of the FRPs degrade as the temperature exceeds their glass transition temperature ($T_g$). The $T_g$ of some commercially available FRPs are in between 60°C and 82°C (ACI, 2008). An investigation carried out on a full-scale FRP bridge showed that the maximum temperature at the bridge deck during summer would be approximately 60°C (Sirimanna et al., 2011). Therefore, the elevated temperature may deteriorate the material properties of the GFRP and UFC composite beam materials and as a result, the flexural behavior of these beams will be affected.

The objective of this study is to investigate the flexural behavior of the GFRP and UFC (GFRP-UFC) composite beams subjected to elevated temperature. Large-scale four point bending tests were conducted on the GFRP-UFC composite beams at temperatures between 20°C and 90°C.
EXPERIMENT PROGRAM

Material Properties at Elevated Temperature

The GFRP-UFC composite beam consists of GFRP I-beam, UFC slab, FRP bolts, and epoxy adhesive. The influence of elevated temperature on the mechanical properties of these materials were investigated. Tensile and compressive properties of the GFRP flange and GFRP web, compressive properties of the UFC, and shear strength of the FRP bolts and epoxy adhesive at elevated temperature were investigated and the test results are shown in Table 1, Table 2, and Table 3, respectively. The $T_c$ of vinyl ester resin (resin matrix in GFRP), the resin inside the FRP bolts, and the epoxy adhesive were determined by the test method suggested by Japan Industrial Standards K7121 (JIS, 1987) and they were 58°C, 53°C, and 56°C, respectively. As shown in Table 1, the tensile and compressive strengths of the GFRP flange and GFRP web were significantly deteriorated by elevated temperature. And also, the shear strength of the FRP bolts and the epoxy adhesive were decreased significantly as temperature increases (Table 3). However, as shown in Table 2, there was no significant influence of elevated temperature on the compressive strength of the UFC. This happened because the UFC doesn't contain thermally affected material.

Beam Test at Elevated Temperature

The GFRP I-beams used in this study were manufactured by pulltrusion. The fiber content in the GFRP I-beams and the mechanical properties of the GFRP laminates used in the composite beams have been reported by Wijayawardane et al. (2014). Two types of beams, 1) GFRP I-beams and 2) GFRP-UFC composite beams were tested under four point bending test. The GFRP I-beams were the control specimens. The overall length and height of the GFRP I-beams are 3,500 mm and 250 mm, respectively. The flange is 14 mm in thickness and 95 mm in width and the web is 9 mm in thickness. The size of a precast UFC segments is 300 × 95 × 35 mm and they were attached to the GFRP I-beams using 16 mm diameter FRP bolts and the epoxy adhesive. The cross-sectional details of the GFRP-UFC composite beam are given in Figure 1. The center-to-center spacing of the FRP bolts is 150 mm. The test variables are shown in Table 4 and Figure 2 illustrates the four-point bending setup of a GFRP-UFC composite beam. The flexural and shear spans of the beams were 700 mm and 1,250 mm, respectively. As shown in Figure 2, in all beams, GFRP stiffeners were attached at both sides of the web to prevent web buckling. Except the beams at 20°C (room temperature), all the other beams were gradually heated up to the test temperature and kept constant at the same temperature for an hour before applying the load. Heating of the beams was done inside a heat insulated steel box which was attached with ten electric heaters. Heating of a GFRP-UFC composite beam prior to bending test is shown in Figure 3. During the bending test, the applied load, strain at midspan section, and the deflection at the midspan were recorded.
RESULTS AND DISCUSSION

Figure 4 shows the failure patterns of the control specimens (GFRP I-beams). Figure 4(a) and Figure 4(b) show that the beams G-20 and G-60 failed by delamination of the compression flange near the loading point. In contrast, beam G-90 failed at the midspan by kinking of the compression flange and the web (Figure 4(c)). The main reason for the kink failure in G-90 beam was softening of the vinylester resin due to the glass transition by elevated temperature. The failure patterns of the GFRP-UFC composite beams are shown in Figure 5 and there were two main failure patterns were observed. According to Figure 5(a) and Figure 5(b), both GC-20 and GC-60 beams failed by crushing of the UFC segmental slab at midspan, whereas beam GC-90 failed by shearing of the FRP bolts and epoxy adhesive in the shear span. In beam GC-60, there was a small slip of the UFC segments in the shear span (Figure 5(b)) but no shearing of the FRP bolts observed. As shown in Figure 5(c), there was no UFC segments crushed at the failure of GC-90 beam, but four UFC segments were completely detached from the I-beam’s top flange in the shear span.

</table>
The load and midspan deflection relationship of the control specimens (GFRP I-beams) and the GFRP-UFC composite beams are shown in Figure 6. At all temperatures, the control specimens showed a significantly low flexural capacity and stiffness compared to those of the GFRP-UFC composite beams. This confirms that the installation of the UFC segments to the GFRP I-beam’s compression flange increases the flexural capacity of the GFRP I-beam approximately by 80%, 70%, and 140% at temperatures 20°C, 60°C, and 90°C, respectively. Therefore, use of the UFC is very important and the UFC slab helps to utilize the superior tensile properties of the GFRP. The flexural capacity and the stiffness of both the control specimens and the GFRP-UFC beams decreased...
as temperature increases. However, there was a large decrease in the flexural capacity and stiffness of both beam types at 90°C. This was resulted by the deterioration of the material properties of the GFRP due to glass transition of the vinylester resin. All control specimens and GC-20 beam showed linear load-deflection relationship until failure. But in the beams GC-60 and GC-90, there was a sudden slip of the UFC segments during loading (Figure 6). The reason for this is the failure of the epoxy adhesive between the UFC and the I-beam’s top flange. The glass transition temperature of the epoxy adhesive is 56°C and the shear test results in Table 3 shows that the epoxy adhesive loses its shear capacity by 68% in between 20°C to 60°C.

FIBER MODEL ANALYSIS (FMA)

The flexural behavior of the GFRP-UFC composite beams was analyzed using a simple Fiber Model and the results were compared with the experimental data. All the GFRP-UFC beams were assumed to be behaved under Bernoulli-Euler theory and the temperature throughout the beams was assumed to be constant. In the fiber model, the GFRP-UFC I-beam is divided into a number of horizontal and longitudinal elements and each horizontal element was assigned with the appropriate material properties given in Table 1, Table 2, and Table 3. It was assumed that the material properties of the GFRP flange and GFRP web elements are homogeneous. In the analysis, full interaction between the GFRP I-beam’s top flange and the UFC slab was considered and hence there was no slip between the flange and the UFC slab. A bi-linear stress-strain relationship from the JSCE design code for UFC structures was used to model the UFC (JSCE, 2004). The shear force developed in the shear span at the I-beam’s top flange-UFC slab interface was calculated using the FMA.

The relationship between the load and midspan deflection obtained from the experiment and the analysis is shown in Figure 7. The lines 1 and 3 in Figure 7 represent the vertical load corresponding to the epoxy adhesive shear capacity at 60°C and 90°C, respectively. The line 2 in Figure 7 shows the vertical load corresponding to the FRP bolt shear capacity at 90°C. The FMA well predicted the flexural behavior of beam GC-20. But in beams GC-60 and GC-90, the analysis results were agreed up to the occurrence of UFC segment slip (Figure 7). However, there was a good agreement with the failure loads between the analysis and the experiment. According to the analysis, it was confirmed that the slipping of the UFC segments in beams GC-60 and GC-90 occurred by the failure of the epoxy bond between the top flange and the UFC slab (lines 1 and 3 in Figure 7, respectively). After failure of epoxy adhesive, shear force between the UFC slab and the top flange was mainly taken by the FRP bolts. Therefore, the failure of the epoxy adhesive did not significantly affect the stiffness of the GFRP-UFC composite beams. In FMA, beam GC-90 failed when the vertical load was equal to the shear capacity of the FRP bolts (line 2 in Figure 7). This confirms that the failure of beam GC-90 was due to shearing of the FRP bolts in the shear span, resulted by the glass transition of the FRP bolts at elevated temperature. In the case of GC-60 beam, the FRP bolt shear capacity was not exceeded at beam failure and that resulted crushing of the UFC segments. Therefore, the failure criteria (flexural failure or shear failure) in these GFRP-UFC composite beams is determined by the shear capacity of the FRP bolts at beam temperature.
CONCLUSIONS

This paper presents the influence of elevated temperature on the flexural behavior of the GFRP-UFC composite beams and the main conclusions of the study are summarized below.

1. The flexural capacity and stiffness of the GFRP I-beams are highly influenced by the glass transition temperature of the vinylester resin.

2. Use of the UFC segments significantly improves both the flexural capacity and stiffness of the GFRP I-beams at room and elevated temperatures (less than 90°C). This is because of the elimination of premature delamination or kink failure of the GFRP I-beam by the UFC slab.

3. The failure pattern (flexural failure or shear failure) of these GFRP-UFC composite beams is determined by the shear capacity of the FRP bolts at the temperature of the beam.

4. The proposed simple fiber model analysis method can be used to analyze the flexural behavior of the GFRP and UFC composite beams up to the occurrence of the UFC segment slip.

ABSTRACT

Although pultruded glass fibre reinforced polymer (GFRP) columns under compression have been investigated in the last two decades, results on square hollow sections (SHS) are still limited. In general, three failure modes are categorized: compressive failure, local buckling and global buckling. In this paper, the critical loads for different failure modes of GFRP SHS columns are analysed. Analytical formulations for the boundaries of different failure modes are received, with quantifications of the effects of column slenderness (non-dimensional slenderness, $\lambda$) and plate slenderness (width-thickness ratio, $b/t$). It demonstrates that local buckling will occur on GFRP columns if the $b/t$ is greater than a critical value; compressive failure will occur if $b/t$ is less than the critical value; global buckling will occur if $\lambda$ is greater than 1 and $b/t$ less than a critical value. Furthermore, a failure modes map against $\lambda$ and $b/t$ is formed. Based on this approach, the failure mode of a GFRP column can be determined with knowing its geometric parameters $\lambda$ and $b/t$, and therefore the corresponding load capacity can be determined accordingly. The failure modes map and load capacities of GFRP SHS columns are well validated by experimental results with different $\lambda$ and $b/t$.

KEYWORDS

GFRP columns, width-thickness ratio, local buckling, failure mode, load-carrying capacity.

INTRODUCTION

Pultruded glass fibre reinforced polymer (GFRP) columns under compression have been widely investigated by researchers from 1990s (Zureick and Scott 1997, Barbero 2000, Mottram et al. 2003), particularly on the failure modes and load-carrying capacities of GFRP columns with open section profiles and different slenderness. The failure modes observed are generally categorized as three types: compressive failure, local buckling and global buckling (Hashem and Yuan 2001). For compressive failure it represents the compressive stress reach the material compressive strength and the specimen crushes in the bottom surface (Hashem and Yuan 2000). Local buckling was reported on the flange of pultruded I and box sections under compression (Tomblin and Barbero 1994, Bank et al. 1996). Theoretical analysis on the critical local buckling load of GFRP plates was carried out (Bank and Yin 1996, Qiao et al. 2001, Kollár 2003) based on orthotropic plate theory and different analytical solutions were received for different boundary conditions at edges. Global buckling is found on slender columns (Barbero and Tomblin 1993) and the critical loads are close to Euler equation. It is also noted that for buckling of GFRP columns, the influence of shear deformation should be considered (Roberts 2002) and a modified Euler equation should be applied on the buckling of GFRP columns (Zureick and Scott 1997). Studies (Bai and Keller 2009, Bai et al. 2009) also indicated slender GFRP columns will exhibit shear failure prior to compressive failure due to low elastic modulus and second-order effects.

Different design equations were proposed by researchers (Barbero and DeVivo 1999, Puente et al. 2006) to predict the load-carrying capacities of GFRP columns at different slenderness. Barbero and Tomblin (1994) investigated the interaction between local buckling and global buckling for GFRP columns with intermediate length, and proposed a design equation with an interaction parameter ($c = 0.84$) to fit experimental results. In their design equation, the load reduction factor $\chi$ is related to the non-dimensional slenderness $\lambda$ and mode interaction parameter $c$. This method is used by (Barbero and DeVivo 1999, Lane and Mottram 2002) with different proposals on interaction parameter $c$ and different expression forms (Puente et al. 2006) on reduction factor $\chi$. In these approaches (Barbero and Tomblin 1994, Mottram 2004, Puente et al. 2006), the local buckling load $P_{local}$ is determined theoretically or experimentally based on short columns; and local-global buckling interaction occurs...
when $\lambda$ is between 0.5 and 1.5 (Bank 2007). However, the occurrence of local buckling also depends on the plate slenderness, i.e. the width-thickness ratios $b/t$ of the plates of GFRP members (Pecce and Cosenza 2000). For example, if a short column with low $b/t$ is under compression, it may exhibit compressive failure rather than local buckling. Therefore no local and global buckling interaction will be received on for such intermediate columns with $\lambda$ between 0.5 and 1.5. As a result the effect of $b/t$ should be considered in the design equations of GFRP columns. A recent work (Cardoso et al. 2014) on the compressive strength equation for GFRP SHS columns has defined a relative plate slenderness $\lambda_p$ for GFRP plates and proposed a design equation for GFRP SHS columns. In this equation the reduction factor $\chi$ is a function with column slenderness $\lambda$ and relative plate slenderness $\lambda_p$. This design equation is validated with experimental results on five different SHS sections. A failure modes map with respect to $\lambda$ and $\lambda_p$ for different failure modes are obtained from experimental results.

In this paper, the effects of $\lambda$ and $b/t$ on different failure modes of GFRP SHS columns under compression have been identified through the analytical formulations, forming the theoretical boundaries of these failure modes. It shows local buckling failure will occur if $b/t$ is greater than a critical value which relating to the material properties of GFRP. A failure modes map for GFRP SHS columns under compression with consideration of effects of both $\lambda$ and $b/t$ is formed. Experiments were performed on two square hollow sections with different $b/t$ at different $\lambda$. The load-carrying capacities corresponding to different failure modes resulted from various $\lambda$ and $b/t$ values are formed and validated by experimental results from current study and literatures.

**ANALYTICAL FORMULATION**

**Critical loads for different failure modes**

The critical loads for three types of failure modes can be determined as follows. For compressive failure (crushing), the ultimate load $P_c$ is determined as:

$$ P_c = A \cdot f_c $$ (1)

where $A$ is the section area and $f_c$ is the compressive strength of material.

For global buckling, the critical load $P_{cr}$ refers to Euler equation:

$$ P_{cr} = \frac{\pi^2 E I}{(kL)^2} $$ (2)

where $E$ is the elastic modulus of the material in longitudinal direction; $I$ is the moment of inertia for section; $kL$ is the effective length of column.

For local buckling, the critical load $P_{local}$ is related to the boundary conditions of the GFRP plates at edges. As SHS section are focused in this study, its boundary condition may be considered as RRSS (Rotational Restricted at two unloaded edges, Simple Support at two loaded edges), which is between two critical cases SS (four edges simple supported) and CCSS (clamped on two unloaded edges), according to (Qiao et al. 2001, Shan and Qiao 2008). The local buckling load $N_{cr}$ for an orthotropic plate at two critical boundary conditions SS and CCSS are given in Eqs (3) and (4) respectively:

$$ N_{cr,SS} = \frac{\pi^2}{b} \left[ 2\sqrt{D_{11} D_{22}} + 2(D_{12} + 2D_{66}) \right] $$ (3)

$$ N_{cr,CCSS} = \frac{\pi^2}{b} \left[ \frac{44.9}{\pi^2} \sqrt{D_{11} D_{22}} + \frac{24}{\pi^2} (D_{12} + 2D_{66}) \right] $$ (4)

where $b$ is the width of the GFRP plate; $D_{11}$, $D_{12}$, $D_{22}$, $D_{66}$ represent different flexural stiffnesses of the plate relating to plate thickness $t$ and material properties such as longitudinal modulus $E_1$, transverse modulus $E_2$, shear modulus $G_{12}$, and poisson ratios $\nu_{12}$ and $\nu_{21}$. Therefore the critical local buckling load for a SHS column is determined as:

$$ P_{local} = \frac{A N_{cr}}{b t} $$ (5)

where $b$ and $t$ are the width and thickness of GFRP plate respectively; $N_{cr}$ is the critical local buckling load of a GFRP plate; $A$ is the cross section area.

**Failure modes map for a column subjected to compression**

Non-dimensional slenderness $\lambda$ (Cardoso et al. 2014) can be defined in Eq (6) considering the two possible failure modes (compressive failure and local buckling) for short columns:

$$ \lambda = \sqrt{\frac{\min(P_c-P_{local})}{P_{cr}}} $$ (6)
where $P_c$ is the compressive failure load; $P_{local}$ represents the local buckling load; $P_{cr}$ is the global buckling load. As $\lambda$ is a parameter that relates to the local buckling and global buckling of GFRP columns, and $b/t$ is a parameter that relates to the local buckling and compressive failure, so the critical load equations for GFRP columns under compression can be derived as functions of both $\lambda$ and $b/t$.

Based on the critical loads for three different failure modes in Eqs (1-3), critical values of $\lambda$ and $b/t$ can be determined at balanced failures when 1) $P_c = P_{cr}$; 2) $P_{local} = P_c$; 3) $P_{cr} = P_{local}$.

Table 5 lists the critical values of $\lambda$ and $b/t$ derived from the balanced failure scenarios for a GFRP SHS column with the boundary condition of CCSS. The results show that non-dimensional slenderness $\lambda$ is an important parameter to distinguish compressive failure and global buckling. When $\lambda > 1$, global buckling will occur because the global buckling load is less than compressive failure load, and vice versa. Critical ratio of width to thickness $(b/t)_{critical}$ plays an important role to distinguish compressive failure and local buckling. As can be seen from Eqs. (7) and (8), $(b/t)_{critical}$ can be calculated based on the material properties of GFRP columns. If $b/t$ is greater than $(b/t)_{critical}$, local buckling will occur because the local buckling load is less than compressive failure load, and vice versa. Finally, local buckling will occur prior to global buckling if the $b/t$ is greater than $\lambda(b/t)_{critical}$, and vice versa. Similar formulations can be derived for a GFRP SHS column considering the boundary condition of SSSS.

<td>$b/t &gt; \lambda \cdot (b/t)<em>{critical}$, local buckling; $b/t &lt; \lambda \cdot (b/t)</em>{critical}$, global buckling.</td>
</tr>
</tbody>
</table>

The results for both SSSS and CCSS boundary conditions are illustrated in Figure 8. In Figure 8, three types of failure modes are located in three regions formed by boundary lines (determined from balanced failure scenarios) for two boundary conditions (SSSS and CCSS). Compressive failure and local buckling are separated by the boundary according to the balanced failure, i.e. $P_{local} = P_c$, in the form of a horizontal line, only relating to critical values of $b/t$. Global buckling and compressive failure are separated by the boundary according to the balanced failure, i.e. $P_c = P_{cr}$, in the form of a vertical line where $\lambda = 1$. The boundary line between local buckling and global buckling, is obtained considering balanced failure when $P_{cr} = P_{local}$. Therefore it is related to both $\lambda$ and $b/t$.

**Figure 8 Failure modes map for a GFRP column**

**Load-carrying capacities**

The load-carrying capacity of GFRP columns under compression is determined by their failure modes. Commonly, load-carrying capacity is given in the form of reduction factor $\chi$. Based on previous analysis on the failure modes map for a GFRP column, it can be drawn as the functions of $\lambda$ and $b/t$ as summarized in Table 6.

Figure 9 Load-carrying capacity of a GFRP column against $\lambda$ and $b/t$

Figure 9 presents the load-carrying capacity of a GFRP column as a function of both $\lambda$ and $b/t$. The relationship reveals that for short and thick columns with small $\lambda$ and $b/t$, compressive failure is the dominant failure mode. The increase in both $\lambda$ and $b/t$ reduces the load-carrying capacities of GFRP columns, but with different effects on $\chi$. For global buckling failure, $\chi$ is only related to $\lambda$; while for local buckling failure, $\chi$ is related to the actual value of $b/t$ and its critical value $(b/t)_{critical}$.

**RESULTS AND DISCUSSIONS**

Experimental results from Cardoso et al. (2014) and own study (Xie et al. 2016) were summarized to validate above failure modes map. In the latter two SHS sections with similar material properties but different $b/t$ (section A = 10.2, section B = 16.7) were used to investigate the effects of $b/t$ on failure modes and load-carrying capacities.

Figure 10 presents the failure modes of the GFRP columns investigated and the corresponding critical values of $\lambda$ and $b/t$.

Figure 11 Load-carrying capacities for sections with different $b/t$ compared with experimental data
In Figure 10, the critical \( b/t \) values at boundary conditions SSSS and CCSS are calculated from Eqs (3), (4) and (7) based on the GFRP materials properties, resulting into 10.82 and 14.82 respectively for section A and B used in this study. Then the boundary lines for three different failure modes are calculated according to formulations in Table 5 and plotted in Figure 10. Experimental results with different failure modes are summarized according to their \( \lambda \) and \( b/t \) in hollow points (Cardoso et al. 2014) and solid points (Xie et al. 2016) in this failure modes map. Results reveal that satisfactory agreement are received between theoretical predictions and experimental results. Specimens with \( b/t \) less than the critical value and \( \lambda \) less than 1 exhibited compressive failure; and specimens with \( \lambda \) greater than 1 and \( b/t \) less than the critical value exhibit global buckling. For specimens with \( b/t \) greater than the critical values, local buckling is observed. In the transition regions between boundary conditions SSSS and CCSS and \( \lambda = 1 \), interactions between local buckling and global buckling are observed from experimental results. It demonstrated that using this failure modes map to predict the failure mode of a GFRP column is feasible.

The load-carrying capacities of sections with two different \( b/t \) values and slenderness are shown in Figure 11. Based on the previous analysis in Table 6 and Figure 9, the load-carrying capacities, in the form of reduction factor \( \chi \), is related to \( \lambda \) and \( b/t \) values of GFRP columns. Two load-carrying capacity curves, corresponding different \( b/t \) values of 10.2 for section A and 16.7 for section B respectively, are formed in Figure 11. The curve for section A represents the columns will fail in form of compressive failure when \( \lambda < 1 \) and the critical load is therefore dominated by the compressive failure load \( P_c \). When \( \lambda > 1 \), such the columns with \( b/t \) value of 10.2 will fail through global buckling. However, the curve for section B represents that local buckling may occur when \( \lambda < 1 \). This is because their \( b/t \) value (16.7) is greater than the critical value (14.82), and the load-carrying capacity is therefore dominated by the local buckling load. Again, global buckling will still occur for section B when \( \lambda > 1 \), resulting in a theoretical Euler curve.

Experimental results on critical loads for specimens on section A and B at different slenderness are summarized in Figure 11 using square and circular solid points. Results show overall consistence with the above discussions, that for section A specimens with \( \lambda = 0.8 \), the reduction factors \( \chi \) is close to 1 and exhibited compressive failure. Previous design curves (Barbero and Tomblin 1994, Puente et al. 2006) without considering of effects of \( b/t \) on compressive failure may not be able to predict the critical loads here; with \( \lambda > 1 \), the reduction factors \( \chi \) is dominated by Euler curve. A slight deviation on \( \chi \) between experimental results and predictive curve is found on specimens with \( \lambda = 1.22 \). The reason may be due to imperfections on columns leading to global buckling at \( \lambda \) around 1. For experimental results on section B, specimens with \( \lambda = 0.8 \) and 0.83 exhibited local buckling failure, resulting \( \chi \) as 0.74 and 0.76 respectively, which is close to the theoretical prediction strength curve for \( b/t = 16.7 \). For specimens with \( \lambda = 1.20 \) and 1.24, interaction between local buckling and global buckling were found in the experiments, and the reduction factors \( \chi \) as 0.79 and 0.76, compared well with the theoretic predictions.

**CONCLUSIONS**

In this paper, the effects of non-dimensional slenderness \( \lambda \) and width-thickness ratio \( b/t \) on the failure modes and load-carrying capacities of GFRP SHS columns are theoretically analysed. Critical values for \( \lambda \) and \( b/t \) are received for GFRP SHS columns considering both boundary conditions SSSS and CCSS. These Critical values obtained from analytical formulations determine the boundaries between three different failure modes. A failure modes map for GFRP SHS columns under compression considering the effects of \( \lambda \) and \( b/t \) is therefore obtained. It shows that local buckling will occur if \( b/t \) is greater than a critical value \( (b/t)_{critical} \); compressive failure will occur if \( b/t \) is less than the critical value \( (b/t)_{critical} \); global buckling will occur if \( \lambda > 1 \) and \( b/t < \lambda (b/t)_{critical} \). Experimental results from two SHS with different \( b/t \) at different \( \lambda \) and literatures are used to validate theoretical predictions on failure modes and load-carrying capacities of GFRP SHS columns. Overall, good agreements are demonstrated for the failure modes and load-carrying capacities between theoretical predictions and experimental results.

EXPERIMENTAL STUDY ON BOND BEHAVIOR BETWEEN CONCRETE AND GFRP PULTRUDED I-SECTION USING PUSH-OUT TEST

J.S. Yuan and M.N.S. Hadi
School of Civil, Mining and Environmental Engineering, University of Wollongong, Australia. Email: jy960@uowmail.edu.au

ABSTRACT

This paper presents the experimental results of a push-out test on the bond behavior between glass fiber reinforced polymer (GFRP) I-section and concrete. The specimen is in the form of a concrete rectangular column with the GFRP I-section (I-section) encased in the middle. Four specimens with different configurations were cast and tested. The main parameters involved bond length and the transverse stirrups. The specimens were divided into two groups in accordance to the bond length. The two specimens in Group A had the same bond length of 300 mm, and the transverse steel stirrups were used at one of the specimens. The bond length of the two specimens in Group B was 450 mm, and one of the specimens was also reinforced with stirrups. Push-out was used to conduct this test and all the I-sections were pushed out. The experimental results show that I-sections with longer bond length have high ultimate bond strength. The development of cracks on the concrete is reduced by the stirrups. Nevertheless, the ultimate bond strength of the specimen is not improved when stirrups were used. In addition, a preliminary bond stress-slip model is proposed, and the theoretical results are in close agreement with the experimental results.

INTRODUCTION

Considerable studies have been conducted about the application of GFRP pultruded profiles in hybrid structures in recent years (e.g. Kumar et al. 2004; Correia et al. 2007; EI-Hacha and Chen 2012; Kwan and Ramli 2013). Traditionally, enough bond strength is significant to ensure the transfer of load in hybrid structures (e.g. Malvar et al. 2003; Majdi et al. 2014; Barbieri et al. 2016). Nevertheless, the studies about the bond behavior between GFRP pultruded profiles and concrete are so far limited. Most of the studies about the bond behavior of Fiber Reinforced Polymer (FRP) to concrete are related to FRP strips as well as FRP bars (e.g. Teng et al. 2002; Lu et al. 2005; Lu et al. 2006; Baena et al. 2009; Vilanova et al. 2015). For FRP strips and GFRP pultruded profiles, the bond mechanism at the interface between FRP and concrete is different. Usually the epoxy resins are used to bond the FRP strips on the surface of concrete, therefore, the bond force is mainly offered by the adhesion force of the epoxy. In terms of FRP bars, although no epoxy resins are used between the concrete and FRP bars, the size effect cannot be ignored since the FRP pultruded profiles traditionally have a large surface. Therefore, the previous bond-slip theories for FRP strips and FRP bars are not suitable for the GFRP pultruded profiles.

Due to the increasing application of GFRP pultruded profiles in the hybrid structures, there is a pressing need to investigate the bond behavior between GFRP pultruded profiles and concrete. Therefore, in this experimental study, the bond behavior between GFRP pultruded profiles and concrete was investigated preliminarily. The GFRP pultruded profiles used in this research study was I-section, and the tests were conducted using push-out. The Parameters investigated in this study included the bond length and stirrups. Based on the experimental results, the bond stress-slip curves at the loaded end were analyzed. Furthermore, the mechanism of the load transfer along the interface between the I-section and the concrete was discussed. Lastly, a preliminary bond stress-slip constitutive model was proposed to predict the bond stress, and the predictions from this model were in close agreement with the experimental results.

EXPERIMENTAL PROGRAM

Design of Specimens

A total of four specimens (Figure 1) were fabricated and tested. Four specimens have the same cross-section with a width of 200 mm and a length of 350 mm. The dimension of the I-section was 10 mm in thickness (both in flange and web), 100 mm in width and 200 mm in height. For all the specimens, the I-section was placed at the center of the concrete, and the web of which was parallel with the long side of the cross-section. A part of the I-section (50 mm or 100 mm height) at the loaded end was left outside of concrete for pushing out. A 50 mm height debonding zone was left at the bottom of the I-section for the debonding. This debonding zone was used to avoid the failure of the concrete around the bottom end of the I-section during the test. Table 1 shows the different configurations of the specimens. The label of the specimens consists of two parts. The first part is the letter A or B indicating the name of the group, and the second part is the letter S denoting that the stirrups were used in this specimen.

Four specimens were divided into two groups (Group A and Group B) in accordance with the different bond length. The bond length of two specimens in Group A is 300 mm. Specimen A was composed of I-section and concrete as shown in Figure 1(a). Steel stirrups were used in Specimen AS to investigate the effect of stirrups on the bond strength [Figure 1(b)]. In order to analyze the influence of the bond length, the bond length of two specimens in Group B were extended to 450 mm. Specimen B in Figure 1(c) was composed of concrete and the I-section. Concrete in Specimen BS was confined by stirrups [Figure 1(d)].

Material Properties and Test Setup

For R10 steel bars, five samples were tested in tension based on the AS 1391 (2007), and the average tensile yield strength was 309 MPa. Concrete cylinders (100 mm × 200 mm/diameter × height) were cast to determine the compressive strength of concrete, and the average compressive strength of concrete at 28 days was 31.8 MPa. The I-sections were provided by the Treadwell Group Company (Treadwell 2016), and were manufactured by a pultrusion technology. The material properties of the I-section were determined in the longitudinal direction both in the web and flange. Tensile testing was conducted following ISO 527 (1997) and the dimension of the five coupons was 25 mm × 250 mm. The average tensile strength was 381 MPa at the flange and 353 MPa at the web. The compressive testing was conducted using ASTM: D695 (2002). Five coupons with dimensions of 12.7 mm × 38.1 mm were tested. The average compressive strength of the coupons was 214 MPa at the flange and 234 MPa at the web.

The push-out test was conducted using the 5000 kN testing machine. As shown in Figure 2(a) and Figure 2(b), the specimens were placed vertically on the testing machine. Two steel blocks were placed under the bottom of the specimen. Adequate space under the specimen was left for the slip of the I-section. One steel plate was placed horizontally at the top of the I-section to distribute the load uniformly. The load and displacement data were
recorded by an electronic data-logger connected to a computer every 2 seconds. After all these setups were done, the specimens were loaded by a displacement controlled load with a rate of 0.1 mm/min. When the I-section was pushed out and the load did not increase, the test was terminated.

EXPERIMENTAL RESULTS AND DISCUSSION

Bond Stress-slip Curves

Table 2 shows the experimental results of the push-out test. The ultimate bond load \((P_s)\) and ultimate load \((P_u)\), ultimate bond stress \((\tau_s)\) and the ultimate stress \((\tau_u)\), the definition of which is discussed in the following sections. All the bond stress mentioned in this study is the average bond stress \((\tau)\) and it is computed as:

\[
\tau = \frac{P}{A}
\]

where \(A\) is the bond area of the I-section and \(P\) is the applied load at the loaded end.

All the I-sections in the four specimens were pushed out, and the four specimens showed similar bond stress-slip curves as shown in Figure 2(c). The representative bond stress-slip curve is shown in Figure 3(a). In the first stage (O-A), the initial bond stress increased slowly. Afterwards, the bond stress almost linearly increased from Point A to ultimate bond stress \((\tau_s)\) at Point B with a larger slope. After Point B, the bond stress curve experienced a slight decrease to Point C, and then increased again to the ultimate stress \((\tau_u)\) at Point D. A descending branch could be observed after Point D. Finally, the slip showed a stable increase and the I-section was pushed out gradually.

**Slip process of I-section**

The surfaces of GFRP pultruded profiles are smooth, so the influence of the mechanical bearing force on the bond strength can be ignored for the I-section. Only the chemical adhesion force and the friction force were considered for the bond strength between the I-section and the concrete. The slip process of the I-section is analyzed in Figure 3(b). In this study, the interface between the I-section and the concrete was divided into two zones, the bond zone and the slip zone. The interface in the bond zone was intact without slip, so the bond force in the bond zone was mainly dependent on the chemical adhesion force and the friction force. In the slip zone, the chemical adhesion force was degraded which was attributed to the slip at the interface, so only the friction force contributed to the bond force.
When the I-section was loaded in the initial stage (O-A) as shown in Figure 3(b), the entire interface between the concrete and the I-section was the bond zone which provided the bond force to balance the applied load. As the increase of the applied load, the average bond stress was further improved to balance the increase of the load. Afterwards, different deformation between the concrete and the I-section was enlarged and caused a sudden relative slip at the interface. Therefore, a small slip zone occurred at the top end of the specimen (Point A). This relative slip damaged the original interface and caused the disappearance of the chemical adhesive force. Then, only the friction force was left in this slip zone. It was the reason why a fluctuation at Point A occurred as shown in Figure 3(a). Afterwards, the slip zone was increased further with the increase of the average bond stress and the applied load (Stage A-B). When the bond stress reached the ultimate bond stress (Point B), the I-section could not provide larger bond strength. As a result, the equilibrium of the force was destroyed and the original interface was broken totally. The I-section was pushed out at Point B, and a slight drop at the bond stress-slip curves was observed at the same time. Then, the slip zone was extended to the whole interface (Stage B-C).

The sudden slip at Point B caused a coarse interface with a larger friction coefficient. This new interface could provide a larger friction force to balance the applied load. Hence, the applied load increased again from Point C, and the ultimate load (\(P_u\)) was obtained at Point D as shown in Figure 3(a). With the increase of the slip, the interface was smoothed, as a result, the friction coefficient was decreased, and the load and the friction force reached the equilibrium state again. Lastly, the I-section was pushed out gradually.

Although the ultimate stress (\(\tau_u\)) was obtained at Point D, this maximum stress could not reflect the bond behavior based on the above-mentioned analyses. At Point D, the original interface had been broken totally, and the ultimate stress (\(\tau_u\)) was mainly dependent on the friction force, rather than the chemical adhesion force. Moreover, the influence of the randomness of stage B-C on the stress at Point D cannot be predicted. While the stress at Point B was mainly dependent on the chemical adhesion force at the interface, which could reflect the bond behavior more reasonably. Therefore, the bond stress at Point B was considered as the ultimate bond stress (\(\tau_u\)) in this study.

**Effect of Stirrups and Bond Length**

Based on the analyses of the test results, the bond strength was not improved by the application of stirrups. The reason for this may be that the application of stirrups affected the vibration of concrete during the casting, causing a decrease of the bond at the interface. Nevertheless, the development of the cracks was reduced by stirrups at Specimen AS and Specimen BS.

In terms of the bond length, many previous studies have proved that the bond behavior of steel bars or FRP bars was affected by the bond length, for example, Baena et al. (2009), Lin and Zhang (2013) as well as Torre-Casanova et al. (2013). In this experimental study, the influence of the bond length was investigated through the comparison between Group A and Group B. The test results showed that the longer bond length improved the ultimate bond stress (\(\tau_u\)) at the interface between the I-section and the concrete. For example, the ultimate bond stress (\(\tau_u\)) increased from 0.46 MPa in Specimen A to 0.51 MPa in Specimen B due to the increase of the bond length.

**THEORETICAL ANALYSIS**

Several bond stress-slip constitutive models for FRP bars have been proposed in recent years, and a detailed review had been conducted by Lin and Zhang (2014). Among these models, the BPE model proposed by Eligehausen et al. (1982) is the classical model. This model was developed for the bond of steel bars to concrete, and then successfully used for the bond behavior of FRP bars to concrete by Rossetti et al. (1995). The bond stress-slip
curve in this model is divided into different parts based on some parameters, such as the ultimate bond stress ($\tau_s$), the slip corresponding to the peak bond stress ($s_{ts}$) and the parameters $s_1$, $s_2$, $\alpha$ and $\beta$. This bond stress-slip relationship is given as below:

$$\tau = \tau_s \left( \frac{s}{s_{ts}} \right)^{\alpha} \quad (0 < s \leq s_{ts}) \quad (2)$$

$$\tau = \tau_s \left( s_{ts} < s \leq s_1 \right) \quad (3)$$

$$\tau = \tau_s - (\tau_s - \tau_r) \left( \frac{s - s_1}{s_2 - s_1} \right) \quad (s_1 < s \leq s_2) \quad (4)$$

$$\tau = \tau_r = \beta \tau_s \left( s_2 < s \right) \quad (5)$$

Due to the similar material properties for GFRP bars and GFRP I-section, the BPE model is used to investigate the bond behavior of the GFRP I-section to concrete in this study. During the test, the original interface was broken at Point B, and the stage B-C was difficult to predict due to the randomness. Therefore, the model in this study just focuses on the curvilinear ascending branch of the bond stress-slip curves. Using curve fitting on the experimental results, the parameter $\alpha$ in Eq. 2 is determined as 2.5. Therefore, the bond stress-slip relationship in this study is proposed as:

$$\tau = \tau_s \left( \frac{s}{s_{ts}} \right)^{2.5} \quad (0 < s \leq s_{ts}) \quad (6)$$

where $s$ is the slip at the loaded end and $\tau$ is the average bond stress. The comparison between the theoretical model and the test results are presented in Figure 4. The test results of the ultimate bond stress ($\tau_s$) and the loaded end slip ($s_{ts}$) are used in this calculation. A close agreement is observed in the ascending branch for the four specimens.

The prediction of the bond stress in Eq. 6 requires the given ultimate bond stress ($\tau_s$) and the given loaded end slip ($s_{ts}$). For GFRP bars, some empirical equations were proposed to obtain this bond stress ($\tau_s$) and the corresponding slip ($s_{ts}$). Nevertheless, as a preliminary test, the data is not sufficient for an accurate empirical model to predict these two parameters in this study. Therefore, more studies should be conducted to estimate the ultimate bond stress ($\tau_s$) and the loaded end slip ($s_{ts}$).

CONCLUSION

In this paper, the experimental results and the bond stress-slip model on the bond behavior between the GFRP I-section and the concrete were reported firstly. Four specimens with different configurations were tested using push-out. Based on this research study, the following conclusions are drawn:
The bond behavior of the GFRP I-section to concrete is influenced by stirrups and the bond length. The ultimate bond strength cannot be improved by the stirrups in this study. However, the development of cracks on the concrete is delayed by the application of stirrups. The ultimate bond stress is improved by the longer bond length. A theoretical model is proposed to predict the bond stress-slip relationship at the loaded end of the I-section. The results of the proposed model are in close agreement with the experimental results. Nevertheless, this model is based on the given ultimate bond stress ($\tau_u$) and the corresponding loaded end slip ($s_{te}$). As a preliminary study, the ultimate bond stress and the corresponding loaded end slip cannot be predicted in this study, so a method for predicting the ultimate bond stress and the corresponding loaded end slip needs to be established in future.

ABSTRACT

The objective of the study presented in this paper is to expand the understanding of the compression behaviour of square concrete columns internally reinforced with Glass Fiber Reinforced Polymer (GFRP) bars. A total of six columns were tested with the test variables being the type of internal reinforcement (steel bars and GFRP bars) and magnitude of load eccentricity. Results from this study showed that GFRP reinforced columns achieved a lower load carrying capacity as compared to the steel reinforced column specimens for both concentric and eccentric loading conditions. The load carrying capacity of the concentrically loaded GFRP reinforced column was 4.8% lower than its steel counterpart; whereas the load carrying capacity of the eccentricity loaded GFRP reinforced specimens were on average 18.5% lower than their steel counterparts. In addition, the eccentrically loaded GFRP columns achieved an increase in load after concrete spalling unlike the steel reinforced columns.

KEYWORDS

Reinforced concrete column, GFRP bar, eccentric loading, ductility.

INTRODUCTION

The use of reinforcement with FRP composite materials have emerged as one of the alternatives to steel reinforcement for concrete structures prone to corrosion issues (ACI 440.1R–15 2015). However, the mechanical behaviour of FRP reinforcement is different from that of steel reinforcement. In general FRP bars have a higher strength-to-weight ratio, but lower Young’s modulus as compared to steel. Furthermore, when subjected to tension, FRP bars do not experience any plastic behaviour before rupture. Also, the compressive strengths of FRP bars are relatively low compared to the tensile strengths and are subjected to significant variations. Therefore, due to the differences in properties, GFRP bars cannot simply replace steel bars (ISIS 2007). The level of understanding of the behaviour of FRP reinforced compression members has not reached a level where design standards are available for such members. Having said this, the current ACI 440.1R – 15 (2015) design guideline mentions to neglect the compressive contribution of FRP reinforcement when used as reinforcement in columns, in compression members, or as compression reinforcement in flexural members.

Most of the findings of studies investigating FRP reinforced concrete columns have been reported based on testing under concentric loading (Afifi et al. 2014; Tobbi et al. 2012; De Luca et al. 2010). However, in reality for columns nominally carrying only axial compression load, bending moments always exist due to unintentional load-eccentricities and construction errors.

Consequently, this study investigates the behaviour of GFRP-reinforced concrete columns subjected to concentric and eccentric loading. A total of six columns were tested and the failure modes and ductility of the columns were reported based on the results of the experimental program.

EXPERIMENTAL PROGRAM

Design of Columns

In this study, six square concrete columns were cast and tested under concentric and eccentric loads. All the columns had a side dimension of 210 mm and a height of 800 mm. The columns were divided into two groups.
Table 1 shows the test matrix. The first group of columns were reinforced longitudinally and transversally with steel bars (Group RS). The second group of specimens were reinforced with GFRP bars (Group RF). For comparison purposes, the longitudinal and transverse reinforcement ratios of the two groups of specimens were similar. Each group consisted of three specimens with one specimen tested concentrically, one tested under 25 mm eccentricity and one tested under 50 mm eccentricity. The columns are identified by the type of internal reinforcement and magnitude of load eccentricity. For example, Column RF-50 is reinforced with GFRP bars and is eccentrically loaded at 50 mm from the centreline.

### Material Testing

All the concrete columns were cast on the same day with ready-mixed, normal strength concrete provided by a local supplier. The average compressive cylinder strength of the concrete at 28 days as determined by the test method AS 1012.9-1999 (Standards Australia 1999) was 29.3 MPa. The Group RS columns were longitudinally reinforced with deformed steel N12 bars and transversally reinforced with plane steel R10 bars fabricated into square ties. The tensile properties of the steel bars were determined in accordance with AS 1391-2007 (Standards Australia 2007) and are reported in Table 2. Sand coated #4 GFRP bars with a nominal diameter of 12.7 mm and #3 GFRP square stirrups of 9.5 mm nominal diameter were used as longitudinally and transverse reinforcement, respectively. Four samples of each diameter were tested in accordance with ASTM D7205-06 (2011) to determine the tensile properties of the GFRP bars, as shown in Table 2. The GFRP reinforcement was supplied by Pultrall Inc. (2012) with a sand-coated surface to improve the bond performance between the bars and surrounding concrete. According to Ehsani et al. (1995) the minimum ratio of radius of bend to the stirrup diameter for GFRP bars is three. However, in this study the radius of bend was only 12.7 mm due to manufacturing errors.

### Column Preparation

The formwork used for moulding the concrete columns was made from 17 mm thick plywood. The longitudinal steel and GFRP bars were cut to 760 mm to ensure a clear cover of 20 mm was maintained at the top and bottom of the reinforcement cage. The steel stirrups used in the Group RS columns were fabricated having similar dimensions to that of the GFRP stirrups but varied in the radius of the bends, as shown in Figure 1. To prevent premature failure at the ends of the columns, two layers of CFRP sheets were wrapped around the top and bottom of the columns with a width of 100 mm. To prevent stress concentrations at the sharp edges, a corner radius of 20 mm was applied at the locations of the CFRP sheet wrapping. In addition, for each eccentrically loaded column specimen, two layers of CFRP wrap were applied longitudinally on the tension zone in combination with the two layers wrapped circumferentially to ensure no premature tensile failure occurred at these regions.
INSTRUMENTATION AND COLUMN TESTING

All of the specimens were tested with the Denison 5000 kN compression testing machine until failure at the University of Wollongong, Australia. The top and bottom ends of the columns were capped with high strength plaster to ensure the bearing surfaces were parallel and the load was distributed evenly during testing. The eccentric load was applied to the column specimen by the interaction of two loading heads attached to both ends of the columns, as illustrated in Hadi and Widiarsa (2015) and shown in Figure 2. Two linear variable differential transformers (LVDT’s) were connected directly to the testing machine at both ends to measure the axial displacements. In addition, a laser triangulation was positioned horizontally at mid-height of the eccentrically loaded columns on the tension side to measure the lateral deflections (δ). The LVDTs and laser triangulation were connected to a data logger to record readings on a control computer at a user controlled time interval.

EXPERIMENTAL RESULTS AND DISCUSSION

Failure modes

The failure modes of the concentrically and eccentrically loaded columns are shown in Figure 3. The failure of the steel reinforced column under concentric loading was marked by the buckling of the four longitudinal bars.
However, the failure mode of the GFRP reinforced column under the same loading was brittle in nature and occurred by the explosive rupture of some of the stirrups and the longitudinal bars. In addition, it was seen that one stirrup experienced slippage (at the splice locations) of the overlap regions.

The failure pattern of the steel reinforced eccentrically loaded columns was characterized by the buckling of the longitudinal bars in compression after the spalling of the concrete cover in the compression region. On the other hand, the failure region of the eccentrically loaded GFRP reinforced was at the top of the specimen in compression and was due to the explosive rupture of the GFRP stirrups and longitudinal bars. This failure area away from the instrumented region may have been due to stress concentrations at the transition of the sharp and rounded edges at the top and bottom ends of the columns. The bars in tension did not fail for all columns.

Ductility and Behaviour of Columns

The experimental results of all the columns are summarized in Table 3. The axial and lateral-displacement relationship of the columns is also shown in Figures 4-6. Initially, all the columns experienced similar behaviour, with the ascending region of the load-displacement curve being almost linear up to the beginning of concrete spalling. A decrease in maximum load of 4.8% relative to Column RS-0 was achieved for Column RF-0. However, a decrease in first maximum load of 19.3% and 17.7% relative to Column RS-25 and RS-50, respectively, was achieved for Column RF-25 and RF-50, respectively. It should be noted that the initial slope of the load-displacement curve of Specimen RF-25 was lower than that of the other specimens which could be due to errors in aligning the specimen resulting in load not being applied exactly at 25 mm eccentricity.

The ductility ($\lambda$) of the columns was calculated based on the ratio of the ultimate displacement ($\delta_u$) divided by the yield displacement ($\delta_y$). For the steel reinforced columns, no increase in strength occurred after concrete spalling and the ultimate displacement was taken at 80% of $P_{\text{max}}$. However, the GFRP reinforced columns were able to sustain an increase in load after the sudden concrete spalling and eventually a second peak load ($P_{\text{peak}}$) was achieved. Therefore, for the GFRP reinforced columns the ultimate displacements was taken at either the first fracture load of the GFRP reinforcement ($P_{\text{fracture}}$), at the peak load ($P_{\text{peak}}$) or at 80% of $P_{\text{peak}}$, whichever gave the smallest axial displacement. For the eccentric loaded GFRP specimens, it was safer to define the ultimate displacement at this peak load rather than at 80% of peak load considering the unpredictable and sudden brittle failure of the internal GFRP reinforcement after peak load unlike the ductile failure mode of the steel reinforced columns.

Based on the ductility definition, the ductility of Column RS-0 was substantially greater than the ductility of the Column RF-0. On the other hand, the ductility of the 25 mm eccentrically loaded columns was similar while the ductility of Column RF-50 was higher than that of Column RS-50. Having said this, the eventual failure mechanism of the GFRP reinforced columns was sudden in nature and brittle, whereas the steel reinforced columns did not fail suddenly but continued to displace until the termination of testing.

CONCLUSIONS

Based on the experimental results of this study, the following conclusions can be drawn: 1. The steel reinforced columns achieved a higher load carrying capacity as compared to the GFRP reinforced columns for all loading conditions; 2. The load carrying capacity Column RF-0 was 4.8% lower than its steel counterpart; whereas the load carrying capacity of Columns RF-25 and RF-50 loaded eccentrically were on average 18.5% lower than their steel counterparts; 3. The eccentrically loaded GFRP columns achieved an increase in load after concrete spalling unlike the steel reinforced columns; and 4. The ductility of the concentrically loaded steel reinforced column was substantially higher than that of the equivalent GFRP reinforced column. However, the ductility of the eccentrically loaded columns was comparable and even higher than that of the equivalent steel reinforced columns. However, the eventual failure of the GFRP reinforced columns was brittle and sudden in nature.

ABSTRACT

Hybrid fiber-reinforced polymer (FRP)-concrete-steel double-skin tubular columns (DSTCs) consist of an outer tube made of FRP and an inner tube made of steel, with the space between filled with concrete. A significant amount of research has been conducted on hybrid DSTCs with an outer tube made of glass FRP (GFRP), carbon FRP (CFRP), or aramid FRP (AFRP). One important finding of the existing research is that the ductility of the column depends significantly on the rupture strain of the FRP tube, among other factors. Against this background, this paper presents an experimental study where hybrid DSTCs with a large rupture strain (LRS) FRP tube, namely, polyethylene terephthalate (PET) FRP tube, were tested under axial compression. PET FRP composites have emerged recently as an economical and environmentally friendly material with a rupture strain of over 7%. Results from a total of four DSTC specimens are presented, with the main test variable being the thicknesses of the steel tube. The test results confirmed the ample ductility of the column and suggested that the diameter-to-thickness ratio of the inner steel tube is a more critical parameter in such DSTCs than in DSTCs with a GFRP, AFRP or CFRP outer tube.

KEYWORDS

FRP, steel, concrete, large rupture strain, confinement, buckling.

INTRODUCTION

Hybrid fiber-reinforced polymer (FRP)-concrete-steel double-skin tubular columns (referred to as hybrid DSTCs) are an emerging form of hybrid columns proposed at The Hong Kong Polytechnic University (Teng et al. 2004, 2007). A hybrid DSTC consists of an outer tube made of FRP and an inner tube made of steel, with the space between filled with concrete (Figure 1). In hybrid DSTCs, the three constituent materials (i.e. FRP, steel and concrete) are optimally combined to achieve several advantages including their excellent corrosion resistance and ductility (Teng et al. 2007). A significant number of studies have been conducted on hybrid DSTCs (e.g. Wong et al. 2008; Yu et al. 2010; Yu and Teng 2013; Fanggi and Ozbakkaloglu 2013; Ozbakkaloglu and Louk Fanggi 2014). The existing studies, however, have generally been limited to the use of an outer tube made of glass FRP (GFRP) (e.g. Wong et al. 2008), carbon FRP (CFRP) (Fanggi and Ozbakkaloglu 2013) or aramid FRP (AFRP) (Fanggi and Ozbakkaloglu 2014). GFRP, CFRP and AFRP are referred to collectively as conventional FRPs hereafter in this paper. One important finding of the existing research is that the ductility of the column depends significantly on the rupture strain of the FRP tube, among other factors. Against this background, this paper presents results from stub column tests of four hybrid DSTCs with a large rupture strain (LRS) FRP tube, namely, polyethylene terephthalate (PET) FRP tube. PET FRP composites have emerged recently as an economical and environmentally friendly material with a rupture strain of over 7%. During the test, the buckling of steel tube in hybrid DSTCs, which is expected to occur under large axial deformations, was paid special attention to.

TEST SPECIMENS

The hybrid DSTC specimens included two pairs of specimens; each pair of specimens were nominally identical. The specimens all had a nominal diameter (i.e. the outer diameter of concrete) of 208 mm and a height of 500 mm. The FRP outer tubes were all composed of three plies of PET-FRP, while two types of steel tubes (i.e. Types A and B) were used. Types A and B steel tubes had the same outer diameter of 139.7 mm, but had thicknesses of 3.5 mm and 5.4 mm respectively, leading to two different diameter-to-thickness (D/t) ratios (i.e. 39.9 and 25.9 respectively). For ease of reference, each specimen is given a name, which starts with a letter to indicate the type
of the steel tube (i.e. A or B) together with an Arabic numeral to indicate the number of plies of FRP (i.e. 3); the Roman numeral at the end is used to differentiate two nominally identical specimens.

![Figure 1 Cross-section of hybrid DSTCs with a PET-FRP tube](image)

All specimens were cast in one batch using ready-mix concrete from a local manufacturer. Results from three standard concrete cylinder (150 mm x 300 mm) tests showed that the elastic modulus, compressive strength and compressive strain at peak stress of the concrete were 25.2 GPa, 28.4 MPa and 0.0025 respectively. For each type of steel tube, tensile tests of two steel coupons were conducted. The average values of elastic modulus, yield stress and tensile strength are 193 GPa, 325 MPa and 470 MPa respectively for Type A steel tubes, while are 194 GPa, 270 MPa and 360 MPa for Type B steel tubes. In addition, tensile tests on six coupons were conducted to determine the mechanical properties of the PET-FRP tube and these tests showed that the PET-FRP used in the present study had an average rupture strain of 0.0956 and an average tensile strength of 823.9 MPa based on a nominal thickness of 0.819 mm per ply.

**TEST SET-UP AND INSTRUMENTATION**

For each specimen, four axial strain gauges and four hoop strain gauges with a gauge length of 20 mm were installed on the outer surface of the FRP tube. These strain gauges were evenly distributed around the circumference at the mid-height of the specimen, with one located at the centre of the overlapping zone. In addition, two axial strain gauges with a gauge length of 10 mm were applied at the mid-height of the steel tube for each specimen. For each specimen, two linear variable displacement transducers (LVDTs) placed 180° apart from each other were used to measure the overall axial shortening, while another two LVDTs placed 180° apart from each other were used to measure the axial deformation of the 150 mm mid-height region. The layout of these LVDTs and the test set-up are shown in Figure 2. To monitor the buckling process of the inner steel tube in the DSTC specimens, a portable action camera was installed on the bottom surface of the top loading plate (Figure 2). All the compression tests were conducted at the University of Wollongong using a 500 ton Denison Compression Testing Machine with a displacement control rate of 0.6 mm per minute.

![Figure 2 Test set-up](image)

**TEST RESULTS AND DISCUSSIONS**

**General Behaviour**

All specimens failed by hoop rupture of the FRP tube at or close to the mid-height of the specimens (Figure 3a). The inner steel tube experienced significant buckling (Figure 3b) which led to considerable load reduction during the test; such load reduction, however, could be recovered in the later stage of testing, and at the ultimate state (i.e. FRP rupture) the specimens could take even a higher load than the first peak (Figure 4). This observation is clearly
different from that from tests of DSTC specimens with a conventional FRP tube (Wong et al. 2008; Yu and Teng 2013; Fanggi and Ozbakkaloglu 2014), and is mainly due to the extremely large axial shortening that the steel tube in the PET-FRP DSTC specimens experienced. Another test observation associated with the extremely large axial deformation was the partial debonding and local buckling of the PET-FRP tube at the finishing end of the overlapping zone (Figure 3). Nevertheless, such debonding/buckling only happened within a small region at the very late stage of tests (i.e. close to the ultimate state), and is thus believed to have little effect on the overall behaviour of the specimens.

![Figure 3 Typical failure mode](image)

**Axial Load-Shortening Behaviour**

The axial load-shortening curves of the four specimens are shown in Figure 4, where all the curves are terminated at the point of FRP rupture. The curves of Specimens A3-I, II can generally be divided into three branches (Figure 4): (1) an approximately bilinear ascending branch before the peak load; (2) a gradual descending branch which was caused by inward buckling of the inner steel tube and the associated inward concrete spalling; (3) another ascending branch where the axial load increased approximately linearly with the axial shortening until the final failure by rupture of the FRP tube. It is evident that the curves shown in Figure 4 are significantly different from the axial load-shortening curves of DSTCs with a conventional FRP tube (Wong et al. 2008; Yu and Teng 2013; Fanggi and Ozbakkaloglu 2014) which typically had an approximately bilinear shape (i.e. similar to the first branch of the curves shown in Figure 4). This is not surprising as the rupture of FRP usually occurs before the first peak if conventional FRPs, which have a much smaller rupture strain than PET-FRP, are used to fabricate the outer tube. For Specimens B3-I, II, Figure 4 shows that the curves of may also be divided into three branches in the same way as discussed above for Specimens A3-I, II, but the load decrease in the second branch and the load increase in the third branch were both much less pronounced. The second and third branches of Specimens B3-I, II may thus also be seen as a single branch with an approximately constant load. It is evident that all the hybrid DSTCs possessed extremely good ductility with ultimate shortenings of up to around 16% of their heights (i.e. 500 mm).

![Figure 4 Axial load-shortening curves](image)
Buckling Behaviour of Inner Steel Tube

The inner steel tubes in the DSTC specimens experienced significant local buckling due to the extremely large axial shortening that they were subjected to, as well as the lack of internal support (Figure 3b). The deformed shapes of the inner steel tube at different stages of loading, as recorded by the action camera (see Figure 2), are shown in Figure 5 for Specimen B3-III. The four subfigures in Figure 5 are corresponding to four points on the load-shortening curve shown in Figure 4, respectively. The buckling process of the inner steel tube can be described as follows: (1) no apparent bucking occurred before the first peak (i.e. Point B), as evident from the deformed shape of the steel tube at Point A when the axial load was 98% that of Point B; (2) at Point B, a slight wrinkle was noticed (Figure 5-B); (3) the first wrinkle developed with the decrease of load, and new wrinkles appeared at various circumferential locations close to the mid-height of the tube (the numbers in Figure 5 indicate the order in which the wrinkles occurred); the wrinkles became quite significant at the trough point of the load-shortening curve (i.e. Point C, see Figure 5-C); (5) after Point C, no new wrinkles were formed, but the existing wrinkles kept progressing with an increasing load until the rupture of the FRP tube (see Figures 5-D).

Figure 5. Buckling process of inner steel tube

CONCLUSIONS

This paper has presented results from four stub columns tests on hybrid DSTCs with a large rupture strain FRP tube (i.e. PET-FRP tube). The test results showed that hybrid DSTCs with a PET-FRP tube possess extremely good ductility despite the severe buckling of the inner steel tube. The test result also showed that the behaviour of PET-FRP DSTCs depends significantly on the diameter-to-thickness ratio of the inner steel tube.

FRP-CONFINED CONCRETE-ENCASED CROSS-SHAPED STEEL COLUMNS: STUB COLUMN TESTS

L. Huang¹, T. Yu¹, S.S. Zhang¹ and Z.Y. Wang²

ABSTRACT

FRP-confined concrete-encased cross-shaped steel columns (FCCSCs) are a new form of hybrid columns recently developed at the University of Wollongong. An FCCSC consists of a square FRP outer tube, a cross-shaped steel section and concrete filled in between. This sectional configuration ensures that the concrete is very effectively confined despite the square shape of the column, and that the steel section is well protected and constrained by the FRP tube from corrosion and buckling, leading to a column that is highly ductile and corrosion-resistant. In this paper, results from a series of stub column tests are presented to demonstrate some of the expected advantages of the new column form.

KEYWORDS

FRP, steel section, concrete, tubular column, confinement.

INTRODUCTION

In the past two decades, fiber-reinforced polymer (FRP) has become increasingly popular as a confining material for both the strengthening of existing reinforced concrete columns (Teng et al. 2002) and for new construction (Teng et al. 2007; Yu et al. 2016a). As a result, extensive research has been conducted on the behavior of FRP-confined concrete (e.g. Fam and Rizkalla 2001; Teng et al. 2007; Yu et al. 2010). Existing studies have revealed that the FRP confinement is much more effective in circular columns than in square columns (Teng et al. 2002; Yu et al. 2013).

Against this background, a new form of hybrid columns incorporating an FRP confining tube has recently been developed at the University of Wollongong. The new form of columns is termed FRP-confined concrete-encased cross-shaped steel columns (FCCSCs). An FCCSC consists of a square FRP outer tube, a cross-shaped steel section and concrete filled in between (Figure 1). The square FRP tube typically has four rounded corners and contains fibers close to the hoop direction, while the width of the four flanges of the steel section is typically slightly smaller than that of the four flat sides of the FRP tube. In FCCSCs, the concrete is very effectively confined despite the square shape of the column: the cross-shaped steel section consists of two pairs of flanges connected by webs, so its confinement to the lateral expansion of the concrete infill depends on not only the flexural stiffness of the flanges, but also the axial stiffness of the web; this additional confinement is particularly important to the regions that are otherwise not effectively confined by the square FRP tube (i.e. the regions close to the four flat sides). In addition, the cross-shaped steel section serves as ductile longitudinal reinforcement needed for columns, in particular for those that are subjected to comparable loads in two lateral directions. The FRP tube protects the steel section from environment attacks and constrains its possible buckling, so a layer of concrete cover between the FRP tube and the steel flanges is not always needed. Nevertheless, in the cases where a thin steel section is used, such concrete cover may be provided to reduce the thickness of FRP tube needed for ductile response of the column. FCCSCs can be seen as a variation of concrete-filled FRP tubes with an embedded steel I-section (Karimi et al. 2011; Zakaib and Fam 2012; Yu et al. 2016b).

To demonstrate the concept of FCCSCs, results from two FCCSC specimens tested at the University of Wollongong are presented in this paper. For comparison, results of two square FRP-confined plain concrete (FCPC) columns tested in parallel with the FCCSC specimens are also presented.
TEST SPECIMENS

The test specimens included two nominally identical FCCSC specimens and two nominally identical FCPC specimens. The specimens all had a nominal width of 200 mm (width of the concrete core) and a height of 600 mm. The FRP tubes were fabricated via a wet-layup process by wrapping resin-impregnated glass fiber sheets around a foam core, with an overlapping length of 150 mm; the overlapping zone was limited within one side of the tube. The FRP tubes all had rounded corners with a radius of 25 mm, and were all composed of three plies of FRP. The cross-shaped steel sections were fabricated by welding two H-sections together (i.e. one was cut into two T-shaped sections before welding to the other), and their dimensions are also shown in Figure 1. When preparing for the specimens, the prefabricated FRP tubes were used as the mould for casting concrete; for each FCCSC specimen, a cross-shaped steel section was put into the square FRP tube, which was fixed to a wooden frame, before casting concrete.

All specimens were cast in one batch using ready-mix self-compacting concrete from a local manufacturer. Results from standard concrete cylinder (150 mm x 300 mm) tests showed that the compressive strength and compressive strain at peak stress of the concrete were 35.1 MPa and 0.0026 respectively. For the steel sections, tensile tests of steel coupons showed that the elastic modulus, yield stress and tensile strength are 216.6 GPa, 359.8 MPa and 516.5 MPa, respectively. In addition, an axial compression test was conducted on a steel section, which was identical to those in the FCCSC specimens, and the results showed that its ultimate load was 1662.5 kN. For the FRP tubes, tensile tests on FRP coupons showed that the FRP used in the present study had an average elastic modulus of 74.0 GPa based on a nominal thickness of 0.174 mm per ply.

TEST SET-UP AND INSTRUMENTATION

For each specimen, two linear variable displacement transducers (LVDTs) placed 180° apart from each other were used to measure the overall axial shortening, while another two LVDTs placed 180° apart from each other were used to measure the axial deformation of the 150 mm mid-height region. The layout of these LVDTs and the test
set-up are shown in Figure 2. In addition, for each specimen, five (for FCPC specimens) or seven (for FCCSC specimens) hoop strain gauges with a gauge length of 20 mm were used to measure the hoop strain distributions at the mid-height of the specimens. All the compression tests were conducted at the University of Wollongong using a 500 ton Denison Compression Testing Machine with a displacement control rate of 0.6 mm per minute.

**TEST RESULTS AND DISCUSSIONS**

**Failure Modes**

All the specimens, including g FCCSC specimens and FCPC specimens, failed by the rupture of FRP tube under hoop tension, but the location of FRP rupture was somewhat different for the two types of specimens. Figure 3 shows the four specimens after tests. Figures 3a and 3b shows that the rupture of FRP tube in FCCSC specimens was close to the mid-height of the specimens; the FRP rupture was found to be distributed in both the corner regions and the flat sides (Figure 3b). By contrast, the rupture of FRP tube in FCPC specimens occurred within one of the flat sides close to the top of the columns (Figures 3c and 3d).

![Figure 3 Specimens after test: (a) FCCSC-I; (b) FCCSC-II; (c) FCPC-I; (d) FCPC-II.](image)

**Axial Load-Shortening Behavior**

The axial load-shortening curves of the four specimens are shown in Figure 4, where all the curves are terminated at the point of FRP rupture. Figure 4 shows that the curves of the two FCPC specimens both have a descend branch after the peak load, although the load decrease was generally gradual before the rupture of FRP tube. By contrast, the curves of the two FCCSC specimens feature a bilinear shape, consisting of two ascending branches. This difference was due to the existence of a cross-shaped steel section in FCCSC specimens, which not only contributed directly to the axial load capacity of the columns, but also provided additional confinement to the concrete.

![Figure 4 Axial load-shortening curves](image)

The key test results are summarized in Table 1. In this table, \(P_u\) is the ultimate load of the FCPC or FCCSC specimens from the test; \(S_u\) is the ultimate axial shortening of the FCPC or FCCSC specimens from the test, which is the shortening at the rupture of the FRP tube; \(P_c\) is equal to the peak average stress of confined concrete in the FCPC specimens times the net area of the concrete in FCCSC specimens; \(P_s\) is ultimate load from the compression test of steel section only; \((P_c+P_s)\) represents the ultimate load of the specimen if the steel section did not interact
with the concrete and the FRP tube in FCCSC specimens. It is evident from Table 1 that the ultimate loads \( P_u \) of FCCSC specimens are significantly higher than the \( (P_s + P_p) \) value, indicating that the strength of concrete in the FCCSCs were significantly enhanced by the additional confinement from the cross-shaped steel section. It is also evident that the ultimate shortenings of the FCCSC specimens are significantly higher than those of the two FCPC specimens. This is believed to be due to the following two reasons: (1) the steel section provided additional confinement to the lateral expansion of concrete, so that at the same axial strain, the hoop strain of FRP tube was smaller in FCCSC specimens than in FCPC specimens; (2) the existence of steel section reduced non-uniformity of lateral expansion of concrete, so that the average rupture strains of FRP tube was larger in FCCSC specimens than in FCPC specimens.

### CONCLUSIONS

This paper has presented a newly proposed hybrid column with a square FRP confining tube (i.e. FCCSCs). The new column consists of a square FRP outer tube and a cross-shaped steel section, with the space between filled with concrete. This sectional configuration ensures that the concrete is very effectively confined despite the square shape of the column, leading to a column that is highly ductile. This paper has also presented results from axial compression tests on stub columns to demonstrate the concept of FCCSCs. The results confirmed the excellent performance of FCCSCs. Compared with the concrete in FCPCs, the concrete in FCCSCs has a much larger ultimate axial shortening and a larger compressive strength, when the same FRP tube is used.

SEISMIC PERFORMANCE OF CONCRETE-FILLED SQUARE STEEL TUBE WITH FRP-CONFINED CONCRETE CORE

S. Cheng and P. Feng
Department of Civil Engineering, Tsinghua University, Beijing 100084, China

ABSTRACT

In this study, the experimental programs that investigated the mechanical behavior and seismic performance of concrete-filled square steel tube with fiber-reinforced polymer (FRP)-confined concrete core (SCFC) column were conducted. SCFC specimens were fabricated with three parameters of concrete strength grade, FRP tube thickness and steel tube thickness and tested under axial compression, with four parameters of axial compression ratio, concrete strength grade, FRP tube thickness and steel tube thickness and tested under constant axial compression and reversed-cyclic lateral loading. The failure mode, load-displacement relationship were clarified for the specimens. Additionally, the laser scanning technique was used to obtain the transformations of specimens. In the seismic experiments, the hysteretic responses and envelope curve were received, the Energy-dissipation capacity, the loss of stiffness and equivalent viscous damping ratio were discussed. Results show SCFC columns exhibit favorable energy dissipation and ductility, even when the columns were subjected to high axial loads.

KEYWORDS

Seismic performance, moment-bearing capacity, lateral displacement ductility, stiffness, energy-dissipation, laser scanning.

INTRODUCTION

Researchers devoting to promote the mechanical behavior and seismic performance of columns have been undergoing a steady growth due to the increasing demand for better performance and cost reduction. A number of studies have been carried out to investigate the seismic behaviors of different columns, such as several typical columns including the steel reinforced high-strength concrete column (Varma et al. 2002), the concrete-filled FRP tube column (Zhu and Mirmiran 2006), the concrete-filled steel tube column (Sakino et al. 2002), and shaped-steel reinforced concrete column (Parra-Montesinos and Wight 2000).

Feng et al. (2015) proposed a novel column section named SCFC (Figure 1), which combined three materials within one section in order to take the merits of each material to develop a high level of load-bearing capacity, ductility and the residual load bearing capacity. The section of SCFC is composed of concrete-filled square steel tube with FRP-confined concrete core (FCCC).

AXIAL COMPRESSION EXPERIMENTS

Experimental investigation

The experimental investigation of 62 SCFC stub columns (170 mm in width and 500 mm in height) under axial compression was carried out. The typical specimen under axial compression is shown in Figure 2. The specimens
with a single FCCC were loaded under two schemes, monotonic axial compression and cyclic axial compression. The influences of four design parameters on the mechanical behavior of stub columns were examined. The specimens with multiple FCCC’s were loaded under monotonic compression only. Meanwhile, the effects of sectional configuration, thickness, and material strength on the mechanical behavior were considered. Additionally, a three dimensional scanning technique was adopted during experiments to detect the deformation of specimens at several significant loading steps. From the axial compression experiments, the failure process and failure mode were both obtained, which reveal that the SCFC has several significant advantages which differ from traditional elements, including significant post-yield stiffness and post-peak residual load-bearing capacity.

Figure 2 SCFC stub column under axial compression

Failure mode

In general, most SCFC specimens exhibited similar mechanical behavior when subjected to a monotonically axial compression (Figure 3). Initially, no obvious lateral deformation was observed within 0 to 3 mm of axial displacement. After that, small local bucklings on the steel tube surface dilated slightly outwards. During the subsequent loading process, obvious lateral deformations developed and rupture of the inner FRP tube followed, as evidenced by a loud sound. Meanwhile, the square steel tube showed symmetrical dilation, transforming the section to a circular shape. After rupture of the FRP tube a larger lateral deformation was noticed on the steel tube, with the formation of one to three outward foldings. The loading process of the SCFC specimens was terminated manually when the axial displacement reached around 40 mm to 50 mm.

Figure 3 Significant states of SCFC stub column under axial compression loading

Axial load-displacement relationships

Overall, all SCFC specimens exhibited similar mechanical behavior when subjected to monotonically axial compression and cyclic axial compression, respectively. As shown in Figure 4, the red curve shows the specimen under monotonically axial compression, the grey curve shows the cyclic axial compression for the specimens with same configuration, the black dash curve is the envelope curve obtained from the cyclic curve. The envelope curves of all specimens could be obtained by connecting the initial unloading points on the cyclic stress-strain curves within the strain range for cyclic loading. Overall, the envelope curves of all specimens present the similar trend with monotonic curve, which show the monotonically ascending bi-linear segments with a large post-peak deformation and certain residual load bearing capacity.

Figure 4 Axial load-displacement relationships
Laser scanning for large deformation

Considering the large deformation of specimen, the technique of laser scanning was adopted to obtain the deformations of specimens at prescribed states during loading process. The laser scanning technique could quickly and accurately receive the space coordinates of object, which results of measured graphics could be converted to the coordinates database. Therefore, the deformation situations at prescribed states could be obtained and used to analyze the corresponding stress-deformation relationships. In this experiment, the stub columns have large axial and lateral deformations before failure, which is tough to be measured by strain gauges for that the measured region of strain gauge is limited and the valid measurement range of deformation is generally lower than 20000 µe. Therefore, the laser scanning technique was adopted to obtain the deformations of specimens in this test, which contains three significant steps. As shown in Figure 5, the first step is to distribute the coordinate markers on the specimen for deformation tracing, including the griddings and the points. The second step is to scan the specimens at prescribed states during loading process manually; meanwhile, the scanned graphic could be recorded by data logger. The third step is to convert the graphics to space model for quantified analysis.

Figure 5 Laser scanning steps

Figure 6 shows the corresponding relationship between the 7 prescribed states in axial load-displacement curve and scanned three-dimensional model. The 7 prescribed states in curve include the original point, the middle point during elastic period, the yielding point, the middle point during strengthening period, the peak point, the middle point during post-peak ductile period and the loading terminated point. Figure 6 presents the finite element analysis by using the laser scanning results, which gives the deformation situations of steel tube from square to circular and corresponding confinement stress-strain relationships.

Figure 6 Results of laser scanning

AXIAL AND LATERAL COMBINED LOADING EXPERIMENTS

Experimental investigation

In the seismic experimental investigation (Figure 7), 14 SCFC specimens were fabricated with four differing parameters: axial compression ratio, concrete strength, FRP tube thickness, and steel tube thickness and tested under constant axial compression and reversed-cyclic lateral loading. From the seismic experiments, it shows the high level of load-bearing and energy dissipation capacity of SCFC, which fully took the advantages of material strength and their interaction mechanisms.
Figure 7 SCFC columns under constant axial compression and incrementally increasing lateral loadings

Specimens

A total of 14 specimens are fabricated with four parameters and tested under constant axial compression and incrementally increasing lateral deformation cycles. The four parameters include concrete strength grade (C30, C50, C80), FRP tube wall thickness (3 mm, 5 mm, 8 mm), steel tube wall thickness (6 mm, 10 mm) and design axial compression ratio (0.6, 0.8, 1.0) are investigated, yielding results for 14 different SCFC specimens. The levels of constant axial compression were established to simulate the loading conditions of typical heavy building columns, therefore, 60%, 80% and 100% of nominal column eccentric load capacity were chosen as the axial compression ratios, where the eccentric load capacity have not consider the confinement of FRP tube and steel tube. The specimens were designed as cantilever beams. Each specimen was designed to have a cross section of 300 mm outer width of the column and a cantilever height of 1.5 m. Lateral loading cyclic loading was applied to the specimens at a section 0.2 m below the column tip, which resulted in a shear span (h) of 1.3 m. In addition, each column was fixed into a heavily reinforced concrete footing that was 2100 mm in length, 500 mm in width, and 600 mm in height. To avoid the tearing of welding lines, the two surfaces with welding lines are posed parallel to direction of pull and push.

Experimental observation and failure modes

In general, all specimens exhibited similar hysteretic responses under simulated seismic loading as shown in Figure 7. Initially, no obvious lateral deformation was observed when loading axial compression force and lateral force until the drift ratio reached 0.5 to 1.5%. Around this range of drift ratio, local buckling outwards occur slightly on the steel tube surfaces at 50 mm to 150 mm from the top of the RC footing. After that, with loading process, the local bucklings developed to be a symmetrical rounded elephant foot outwards, as shown in Figure 7. During the subsequent loading process, the ruptures of inner FRP propagated, as evidenced by several crack sounds at a range of drift ratio within 2.0 to 4.0% for majority specimens. Meanwhile, the rupture of FRP indicates the failure of specimen therefore the loading process of specimens was terminated manually.

Hysteretic moment (M)-lateral drift (Δ/h) response

The hysteretic responses of hysteretic moment (M)- lateral drift (Δ/h) for typical specimens are shown in Figure 8. Hysteretic moment (M)-lateral drift (Δ/h) curves that were obtained by averaging the measurements from pull and push directions after correcting lateral moments for P-Δ effects (i.e., $M = F \times h + P \times \Delta$), where $F$ is lateral load, h is shear span of the column, $P$ is the imposed axial load and $\Delta$ is lateral displacement. All the specimens showed a flexure dominant behavior with well-rounded hysteresis loops. Figure 8 shows the hysteretic moment-lateral drift responses of typical specimens, which represents the typical specimens filled with the concrete strength grade of C30, C50 and C80, respectively.
Displacement ductility and moment-bearing capacity

As shown in Figure 9, the envelope curves of all columns were given to compare the hysteretic moment-lateral drift responses. All hysteretic moment-lateral drift responses of specimens can be divided into two types of envelope curves, which include the type I of tri-linear and type II of bi-linear envelope curves. The typical representatives of tri-linear envelope curves include the specimens filled with concrete strength grade of C30 and C50, which following a path of elastic period, strengthening period and softening period. The typical representatives of bi-linear envelope curves include the specimens filled with concrete strength grade of C80, which following a path of elastic period and strengthening period. The difference of bi-linear from tri-linear are without softening period, which are resulted from the rupture of FRP at the last loading cycle before the maximum moment capacity dropping.

Energy-dissipation capacity and equivalent viscous damping ratio

This energy-dissipation capacity of each column was determined at each cycle by calculating the area of corresponding lateral load-displacement hysteretic curve, as shown in Figure 10. Further, the loss of stiffness and the increase of damping ratio due to energy-dissipation were analyzed as two effective criteria, as shown in Figure 11. Last, the equivalent viscous damping ratios of the columns against drift ratio were plotted to evaluates the energy-dissipation capacity of SCFC column (Figure 12). Overall, results show that the seismic performance of SCFC column was demonstrated by 14 specimens to be effective in energy-dissipation and delivered favorable ductility under high axial loads, which is adoptable in regions of high seismicity.

CONCLUSIONS

This paper studied the mechanical behavior and seismic performance of hybrid SCFC sections. Results show that the SCFC column is effective in energy-dissipation and delivered favorable ductility under high axial loads, which is adoptable in regions of high seismicity.

ABSTRACT

This paper presents a comparative study of the axial load-bearing capacity and stress-strain curves of recycled aggregate concrete (RAC) and natural aggregate concrete (NAC) columns confined by hand laid-up glass fiber reinforced polymer (GFRP). One significant problem in using RAC in a structural role is the unpredictability of its load-bearing capacity, thus this paper presents a large amount of experimental data to analyze the scatter of confined and unconfined concrete columns under axial compression. Results indicate that GFRP confinement reduces the scatter in the stress-strain response of RAC columns, but owing to the unpredictability of the ultimate rupture state of hand laid-up GFRP, it is ineffective at reducing the scatter in both of ultimate strength and strain. Additionally, systematic differences in stress-strain response between NAC and RAC GFRP-confined columns were demonstrated by the test program and are discussed in this paper.

KEYWORDS

FRP, confined concrete, recycled aggregate concrete (RAC), scatter, mechanical properties.

INTRODUCTION

The production and use of recycled aggregate concrete (RAC) has been researched extensively in recent years as the environmental and economic costs of natural aggregate concretes (NAC) become clear. However, despite its smaller environmental impact and potential for superior economic performance (CANZ TR14 2011), the material has yet to see significant application in structural concrete because it demonstrates poorer short- and long-term performance than NAC does in areas such as slump and constructability (Tangchirapat et al. 2013), compressive strength (Zhao et al. 2014), and creep and drying shrinkage (Yang 2011). An additional problem is the considerable scatter observed in the mechanical properties of RAC, particularly in its compressive strength.

There have been numerous attempts to develop a means of rectifying these performance deficits: researchers have included different admixtures in mix designs to control slump and strength (Tangchirapat et al. 2013), used different moisture conditioning regimens in aggregate storage (Mefteh et al. 2013), and employed different crushing and processing procedures to manufacture recycled aggregates (Akbarnezhad et al. 2013). Unfortunately, the more effective of these methods (crushing and admixture addition) also require potentially significant expenditures, calling into question the economics of RAC use.

There is one other avenue of research into improving the performance of RAC, namely research into confined RAC columns. Traditionally there are two materials used in the confinement of concrete, steel and fiber-reinforced polymer (FRP). At present there is some research on the short- and long-term performance of steel-confined RAC, but only very limited research on GFRP-confined RAC (Xiao et al. 2012; Xiao and Yang 2009; Zhao et al. 2014). Past research on steel-confined RAC has shown many beneficial effects, including increased bearing strength (Yang and Han 2006) and reduced drying shrinkage (Yang 2011).
Steel confinement, however, has a number of disadvantages, including issues with corrosion, self-weight (especially during construction, when it must double as a form for concrete and bear all self- and construction loads), and less effective confinement than FRP with fibers wound radially (Teng and Lam 2004). Thus for certain structural uses FRP confinement is preferable to the use of steel tubes, but at present very little data exists regarding its use with RAC. Xiao and Huang (2012) tested only three GFRP-confined specimens, and while Zhao et al. (2014) tested eighteen, this amounted to only two specimens for any given replacement ratio and degree of confinement.

Given the limited test data and the higher scatter usually observed in the mechanical properties of RAC, it is necessary to produce more test data in order to better understand the behavior of GFRP-confined RAC before it can be applied to real-world structural design. The study performed by the authors tested a significant number of NAC and RAC specimens in order to analyze two phenomena: the scatter in load-bearing capacity of GFRP-confined RAC columns, and the differences in behavior between confined columns made of RAC and NAC. This paper presents the experimental program and the resulting data, analyzes the scatter in mechanical properties of both types of concrete columns, and discusses the qualitative differences in their stress-strain behavior and failure modes.

**EXPERIMENTAL PROGRAM**

**Materials and Preparation**

Natural coarse aggregates came from stockpiles maintained by Tsinghua University’s civil engineering department for research purposes, with maximum nominal sizes of 12.5 mm and 25 mm, respectively, blended to meet the grading requirements laid out in ASTM C33-13 (ASTM 2013) for size number 67 coarse aggregate. Recycled aggregates were from a commercial supplier in Beijing, and their size distribution also met the above standard. Hand sorting of a representative sample of recycled aggregate revealed a deleterious materials content of 2-3% by volume (most impurities were of lower density than stone, so a weight percentage would be misleadingly low), primarily ceramics, glass, organic materials, and foams, with small amounts of dirt, plastic, and reinforcing steel. When casting specimens, the recycled aggregate was intentionally not washed or sieved to remove impurities in an attempt to reflect the ordinary treatment of natural coarse aggregates in real engineering practice. Table 1 gives several other properties of the two types of coarse aggregate.

The mix design used was calculated in accordance with the Chinese standard JGJ55-2011 (CABP 2011) “Specification for Mix Proportion Design of Ordinary Concrete” to the specifications for C30 concrete, with a target 28-day cube compressive strength of 30 MPa, which corresponds to a cylinder compressive strength of approximately 24 MPa (Elwell and Fu 1995). Mix proportions are shown in Table 2. The values for water and coarse aggregate are based on the aggregate being in saturated surface-dry (SSD) condition; in the actual mixing, the amounts of both were altered based on the moisture content of the aggregates, which was measured several days before, to maintain a uniform free water-cement ratio. Slump was controlled and maintained at workable levels (in the range of 80-100 mm) through the addition of water reducer.

The GFRP confinement layer was formed by hand lay-up using a unidirectional sheet of glass fibers with a nominal thickness of 0.169 mm and an area density of 430 g/m². To verify its material properties, tensile coupon tests were performed in accordance with the Chinese standard GB/T 1447-2005 (AQSIQ and SAC 2005). Five single-layer coupons with midspan width 10mm and length 180 mm were cut and bonded to aluminum clamping surfaces, then tested to tensile failure. The tensile coupon tests of FRP showed that the average tensile strength was 320.1 MPa; the ultimate tensile strain was 0.021; and the secant elastic modulus was 18.7 GPa. Note that modulus of elasticity and tensile strength are both based on the specimen thickness. Additionally, the bonding agent used to affix strain gauges was insufficiently durable to obtain reliable rupture strain results, so rupture strain is taken from test data from previous research using same glass fiber and epoxy.

**Specimens Preparation**

The test specimens were concrete cylinders, each 500 mm long with a radius of 152mm. In total, forty were cast and tested, twenty each of NAC and RAC. The test variable was the presence and thickness of the GFRP confining wraps, so for each type of concrete five columns were wrapped with a single layer, five with two layers, and five with three. The remaining five were a control group which was tested without FRP confinement. GFRP was adhered to the columns by wet lay-up using a structural epoxy resin. For all specimens, 100 mm of overlap was provided between the leading and trailing edges of the FRP wrap. To avoid localized failure at the column ends, a two-layer strip of GFRP 60 mm wide was adhered overtop the confinement. Also, the column ends were sanded flat, roughened, and capped with mortar roughly one week before compression testing to ensure a uniform stress distribution.

Specimens were cured at low room temperature (approximately 15 °C) in the lab under dry conditions, but were not demolded until the day that the GFRP confinement was applied. In accordance with common engineering practice in mainland China, the epoxy was applied and confinement affixed by hand with no machine wrapping or tensioning. Both NAC and RAC specimens were tested at an age of between 27 and 32 days. This spacing was necessary due to the number of specimens. Smaller cylindrical specimens used in strength testing were cast from the same batches of concrete used to make the larger columns, and cured for 28 days under the same conditions as the larger columns. They were demolded shortly before testing.

The specimens were designated as follows: the first letter (N or R) refers to natural or recycled aggregate, the second letter (G or U) refers to glass fiber confinement or unconfined, the third number (0-3) refers to the number of layers of GFRP, and the final number (1-5) is the specimen number. For example, NG-1-4 is the fourth of five specimens with natural aggregate and one layer of GFRP confinement. See Table 3 for details.

**Test Apparatus and Instrumentation**

Compression testing was carried out on a hydraulic compression testing machine with a load capacity of 500 t. Loads were applied at a rate of 2-2.5 kN/s (load-controlled) until total load reached roughly 60% of estimated peak load, then at a rate of 0.5 mm/min (displacement-controlled) until specimen failure. A pre-load of 20 kN was applied to each specimen before testing to limit the effects of column end conditions and imperfect load contact on the stress-strain curve and prevent stress concentrations. Each confined column had four hoop strain gauges and two longitudinal strain gauges spaced uniformly around the circumference at mid-height, while concrete
columns had two hoop and two longitudinal strain gauges attached. All columns additionally had four linear variable differential transformers (LVDTs) placed around them.

RESULTS AND DISCUSSIONS

Overall Behavior

Observation of the loading processes of unconfined RAC and NAC specimens showed the cracking and failure processes in RAC columns were much more gradual and drawn-out. Figure 1 shows the typical failure modes of unconfined RAC and NAC specimens after testing. RAC columns display visible cracking but are substantially more intact and cohesive than NAC ones. Generally, NAC columns shattered upon handling after loading, while RAC columns still maintained sufficient cohesion to remain in one piece.

![Figure 1 Typical failure modes of unconfined specimens: (a) RAC and (b) NAC](image)

For GFRP-confined specimens, it was discovered early in testing that, due to the relatively low temperature in the laboratory where the specimens were cured, the epoxy resin used to apply the GFRP confinement had not fully strengthened, and the first several NAC specimens, including specimens NG-1-1, NG-2-1, NG-2-2, NG-3-1, NG-3-2, experienced delamination failure at the GFRP overlap (Figure 2(a)). When this became apparent all remaining samples were recurred at high temperature for 6 hours, and subsequent tests displayed satisfactory failure modes. Specimens which experienced debonding failure had dramatically lower final bearing capacities and axial and radial strains when compared with those in which the GFRP underwent tensile rupture. They are not included in any computations of specimen average strength or the standard deviation thereof, but their stress-strain phenomena are largely consistent with properly cured specimens up to the point where they experience sudden early failure. As such, their stress-strain behaviors are discussed below.

![Figure 2 Typical failure modes of GFRP-confined specimens: (a) Delamination failure at the GFRP overlap, (b) Fiber rupture, (c) Local fiber rupture followed by delamination (rupture point circled in red)](image)
The remaining specimens, both NAC and RAC, failed through tensile rupture of the confining GFRP layers (Figure 2(b)), sometimes followed by delamination after rupture had already occurred locally (Figure 2 (c)). Rupture most commonly occurred in the middle region of the column, away from the overlap. In some cases rupture occurred simultaneously along the length of an element, while others failed more gradually. The latter phenomenon was particularly common in GFRP-confined RAC specimens, which had a generally more gradual and “softer” failure process than the NAC specimens did. Especially, one phenomenon of note was found upon examination of specimens RG-3-1 and RG-3-3 after the testing program was complete; both had failed at a relatively low level of axial stress and radial strain. After observing video of the experiments it was possible to locate the points at which the GFRP confinement had failed, and upon examination it was found that RG-3-1 had a piece of reinforcing steel protruding beyond the surface of the cracked concrete in that region, while RG-3-3 contained shattered glass. Past research offers no indication that deleterious materials in concrete can cause premature FRP rupture, but it is known that a significant amount of the variability in confining FRP rupture strain is due to localized, unmeasured strains in FRP stemming from the non-uniform nature of concrete cracking. (Lam and Teng 2004).

**Stress-Strain Behavior and Scatter**

The stress–strain curves of the six groups of GFRP-confined specimens are shown in Figure 3(a-f), respectively. It is evident that there are some noticeable differences between GFRP-confined NAC and RAC specimens. The most obvious is that stress–strain curves in the confined RAC specimens have a significantly more “rounded” transition between two relatively linear phases when compared with specimens made of NAC, which is broadly in line with the results observed by Zhao, et al. (2014). Also, there is a pronounced “lag” between concrete cracking and the engagement of the confining GFRP in NAC columns with one and two layers of confinement, which is reflected in the decrease in stress seen in the stress-strain curves (Figure 3(b) and 3(d)) immediately following transition before strengthening begins. This phenomenon has been observed in other research involving relatively low confinement stiffness and high concrete strength (Vincent and Ozbakkaloglu 2013), but is totally absent from the stress-strain curves of the confined RAC columns in this research. This absence is likely due in part to their lower strength.

Especially, the curves of five nominally identical GFRP-confined RAC specimens in each group agree well with each other (Fig. 3(a, c, and e)). These stress-strain curves of GFRP-confined RAC columns in each group follow the very similar development process, but stop in different ultimate condition. The confined specimens exhibited little scatter in stress at any given radial strain before ultimate failure. This effect is most pronounced early in loading, particularly when radial strain is below 60% of its ultimate value. To summarize, GFRP confinement does significantly reduce scatter at points along the stress-strain curve, as the confinement of GFRP acts to resist the cracking and expansion behaviors of concrete. While the tensile rupture state of GFRP cannot be predicted reliably and this unreliability contributes to scatter in ultimate strength, which is discussed in the following section.

**Ultimate Condition and Scatter**

The peak axial stresses ($f_{uc}$) of the confined concrete, corresponding axial strains ($\varepsilon_{uc}$) of all the specimens at ultimate condition are summarized in Table 4, including the average value, standard deviation (Std. Dev.), and coefficient of variation (CV). In line with past research into recycled aggregates and confined RAC columns, the RAC specimens were found to have significantly lower bearing strength than the NAC columns using the same mix proportion, regardless of the presence and degree of GFRP confinement. The average ultimate strength of NAC columns in all three confinement groups was higher than that of RAC columns by roughly 20%. Additionally, there was no significant difference in strength variability between RAC and NAC columns within a confinement group, with all the coefficients of variation around 5%. However, it was found that there was significant variability in the ultimate strain ($\varepsilon_{uc}$) of RAC columns confined by GFRP. RAC columns confined by GFRP failed at variable axial strain: the failure strains of RAC columns with one layer had a coefficient of variation of 10.96%, those with two, 6.14%, and those with three, 11.83%. The coefficient of variation of failure strains of confined NAC columns with one layer of GFRP was also 9.41%, and reliable numbers are not available for two- and three-layer confined NAC columns due to the curing issues mentioned above. Most importantly, GFRP applied to RAC columns by hand using a wet lay-up process does not exhibit any significant restraint on variability compared with unconfined
RAC columns; it was found that the ultimate strength and strain of unconfined NAC and RAC columns had similar variability to the ultimate strengths of such columns which were confined by hand lay-up GFRP.

CONCLUSIONS

This experimental program investigated the behavior under axial compression of RAC columns confined by GFRP sheathes formed by hand lay-up processes. Through analysis of property scatter among multiple nominally identical elements and analysis and comparison of the stress-strain behavior of RAC and NAC columns both confined and unconfined, the following conclusions were reached:

1. GFRP confinement formed by hand lay-up processes does not significantly reduce scatter in the axial load-bearing capacity of RAC columns because GFRP ultimate rupture strain and state are not predictable when applied this way. Even though there is evidence that GFRP acts to restrain variability in RAC under compression, this action is not sufficient to outweigh the variability in GFRP’s own failure state.

2. GFRP confinement does significantly reduce scatter at points along the stress-strain curve, as it acts to regularize the cracking and expansion behaviors of concrete. This effect is most pronounced early in loading, particularly when radial strain is below 60% of its ultimate value. Since this level of axial strain is generally not reached until loads reach more than 80% of their ultimate value, in practice, this means that for most of the loading process the stress-strain curves of GFRP-confined RAC columns are significantly more consistent than those of RAC columns left unconfined.

3. The stress-strain curves of GFRP-confined RAC columns follow the same development process as GFRP-confined ordinary concrete: two mostly linear phases, the first with a higher modulus of elasticity and the second with a lower one. However, they have a “rounder” transition zone between the two than those of NAC columns, due to their more gradual cracking process.

4. It is apparently possible for high-hardness impurities such as ceramic or glass in recycled aggregates to cause premature rupture of GFRP confinement. This phenomenon was observed in several columns, but it requires further investigation due to their small numbers and accidental nature.

ABSTRACT

A hybrid member consisting of filament-wound fiber reinforced polymer (FRP) tube, pultruded FRP Profiles, and concrete is presented and experimentally studied in this paper. The hybrid member is in the form of four FRP profiles in contact with the inner surface of the FRP tube. The internally encased FRP profiles are intended to increase the performance of the concrete-filled FRP tube (CFFT) members subjected to combined bending and axial loads. Also the hybrid member has excellent corrosion resistance and is easy to construction. More particularly, as absolutely no steel utilized in this member, the environmental friendly sea water and sea sand can be directly used to cast concrete and filled in this member. The compressive behavior of this hybrid member was investigated under axial, eccentric compression and four-point bending. And the results from axial compression experiments on 4 CFFT with m-Profiles specimens and 3 traditional CFFT specimens are presented in this paper. The results show a reduction in the peak load of CFFT member when m-Profiles were internally encased it. However, the failure initialled from damage on m-Profiles provides an evident warning before overall failure of the member, and the progressive failure process makes the member to exhibit a relatively good failure ductility compared to the explosive failure of CFFT. The mechanical and failure mechanism of this hybrid member under axial compression are presented in this paper.

CFFT, FRP tube, FRP profiles, axial compression, failure mode.

INTRODUCTION

The concept of using concrete-filled FRP tubes (CFFT) as columns or piles was first introduced 20 years ago (Mirmiran et al. 1998). Since then axial compressive behavior of FRP-confined concrete has received significant attentions, and it is now well known that the confinement of concrete with FRP composites can substantially enhance the compressive strength and ultimate strain of concrete (Lam and Teng 2003; Mirmiran et al. 1998; Ozbakkaloglu et al. 2013; Pessiki et al. 2001). However, most of the columns in actual construction are subjected to combined axial and bending moments due to load eccentricities, construction errors and lateral loads. In fact, a perfect axially loaded column does not exist. Longitudinal reinforcements are necessary when CFFT member is to be used as a column in the construction. In existing studies, Steel bars (Mandal and Fam 2006; Mohamed and Masmoudi 2010), steel I-section (Karimi et al. 2011; Yu et al. 2016), FRP bars (Hadi et al. 2016) and pultruded FRP profiles (Park et al. 2011) were assembled in CFFT to enhance its performance. Especially, the most highly developed application to date is the use of CFFT as pier columns and piles in marine structures. Steel is easy to get rust in marine salt environment. While FRP bars and pultruded FRP profiles have good resistance to salt (Feng et al. 2014), so they are more advantageous when consider using CFFT member in marine structures. Also the pultruded FRP profiles are easy to customized, and using them can avoid reinforcing bar tying and fixing technology. Combining pultruded FRP profiles, winding FRP tubes and concrete to form a hybrid member has been proposed by Park et al. (2011), in which the pultruded PRP profiles with a quadrilateral closed cross section are assembled to a double-wall cylinder and attached the inside of the FRP tube, then with the space filled concrete. A limited studies reported the behavior of this hybrid member under was similar to traditional CFFT member at
the ultimate axial strain level are just around 0.014 (Park et al. 2011). A new type of hybrid member with some improvements was proposed in this paper. Firstly, the pultruded FRP profiles are designed to have an open cross section to increase the mechanical interlock between them and concrete. Secondly, the pultruded FRP profiles were not assembled to a whole cylinder but placed with adequate intervals, considering a through zone is needed for column-beam joint. The performance of this column were systematically tested under axial, eccentric compression and four-point bending. And the results from axial compression experiments are presented in this paper.

EXPERIMENTAL PROGRAM

Specimen Preparation and Fabrication

Six CFFT with m-Profiles specimens and three reference CFFT specimens were prepared. All the specimens had a nominal diameter of 300 mm (diameter of the concrete core) and a height of 800 mm. They were cast with commercial concrete. The details and cross section of the specimens are given in table 1. Each specimen was given a name, in which the number behind a letter ‘T’ indicates the nominal thickness of FRP tube. For specimens with FRP profiles, there are some letters follow the second dash, in which the “FPs” and “sFPs” indicate FRP profiles and slotted FRP profiles, respectively, and the number before them represents the number of m-Profiles (or slotted m-Profiles) internally assembled. As shown in Figure 1 (a) and (b), before casting the m-Profiles were located and temporarily pasted on the FRP tube.

Figure 1 Fabrication and preparation of specimens: (a) locating and temporary fixing of m-Profiles, (b) slotted m-Profiles, and (c) casting concrete

Material Properties

The mechanical properties of prefabricated filament-wound glass FRP (GFRP) tubes in hoop direction were tested, using a tensile split-disk tests according to ASTM D2290-12 (ASTM 2012). Five FRP rings, each having a uniform height of 40 mm, were cut from the FRP tube with a thickness of 3.75 mm. Six hoop strain gauges with a gauge
length of 10 mm were installed, among which two were centered at the top and bottom of rings, whereas the other four gauges were located at 15 mm away from the gaps. The readings of the six strain gauges were found to be close. The average elastic modulus ($E_T$) is 43.64 GPa.

Two type of pultruded FRP profiles used in this study were both customized to have a m-shape cross-section with a curved edge having the same radian as the used FRP tube, as shown in the Figure 2. The only difference of them is whether it was conducted by slotting process. The one with the whole three stiffeners was referred as m-Profiles (Figure 2 (a)), the other one was named as slotted m-Profiles with a letter “s” indicating it was reprocessed by slotting on the two stiffeners after pultrusion. The slotting was shaped as a half round with the diameter and the interval are both 30 mm, as shown in Figure 2 (b). It was intense to increase the mechanical interlock between FRP profiles and concrete. 5 couples were cut from the m-Profiles and tested under compression following ASTM D695-10 (ASTM 2010). The average compressive modulus and strength are 28.89 GPa and 303.40 MPa, respectively.

![Figure 2 Photograph and cross-section of (a) m-Profiles and (b) slotted m-Profiles (dimensions are in mm)](image)

**Setup and Instrumentation**

The specimens were tested under monotonic axial compression using a 20,000 kN capacity universal testing machine. The loading was applied with a displacement control rate of 0.25 mm/min. As shown in Figure 3, the axial compressive test specimens were instrumented with eight linear variable differential transformers (LVDTs). Four of them (i.e. DT 1-4) are mounted on an aluminum cage attached to the mid-height of each specimen. The LVDT cage had a gauge length of 400 mm and it was placed at equal distance from each specimen end. Another four LVDTs (i.e. DT 5-6) were installed at the corners between the top and bottom steel clamps with a gauge length of 600 mm. The recorded deformations were used to correct the LVDT cage measurements. The aluminum cage unexpectedly broke due to the explosive failure of C-T4. But thankfully, the results from the experiments on specimen C-T4-4FPs, C-T4-4sFPs, and C-T4 show the measurements of the LVDTs installed between the top and bottom steel clamps are consistent with the LVDT cage measurements. Hence, for the remaining specimens, just the four LVDTs were installed at the corners between the top and bottom steel clamps were used. Additionally, four axial strain gauges (i.e. AG 1-4) having a gauge length of 10 mm were installed at the midheight of the FRP tube. Hoop strains around the specimen perimeter were measured by eight unidirectional strain gauges (i.e. HG 1-4) having a gauge length of 10 mm that were bonded horizontally on the FRP tube. For specimens with m-Profiles, a strain gauge was glued to each of m-Profile at midheight to measure its longitudinal strain, as shown in Figure 3.
Experimental results and Discussion

Experimental Observation and Failure Modes

All CFFT with m-Profiles specimens exhibited similar mechanical behavior. They exhibited a progressive failure process and have a relative good ductility. This is different from the sudden failure of CFFT specimens. The appearance of the typical specimens with four m-Profiles at different loading stages are showing in Figure 4. During testing, a few cracking noises were heard and followed a few white patches were observed on the FRP tubes. At this loading point the axial strains are around 0.012 for all specimens with four m-Profiles. Especially, as shown in Fig 4 (a), all those patches always appeared at the locations of FRP tube inside attached to m-Profiles. So this patches are potentially caused by the damage of m-Profiles. It will be further analyzed on the longitudinal strain of m-Profiles in the following section. As the test continued the local patches gradually widened and some new patches appeared. Then the load increased reaching their peak load levels. At peak load a catastrophic failure was not observed, just several white patches have developed to local fiber ruptured and FRP tubes still packaged the specimen but didn’t explosively ruptured, as shown in Figure 4 (b). After that specimens still had the carrying capacity. As the displacement continued to increase, accompanied with continuous snapping noise, the loads dropped as a result of a slow fracture of the FRP tube. The local fibers progressively ruptured and caused tearing failure of the FRP tube following its fiber orientation. Eventually, as the tearing developed throughout in the mid-height region and then some encased m-Profiles crushed (Fig 4 (c)), the specimens reached the ultimate states with a large drop in load occurring. Especially, it was very interesting to notice the crushed sections always located at the height corresponding where the first white patch appeared on the FRP tube. After ultimate state, the loads on Specimens with m-Profiles did not drop to zero unlike CFFT specimens. The axial loads in specimen with m-Profiles dropped to around 25% of the peak load, then tests were stopped.

As expected, the reference CFFT specimens C-T4 and C-T6 failed suddenly after reaching their peak load level, accompanied by an instantaneous loss of applied load. The loading processes of specimen C-T8 with the thickest FRP tube was terminated manually when the load reached to 12500 kN. Because the impact caused by the brittle failure at loads higher than 12500 kN beyond the loading capacity limitation of the testing facility.

Longitudinal Strain of m-Profiles

Figure 5 provides longitudinal strains of m-Profiles vs. the axial strains of the specimens from 0 to 0.016. It can be seen that the longitudinal stains in m-Profiles increased linearly with the axial stains of the specimens during the early stage of the loading with a slope closing to 45 degrees, which indicates the deformations of the m-Profiles and the specimen under axial compression are coordinate. Until the axial strain reached to 0.012~0.014, the longitudinal strain in m-Profiles no longer linearly increases with the axial strain of specimens with each drop in the curve representing the m-Profiles began to damage at this strain level. Now it is clear that the local white patches which appeared at this strain level were attributed to the damage in the m-Profiles. As the strain has already exceeded the ultimate strain from material tests, the material strength of m-Profile was fully used without bulking
occurring, which was benefit the inside support from concrete and outside confinement of FRP tube. The test was continued with an increase in load but a decrease in slope, representing the m-Profiles behaved a progressive failure after ultimate strain of itself.

Figure 4 Experimental observation of specimen C-T4-4FPs at initial failure (a), peak load, and ultimate state

Figure 5 Longitudinal strains of m-Profiles vs. the axial strains of the specimens

**Distribution of Hoop Strain**

Strain distributions shown in Figure 6 were established using hoop strains over the perimeter of the specimens recorded at a series of certain axial strain level up to the ultimate condition. It is shown the hoop strain distributions of specimens with m-Profiles all begin to exhibit irregular sharp after the strain beyond 0.014. As axial strain increased from 0.010 to 0.014, one of the strain values rapidly increased. For both specimens C-T4-4FPs and C-T4-4sFPs, one of the strains has already approached to 0.02 at axial strain of 0.014, following the specimens soon reached to their peak load just at strain of 0.0145 and 0.0157, respectively. For specimen C-T8-4sFPs having thicker FRP tube, the maximum strain at axial strain of 0.014 are around 0.016, also way higher than the other measured strains at the same time. Finally, due to the localized strain exceeded the rupture stain, FRP tube prematurely failed under the non-uniform distribution of hoop strains. By contrast, the distributions of CFFT specimens are very similar and all close to a circle shape under every certain axial strains, indicating the uniform distribution of lateral confining pressure. As expected, the FRP tube explosively ruptured due to this kind of uniform hoop straining.
Axial Load-Strain Behavior

The experimental results of the specimens are summarized in Table 1 with the axial load-strain curves shown in Figure 7 (a), where the axial strains of all specimens were based on the average axial shortening of the four LVDTs. It can be seen that CFFT with m-Profiles specimens exhibit similar axial load–strain behavior. The similar shapes of CFFT with m-Profiles specimens include a tri-linear ascending branches with a post-peak deformation segment. There are three critical point in each curve of specimens with m-Profiles, and all of them are marked as point (1), (2), and (3) in the Fig (a) and (b). The critical point (1) indicates the initial damage introduced by the damage occurring on internally m-Profile as the axial strain beyond its ultimate compressive strain. Before point (1), the curve of specimens with m-Profiles are similar to the bilinear ascending shape of CFFTs under compression. After that, the slope decreases due to the development of damage on internally encased m-Profiles but the load continues to increase and reach the peak point (2). From this point the damage developed to FRP tube and it started to rupture from the area where local stress concentration. The curve exhibited a post-peak deformation segment with a slowly decreasing load. The last critical point (3) indicates the ultimate failure, which appear as FRP tube tearing out, m-Profiles crushing and pushing out and concrete spalling. After that, the load rapidly drops to around 25% of the peak. The load and axial strain corresponding to each critical point for every specimen are listed in Table 2.

All the reference CFFT specimens have an approximately bilinear axial load-axial strain relationship in the loading process, as shown in Figure 7 (b), where the first portions of each are almost identical, but the slope of the second portion depends on the thickness of the thickness of FRP tubes. Both the curves of specimens C-T4 and C-T6 have a vertical descending segment, which is due to they failed suddenly after reaching its peak load. The loading processes of specimen C-T8 was terminated manually when the load reached to 12500 kN.

**Influence of introducing m-Profiles**

It is evident to see from Figure 7 and Table 2 that the peak loads of specimens with m-Profiles are lower than that of their counterpart CFFT specimens without m-Profiles. The peak loads of specimens C-T4-4FPs, C-T4-4sFPs, are just 83~87% of specimen C-T4. And the peak loads of specimens C-T8-4FPs and C-T8-4sFPs are also below that of specimen C-T8. This is attributed to the damage on m-Profiles causing a stress concentration on the FRP tube. Consequently, FRP tube prematurely failed under non-uniform hoop straining. The test results shown in Table indicate that the rupture strain of specimens with m-Profiles at peak load is below 60% of their counterpart CFFT specimens. However, the specimens with m-Profiles have a relatively good failure ductile compared to the CFFT specimens. To evaluate the failure ductile of the specimens, the failure ductile index ($DI$) proposed by Han (2002) is used, which was calculated by:

$$DI = \frac{\varepsilon_{max,85\%}}{\varepsilon_{max}}$$

where $\varepsilon_{max,85\%}$ is the axial strain defined at an axial load corresponding to 85% of $P_{max}$ in the descending part of the load strain curve, and $\varepsilon_{max}$ is the axial strain corresponding to $P_{max}$. For those specimens without a descending part, $\varepsilon_{max,85\%}$ was the maximum strain. The obtained $DIs$ were listed in Table 2, which show all the $DIs$ of specimens with m-Profiles are bigger than 1, indicating the specimens have a better failure ductile than CFFT specimens. The slope of the second ascending branch is higher for the specimens with m-Profiles, which is due to the m-Profiles still maintain elastic in the initial stage of the second linear branch, meanwhile concrete has already reached its plastic state with decreasing of stiffness.

**CONCLUSIONS**

From the experimental test results and analysis presented in this paper, the following conclusions can be drawn:
Introducing m-Profiles in CFFT columns results in a decrease in the axial load-carrying capacity, which is due to the damage in the m-Profiles caused a stress concentration on the FRP tube and eventually caused its premature ruptured under non-uniform hoop straining. The test results indicate that the rupture strain of FRP tube at peak load is below 60% of their counterpart CFFT specimen without m-Profiles.

2 CFFT with m-Profiles under compression exhibit a progressive failure process with evident local white patches shown in FRP tube as warning before peak load, and has a good failure ductility with the progressive tearing failure of FRP tube after peak load. It is totally different from the catastrophic failure of CFFT specimens occurring without any evident warning before failure and any failure ductile after failure.

3 The material strength of internal m-Profiles is taken full advantage in compression, as the buckling is restricted by inside support from concrete and outside confinement from the FRP tube. The damage on m-Profiles encased develops until the axial strain beyond the ultimate strain of m-Profile itself.

ABSTRACT

This paper provides the experimental results of a new hybrid beam intended for use in bridge applications. The hybrid beams were made up of hybrid Glass Fibre Reinforced Polymer (GFRP)/steel U-shaped section beams strengthened with a layer of concrete on top. Three hybrid FRP/steel-concrete beams were tested along with one control GFRP-concrete beam under four-point static flexural loading. It was concluded that the hybrid beams had higher flexural stiffness and strength than the control beam, where the beams reinforced with steel showed greater percent cost effectiveness than beams reinforced with CFRP. In addition, the improved connection mechanism used in the hybrid beams was found to provide adequate interface bond strength to maintain full composite action until ultimate failure.

FRP, steel-concrete, beam, flexural, hybrid

INTRODUCTION

Nowadays, extensive researches have been conducted for the application of fiber reinforced polymer (FRP) in civil engineering by utilizing its effective corrosion-resistance. Applications for strengthening and repair are already well established. A growing number of new bridges have been constructed as all-FRP or FRP-concrete hybrid structures [1-9], but also the shortcoming are obviously as higher initial costs and lower stiffness and poor ductility [10,11]. To overcome these drawbacks and to make the best use of materials, combinations of FRP, steel and concrete have been proposed. The advantages of hybrid structural systems include the improved stiffness and cost effectiveness based on material properties of each component.

In this paper, a new hybrid FRP/steel-concrete beam which is proposed. Three hybrid FRP/steel-concrete beams were tested along with one control GFRP-concrete beam under four-point static flexural loading to study the mechanical properties of the proposed hybrid beams.

HYBRID FRP/STEEL-CONCRETE BEAM DESCRIPTION

Although many configurations of hybrid FRP-concrete beams are possible, the proposed hybrid beam shown in Figure 1b, was chosen. The hybrid beam consists of a GFRP/steel U-shape hybrid beam, a GFRP cover plate and a layer of concrete on top. The U shape hybrid beam is compound with outer GFRP layers and inner U-shape steel section which could improve the stiffness of hybrid beam significant. CFRP layer which present more excellent properties than GFRP was not selected in this design due to its expensive cost and lacking of the source of carbon fiber in China at present. Our final objective is to develop a cost-competitive hybrid design comparing to traditional beam design, to suit the situation of China. The GFRP cover plate as formwork, where the concrete on, is anchored over the U-shape hybrid beam. To develop a good bond between GFRP beam and
concrete, 5~10 mm aggregate was applied to the cover plate with epoxy adhesive. Applying too much or too little aggregate could create insufficient bond between GFRP and concrete for the two materials to act compositely. The aggregate distribution percentage was recommended to be 35%~45% to obtain the optimal bond [12].

EXPERIMENTAL PROGRAM

The laboratory test presented in this paper should be considered as pilot test. The test was made to investigate the flexural behaviour of the proposed hybrid beam.

Test specimens

The experimental program consists of two 3500 mm long, one hybrid beam (Beam A) is the FRP U-shape without steel below, named GS0 and two hybrid beam (Beam B) are the FRP/steel U-shape below with the thickness of 2mm and 6mm steel plate, named GS2 and GS6. The dimensions of cross-sections of the two beams are shown in Figure 1.

Material properties

The main materials used in the work are GFRP, steel and normal concrete. The U-shape was made of inner Q235 steel and outer GFRP layers which fabricated by hand lay-up process at present trial stage. Two types of E-glass woven fabric were selected which were bidirectional E-glass woven fabric with a weight of 800 g/m² (0°/90°) and unidirectional fabric with a weight of 400 g/m² (0°), respectively. Vinyl-ester resin was chosen as the matrix. The cover plate had the architecture as [(0°/90°) 2, (0°), (0°/90°), (0°), (0°/90°), (0°)], while the GFRP U-shape and the GFRP/steel U had the architecture as [(0°/90°) 2, (0°), (0°/90°), (0°), (0°/90°), (0°), (0°/90°), (0°/90°)], and [(0°/90°) 2, (0°), (0°/90°), (0°), (0°/90°), (0°), (0°/90°), (0°), (0°/90°), (steel plate)]. The average fiber volume fraction of the GFRP part is about 0.3. The concrete layer on the day of test is 63.52 MPa. The specific material properties of the hybrid beam are recorded in Table 1.

Test set-up and apparatus

The test set-up is shown in Figure 2. Three beams were simply supported on rollers with a span length of 3300 mm and subjected to four point bending. The spacing between the inner loading points was 700 mm. The flexural test was performed by displacement control, and it was divided into two steps (shown in Figure 3). In the first step (Step I), a cyclic force profile was used with the amplitude gradually increased to examine the deflection stabilization. In the second step (Step II), force was increased monotonically until the test specimen failed.
EXPERIMENTAL RESULTS AND DISCUSSIONS

Load-deflection response and failure mode
The load-deflection curves at mid-span and the typical failure modes for all specimens shown in Figure 5 and Figure 6, respectively.

For Beam A, the load-deflection curve showed an almost linear-elastic response during Step I. In Step II, there was a slightly decrease in the slope of the curve due to the damage during Step I. The failure occurred at 241 kN when the concrete crushed inside one of the loading points as shown in Figure 6. After the failure of concrete, the continued loading caused the stress redistribution of the residual section which led to the web buckling of FRP U-shape finally.

For Beam B with two different thickness of steel plate, both the load-deflection curve also showed an almost linear-elastic response during Step I, which indicated a good behaviour of deflection stabilization. However, during Step II the slope of curve began to decrease gradually at this point. The failure occurred at 421.2 kN and 558.1 kN as the similar failure mode as Beam A, see Figure 6. The failure of the concrete was followed by the web buckling of GFRP/steel hybrid U-shape due to the poor capacity of webs in residual section after failing of concrete, shown in Figure 6.

Comparing to GS0, composting steel plate with the thickness of 2mm and 6mm has increased the flexural strength by 174.8% and 231.6%, while the stiffness by 250% and 460%. Thus, as the thickness of hybrid steel plate increase the bearing capacity and the stiffness could be improved significantly. It showed that the failure mode of hybrid GFRP-concrete beam and hybrid GFRP/steel-concrete beam were similar as concrete crushed first, followed the web buckling.

Longitudinal strain distributions
Figure 7 shows the mid-span longitudinal strain distributions through the depth of the three beams at different loads up to the ultimate load. The longitudinal strain distributions remained plane up to ultimate load and the strains increased closely linear with increasing load. The neutral axis was nearly the interface between the interfaces of concrete and U-shape, indicating the concrete was always in compressive state, which was design
to utilize concrete effectively. Meanwhile, as the increase thickness of steel plate the neutral axis were downward to the bottom. The development trends of mid-span longitudinal strain variations at the bottom and top surfaces of the three beams were similar to those of mid-span deflections. Figure 8 shows the yield strain through the depth of GS2 and GS6, it is notable that yield of steel developed from the bottom to the top as load increasing.

**Figure 7** Mid-span longitudinal strain distributions through the depth of Beams

**Figure 8** Yield depth of hybrid GFRP/steel concrete beams varies with load.

**CONCLUSIONS**

The following conclusions are deduced from the experimental results:
• As the increasing thickness of steel plate to hybrid GFRP-concrete beam both the stiffness and the flexural capacity of the section increasing significantly.
• Composite action between GFRP and concrete can be ensured using aggregate coating.
• The strain distribution across the depth of the hybrid beam remained linear until the beam fail. This confirmed the assumption that plane sections remains plane before and after bending.
• The failure mode of both hybrid GFRP-concrete beam and hybrid GFRP/steel-concrete beam were similar which was concrete crushed in compression followed by the web buckling.

ABSTRACT
Corrosion is one of the main issues in the prestressed or steel bridges located in severe corrosive environments. Because of this, a large amount of money and time are required for maintenance and on renovation of bridges. Fiber reinforced polymer (FRP) is a good alternative to address this problem. Even though the HFRP is relatively expensive than the typical construction materials, it has advantages such as high corrosion resistance, low weight, and high tensile strength. This paper demonstrates the use of hybrid fiber reinforced polymer (HFRP) I-beams for construction of a short span pedestrian bridge in Japan. This bridge is the first HFRP short span pedestrian bridge in the world. It is located in a fishery harbor in Kure city, Hiroshima prefecture. The overall length and the width of the bridge are 12 m and 0.896 m, respectively. On-site loading tests were conducted on the bridge and it was satisfied the deflection criterion suggested by the Japan Society of Civil Engineers.

INTRODUCTION
During the fast economic growth period (after 1960) in Japan, a large number of short span pedestrian bridges were constructed. Most of those bridges were constructed using typical construction materials such as steel and prestressed concrete, so that the bridges located in marine environments can severely deteriorate by corrosion. Use of high corrosion resistant materials such as fiber reinforced polymers (FRP) for bridges can reduce the maintenance and renovation costs and time. In addition to the corrosion resistance, the FRP materials have high tensile strength, low weight, and high fatigue resistance. Even though the FRP bridges are associated with large initial cost, in terms of the life cycle cost, they are economical than the conventional construction materials (Nishizaki et al. 2006). And also, the use of the FRP for bridges is better than the steel or concrete as the FRP bridge construction relates with low emission of carbon dioxide (Tanaka et al. 2006).

This paper describes the construction of the first hybrid FRP (HFRP) short span pedestrian bridge in the world. This bridge was constructed in a fishery harbor in Kure city, Hiroshima prefecture, Japan in 2011. The main reason for construction of the HFRP bridge was to replace a deteriorated steel bridge and reduce the renovation and maintenance cost by the new FRP bridge. The steel bridge was used to access a pontoon from the pier and it was severely corroded and became unusable due to the marine environment. The new bridge consists of two HFRP I-beams topped with a glass FRP (GFRP) grating, which was used as the bridge deck. The overall length of the FRP bridge is 12 m and its width is 0.896 m. Figure 1(a) and (b) show the elevation and the cross section of the FRP bridge. The main girders of this bridge were made by joining two of 3 m long HFRP I-beams at both ends of a 6 m long HFRP I-beam. Different bolt types were used for the joints in order to select the best bolt type suitable for the marine environment. As all the structural components of the bridge can be pre-fabricated and transported to the construction site, these bridges have the advantage of rapid construction similar to steel bridges.
MATERIALS AND DESIGN PARAMETERS

Pultruded HFRP I-beam’s flanges consist of both the carbon fibers and the glass fibers and its web consists of glass fibers only. The main reason for having a GFRP web is to reduce the manufacturing cost of the I-beams. The overall width and the height of the HFRP I-beams are 95 mm and 250 mm and the thickness of flange and web are 14 mm and 9 mm, respectively. The details of the HFRP I-beam are shown in Figure 2. The mechanical properties of the HFRP flange and web are reported by the authors elsewhere (Wijayawardane et al. 2014). Hai et al. (2012) conducted four-point flexural tests on the HFRP I-beams and investigated the optimum carbon fiber content which will give the maximum flexural strength. According to that, the carbon fiber content for the HFRP I-beams was chosen for this study, which is 33% by volume.

![Diagram of HFRP pedestrian bridge](image)

Figure 1 Details of HFRP pedestrian bridge, Kure city, Hiroshima, Japan

In this pedestrian bridge, there were four types of beam-to-beam connections used to connect the HFRP I-beam parts together. The type of the beam-to-beam connection was differed by the number of bolts and the bolt type used for the connection. Used bolt types are 1) stainless steel bolts, 2) high corrosion resistant steel (HCRS) bolts, 3) stainless steel bolts with FRP cover, and 4) FRP bolts. Except the FRP bolts, all the other bolt types were made of steel with yield stress of 205 MPa and tensile strength of 520 MPa. The FRP bolts consist of glass fibers and they had tensile strength of 237 MPa, shear strength of 111 MPa, and tensile modulus of 23.7 GPa. The reason for using different bolt types is to understand the speed of deterioration of the bolts by the severe corrosive environment. Figure 3 shows the beam-to-beam connections used in the HFRP pedestrian bridge. The flexural behavior of each beam-to-beam connection having different bolt types was investigated by Hiroshi et al. (2016) and Hai et al. (2014). They conducted large-scale four point bending tests on the HFRP I-beams connected by above bolt types and selected the suitable bolt diameter and number of bolts required for each connection type. As shown in Figure 3, the I-beams were connected using 14 mm thick HFRP plates which are having a tensile modulus of 45.8 GPa.

In order to improve the bonding between the HFRP plates and the HFRP I-beams at the beam-to-beam connections, an epoxy adhesive (Sikadur-30) was used. The epoxy adhesive consist of two compounds and according to the manufacturer’s specification, it will have a shear strength of 10 MPa once it is cured under 20°C for 24 hours. The GFRP material was used for the bridge deck, stiffeners of the HFRP bridge girders, and handrails to enhance the corrosion resistance of the bridge and improve the durability.

The design guidelines provided by the Fisheries Agency in Japan (2003) was used to design the FRP pedestrian bridge. A design live load of 0.75 kN/m and a live load of 1.0 kN/m² was considered on the bridge girders and the bridge deck, respectively. Because of the low modulus of elasticity in FRP materials, the deflection limit becomes the dominant design criterion for FRP bridges. The Japan Society of Civil Engineers (2011) suggests that the
Deflection limitation for pedestrian bridges need to be $L/500$, where $L$ is the bridge span. According to that, the allowable deflection for the FRP pedestrian bridge in Kure city is 24 mm (12,000 m/ 500).

![Figure 2 Cross section of HFRP I-beam (units in mm)](image)

**CONSTRUCTION OF THE PEDESTRIAN BRIDGE**

The FRP bridge in Kure city was constructed very fast because its structural members were prefabricated in a factory and transported to the fishery harbor. In addition to that, there were low manpower and smaller space required for the construction of this bridge as the construction process was a matter of assembling the structural components together. During the fabrication of the HFRP I-beams and other FRP components, diamond bits were used to drill the bolt-holes to avoid excessive temperature increase in the resin matrix included in the FRP material. As shown in Figure 3, four bolt types were used at the beam-to-beam connections and the details of a joint is illustrated in Figure 5. A bolt-end distance of equal to or greater than $3d$ ($d = \text{nominal diameter of the bolt}$) was used, while the longitudinal and transverse spacing were equal to or greater than $4d$. The diameter of bolt-holes was 5% larger than the diameter of the bolts.

The construction sequence of the FRP short span pedestrian bridge is illustrated in Figure 4. At first, as shown in Figure 4(a), the HFRP I-beams were aligned on the supports. Then the epoxy adhesive was prepared by mixing its two compounds using an electric mixer (Figure 4(b)). An epoxy adhesive layer of approximately 0.5 mm to 1.0 mm was applied on the HFRP plates and on the HFRP I-beams at the joint location. It was made sure that

(h) Installing the bridge on the supports
(i) Completed FRP pedestrian bridge and the corroded steel bridge
the bolt-holes were not covered by the epoxy adhesive. The web-web joints were completed before the flange-flange joints. Figure 4(c) and Figure 4(d) shows the applying of the epoxy adhesive at a beam-to-beam joint. A higher torque of 20 N-m was applied to the stainless steel bolts, the HCRS bolts, and the stainless steel bolts with steel cover, whereas a lower torque of 10 N-m was applied to the FRP bolts (Figure 4(e)). This was due to the low tensile strength of the FRP bolts. The FRP bridge was fixed to the supports after finishing the fixing of GFRP stiffeners, installation of the GFRP grating, and fixing the handrails. The completed view of the FRP pedestrian bridge is shown in Figure 4(i).

Figure 5 Typical cross section of HFRP I-beam at joint (units in mm)

ON-SITE LOADING TEST

Before the installation of the FRP bridge, on-site loading tests were conducted to check the maximum deflection at midspan under the service load. As shown in Figure 6, two loading types were applied 1) concentrated load at midspan, 2) distributed load. The concentrated load was applied by ten number of people standing on the bridge and the loading details are given in Table 1. The load was increased by one person by one person getting on to the bridge and gathering at the midspan. In the case of the distributed load, the load was applied by eleven people and all the people were get on to the bridge at once (Figure 6(b)). The load applied under the distributed loading was 7.16 kN. When applying both loading types, mid-span deflection was measured using two LVDT transducers connected to the both girders of the bridge.

</tr>
</tbody>
</table>

Figure 7 shows the relationship between the load and the deflection of each HFRP beam under the concentrated loading. Both beams showed almost same flexural behavior and the maximum deflection at midspan was approximately 22 mm. As recommended in the JSCE (2011) design guidelines, the maximum allowable deflection for this bridge is 24 mm. Therefore, the maximum deflection under the concentrated service load is less than the deflection limit (Figure 7). Under the distributed loading, both HFRP beams showed a deflection approximately
16 mm, which is significantly lower than the deflection limit. However, it is important to increase the stiffness of
the bridge in order to utilize the superior tensile capacity of the HFRP I-beams.

CONCLUSIONS

1. The HFRP I-beams can be used as the bridge girders in short span pedestrian bridges. Therefore, the durability
of the main girders will be increased and hence they can be used in severe corrosive environments.

2. Because all the components of this bridge are fabricated in a factory and transported to the construction site, the
construction time is significantly low as steel bridges. Furthermore, because of the ease of assembly of the bridge,
it will not require large manpower and high skilled labor.

3. The bridge was designed to meet the deflection limitation (L/500) suggested by the JSCE and it showed
satisfactory behavior under service loads. However, in order to utilize the high tensile capacity of the HFRP
material, the stiffness of the bridge need to be further improved.

ABSTRACT

Composite sandwich panels comprising glass-fibre reinforced polymer (GFRP) faces, polyurethane (PUR) foam cores and longitudinal GFRP ribs are being increasingly considered for civil engineering structural applications. Similarly to other fibre reinforced polymer (FRP) components, composite sandwich panels are prone to creep and therefore this phenomenon must be duly considered in their design. However, experimental data about the viscoelasticity of this type of panels and their components is still scarce; furthermore, design guidelines for this particular phenomenon are still not available. This paper presents an experimental and analytical study about the creep response of GFRP-PUR composite panels. Flexural creep tests were conducted in full-scale panels, with and without longitudinal ribs, subjected to different load values. The ribs provided a considerable reduction in creep compliance compared to the simple panels. In order to analytically estimate the creep response of the full-scale panels, a composed creep modelling (CCM) approach is assessed. Therein, the creep behaviour of the individual constituent materials, determined from previous viscoelastic material characterisation studies, is used as input data for Timoshenko beam theory. The predicted and experimental creep curves presented good agreement for different load levels, attesting the adequacy of CCM for the analysis of creep in composite sandwich panels.

KEYWORDS

Composite sandwich panels, ribs, composed creep model, polyurethane foam, glass-fibre reinforced polymer.

INTRODUCTION

The use of composite sandwich panels for civil engineering structural applications is increasingly being considered by practitioners, as illustrated by the successful case studies regarding their use in bridge decks (Keller et al. 2014) and roof structures (Keller et al. 2008, Durand et al. 2012). Their potential for use in building floors has also been highlighted by several authors (Correia et al. 2012, Awad et al. 2012, Mousa and Uddin 2011), especially when the panels are reinforced with longitudinal ribs/webs (hybrid core) (Fam and Sharaf 2010, Correia et al. 2012). However, polymer-based composite sandwich panels, such as those comprising fibre reinforced polymers (FRP) and/or polymer foams, are prone to creep when subjected to significant permanent loads due to the viscoelastic nature of the polymeric materials (Huang and Gibson 1990, Garrido et al. 2014). This means that the effects of creep must be duly accounted for in the design of structural sandwich panels. To that end, data regarding the creep behaviour of sandwich panels and their constituent materials is necessary. Such data is still scarce and is often very much dependent on the sandwich panel architectures used in the corresponding experiments, meaning that their applicability in the analysis of different types of panels is limited.

This paper aims to address this issue by presenting an experimental assessment and analytical modelling of the creep response of two different types of composite sandwich panels, with and without reinforcement ribs. The uncoupling of the panels’ creep behaviour into the individual viscoelastic responses of their constituent materials is proposed. Such an approach, if successful in providing accurate estimates of creep deflections, allows the replacement of large scale creep testing on sandwich panels by small scale material characterisation tests. To this end, creep experiments are reported, carried out using sandwich panels comprising glass-fibre reinforced polymer (GFRP) faces, cores made of polyurethane (PUR) foam, and longitudinal GFRP reinforcement ribs/webs. A fairly simple and easily implementable composed creep modelling (CCM) approach is assessed, in which the creep behaviour of the individual constituent materials, determined from previous viscoelastic characterisation studies, is used as input data for Timoshenko beam theory to estimate the creep response of the full-scale panels. The
experimental creep curves obtained from those panels are compared with the model’s predictions for different load levels to evaluate the model’s accuracy.

LITERATURE REVIEW

Few studies have attempted to model the creep of full-scale sandwich panels using experimentally obtained viscoelastic properties of their constituent materials as a basis. Notable examples of such efforts may be found in the works of Huang and Gibson (1990), Shenoi et al. (1997), and Garrido et al. (2014). Huang and Gibson (1990) presented a study on the flexural creep behaviour of sandwich panels with aluminium faces and PUR foam cores with densities of 32, 48, 64, and 96 kg/m$^3$. The authors performed three-point bending creep experiments at various load levels up to 40% of the panels’ failure load for periods of 1200 h. The authors found that Timoshenko beam theory in combination with the time-dependent creep compliance of the foam cores provided reasonably good creep predictions, with deviations up to 10% from the experimental creep curves. Shenoi et al. (1997) studied the flexural creep response of sandwich panels comprising an FRP facing material and a rigid polyvinyl chloride (PVC) foam core. Sandwich beams were loaded in ten-point bending for periods up to approximately 1000 h. The obtained creep curves were used to estimate the creep compliance of the core material. Garrido et al. (2014) presented experimental and analytical investigations regarding the creep behaviour of a sandwich panel with GFRP faces and PUR foam core with density of 68 kg/m$^3$. The authors experimentally assessed the creep response of the PUR foam in shear, as well as the flexural creep response of the sandwich panel for a period of approximately 3600 h. Using a composed creep model, supported by a time-dependent shear modulus reduction function for the foam and an elastic modulus reduction function for the faces, the authors obtained creep deflection estimates based on Timoshenko beam theory. These compared well with the full-scale sandwich panel’s experimental creep curve.

To the authors’ best knowledge, there are no studies available in the literature regarding the creep of sandwich panels with reinforcement ribs/webs. These elements have shown high efficiency in improving the elastic behaviour (stiffness) of sandwich panels (Fam and Sharaf 2010, Correia et al. 2012). It would also be expectable that they would have a considerable influence in the creep behaviour of such panels.

EXPERIMENTAL PROGRAMME

Materials and Panel Architectures

In the current investigation, sandwich panels with GFRP face sheets were produced by vacuum infusion, moulded directly against the core material blocks. Two different panel typologies were adopted: (i) a simple cored panel with PUR foam, and (ii) a hybrid cored panel with PUR foam and two longitudinal GFRP ribs/webs along the panel edges. These were labelled as the “PUR” and “RIB” typologies, respectively. The mechanical properties of the materials used are given in Table 1. The cross-sectional dimensions of the sandwich panels are illustrated in Figure 1.

Figure 1 Cross-sectional dimensions of the sandwich panels: (a) PUR, and (b) RIB typologies
Experimental Setup

Flexural creep experiments were carried out for the two types of sandwich panel (Figure 2). The PUR panels were tested in a temperature controlled environment, with an average temperature of 19.9 °C ± 0.4 °C and relative humidity (RH) of 63% ± 5% (registered throughout the test duration). The RIB panels were tested in a different room with a high thermal inertia, for which an average temperature of 21.8 °C ± 0.7 °C and RH of 64% ± 6% was registered during the period of the creep experiments. The test durations were 790 h for the RIB panels and 910 h for the PUR panels. The panels were simply supported on steel rollers over a span of 3.30 m, and loaded using concrete slabs (each one with dimensions of 400 mm × 600 mm × 45 mm and weight of 0.26 kN) placed in six rows along the span to simulate a uniformly distributed load. Three specimens per panel type were tested, each with a different nominal load value \( p \): (i) 3.75 kN/m², (ii) 7.50 kN/m², and (iii) 15.00 kN/m².

![Figure 2 Full-scale creep tests setups for: (a) PUR panels, and (b) RIB panels](image)

EXPERIMENTAL RESULTS

The creep curves obtained per panel series are shown in Figure 3. Table 2 gives a detailed summary of the experimental results. This table also includes the exact values of the applied loads for each specimen, as well as a simple estimate of the shear stress percentage relative to the foam’s shear strength in the PUR panels. The elastic response of each panel series was consistent, with elastic compliance \( S_e \) values showing low scatter. The highest average values of this parameter were obtained for the PUR panels. A typical creep response, following a power law development with time, was obtained for the two panel types, as shown in Figure 3. Thus, individual power laws of the type given in Eq. 1 were fitted to the creep curves.

\[
\delta(t) = \delta_0 + m \left( \frac{t}{t_0} \right)^n
\]

In this equation, \( \delta \) is the total mid-span deflection, \( t \) is the time elapsed after load application, \( \delta_0 \) corresponds to the elastic mid-span deflection, \( m \) is the creep amplitude, \( n \) is the time exponent, and \( t_0 \) is the time unit considered. The creep amplitude and creep exponent values are given for each specimen in Table 2, as well as the obtained creep compliance values \( S_t = m/p \), where \( p \) is the applied load. The most pronounced creep response was observed in the PUR foam cored panels, which presented the highest average creep exponent and creep compliance values. The significantly lower creep response of the RIB panels compared to those with PUR foam confirms that
the addition of longitudinal GFRP ribs, besides significantly increasing the elastic stiffness, is quite effective in limiting the panels’ viscoelastic response.

The CCM approach provides predictions of a sandwich panel’s creep response by considering the creep of its individual materials/components and using them as input in an appropriate model of the panel’s structural behaviour. The effects of creep may be taken into account by considering the viscoelastic increase in the material’s deformations as time-dependent reductions ($\chi$) of its stiffness or elastic moduli. In the current study, this procedure was implemented using Timoshenko beam theory. Accordingly, Eq. 2 gives the mid-span deflection of a beam ($\delta^{L/2}$), considering the time ($t$) dependent effects of creep by: (i) affecting the Young’s modulus of the faces ($E_F$) by their respective reduction coefficient, $\chi_F$, and (ii) considering the sandwich panel’s shear stiffness, ($G_{AV}$)$_h$, as resulting from the contributions of the ribs and the foam core, given by ($G_{AV}$)$_h(t) = \chi_c(t)G_{cAV_c} + \chi_r(t)G_rA_{rAV_f}$. In this expression, $\chi_r$ and $\chi_c$ are the reduction factors for the ribs’ in-plane shear modulus ($G_r$) and for the shear modulus ($G_c$) of the core, respectively. In addition, $A_{rAV_f}$ and $A_{rAV_c}$ are the effective shear area of the ribs and core, respectively. Furthermore, in Eq. 2, $p$ represents the uniformly distributed load (load per unit length), $L$ corresponds to the span length, and $I$ is the second moment of inertia of the face sheets.

$$\delta^{L/2}_v(t) = \frac{5}{384} \frac{pl^4}{E_f(t)I} + \frac{1}{8} \frac{pl^2}{(G_{AV})_h(t)}$$

The moduli reduction coefficients for the faces, ribs, and core used in the current study are presented in the following section. Where temperature-dependent properties were available, the applicable test temperatures were taken into account in the modelling.

**Reduction Factors for Constituent Materials**

**PUR foam**

Garrido (2016) characterised the shear creep behaviour of a PUR foam similar to the one used in the current investigation. The author analysed and fitted the results using Findley’s power law (Findley 1960). In that study, the effects of temperature ($T$, in Kelvin) on that behaviour were also considered by extending the power law formulation to include creep parameters given by the Arrhenius equation. Based on the experimental characterisation of the foam’s viscoelastic response, shear modulus reduction factors were proposed for this foam, valid for temperatures between 20° C and 28° C, i.e., the range for which the model parameters were calibrated by the author. These reduction factors are given by the following equation, as a function of temperature and creep time:

$$\chi_c(t, T) = \left(1 + \frac{8.04}{246 \times 10^{-4} e^{\frac{12933}{8315}}}ight) \left(\frac{53.8 e^{\frac{12933}{8315}}}{15^{1.5}}\right)^{-1}$$
**GFRP faces**

In Garrido *et al.* (2016), a thorough characterisation of the flexural creep behaviour of GFRP laminates was carried out, using laminates similar to those of the face sheets in the sandwich panels of the current investigation. In this study the effects of temperature on the laminates’ creep response was also considered. The authors proposed the expression given in Eq. 4 to obtain the Young’s modulus reduction factors for that GFRP material, which is stress-dependent. However, this stress dependency was shown to only be significant for stress levels higher than ~25 MPa, a threshold that is well above the stress levels induced in the GFRP laminates in the current experiments.

\[
\chi_f(\sigma, t, T) = \left( 1 + \frac{27.6}{\sigma} \times 6.16 \times 10^{-13} e^{\left( \frac{-84498}{63167} \right) \sigma} \sinh \left( \frac{\sigma}{0.4} \right) t^{0.166} \right)^{-1}
\]  

**GFRP ribs**

Bottoni *et al.* (2014) carried out shear tests on GFRP specimens (produced by pultrusion, fibre layup not specified by the authors) at a controlled temperature of 20 °C and RH of 60%, for a period of about 760 days. The authors found that the shear creep deformations followed a typical power law development throughout the duration of the experiments. The time-dependent reduction factor given in Eq. 5 was determined from the creep data provided by the authors,

\[
\chi_r(t) = (1 + 0.149 \times t^{0.205})^{-1}
\]

**Model Predictions**

The predicted creep deflection curves are plotted in Figure 4 against the respective experimental results. One may observe that the creep predictions for the PUR panels reproduce quite well the overall development of the experimental curves. A slight overestimation of the creep deflections is obtained for the two lowest load levels. However, for the highest load, the CCM underestimates the experimental creep deflections, most likely due to the nonlinearity of the PUR foam’s creep behaviour at such high stresses. For this panel type, the CCM creep predictions are largely influenced by the creep response of the PUR foam, which exhibits significant viscoelasticity.

![Figure 4 Comparison between CCM predictions and experimental creep curves for the: (a) PUR panels, and (b) RIB panels](image)

In fact, considering the CCM predictions at 900 h of creep time, the creep deformations in shear account for 95% of the total creep deflection (for all load levels), while bending creep deformation accounts for only 5% of that deflection. Regarding the RIB panels, the CCM predictions slightly underestimate the experimental creep curves. However, the overall development of the predicted creep curves agrees well with the experimental results, attesting the adequacy of the CCM formulation in predicting the creep response of sandwich panels with longitudinal GFRP ribs.

**CONCLUSIONS**

Sandwich panels developed for civil engineering applications, presenting two different core solutions, namely (i) a simple PUR foam core, and (ii) a hybrid PUR foam and GFRP rib core, were experimentally and analytically studied regarding their flexural creep behaviour under uniformly distributed loading. The simple PUR foam cored panels exhibited high creep deformations, mostly due to the PUR foam’s marked viscoelasticity. The addition of longitudinal GFRP ribs to the panel core significantly reduced (three-fold) the creep compliance of the sandwich
panels, which presented considerably lower creep deformations for similar loads and time periods. The CCM predictions showed reasonable accuracy, further validating this approach for the prediction of the creep behaviour of full-scale sandwich panels, and extending its applicability to panels with longitudinal reinforcement ribs. The results obtained are particularly encouraging when taking into account the model’s relative simplicity and ease of use in predicting a very complex phenomenon such as the creep of sandwich panels.

ABSTRACT

Non-linear architecture is becoming popular for its streamlined appearance and well fusion with environment. However, it faces construction difficulties because the linear formwork system is unsuitable for non-linear appearance. FRP (Fibre-Reinforced Polymer) curved sandwich panel with PU (Polyurethane) foam core, shows low density, high strength, convenient construction and excellent designability, which can satisfy the requirements for low cost and high speed in the construction of non-linear architecture. Additionally, thus sandwich panels can also act as the self-standing structures for its great mechanical properties, not only the formworks of the structures. However, there are little researches on the mechanical behavior and applications of FRP curved sandwich panels with PU foam core. This paper conducts a series of three-point flexural tests to study the mechanical behavior of such panels, including the influences of different geometrical or physical parameters on the load capacity and failure modes.

KEYWORDS

FRP, curved sandwich panel, flexural test, parameter study, local effect.

INTRODUCTION

The curved FRP sandwich panel with polyurethane (PU) foam core combines the advantages of FRP and PU foam, and provides high-strength, lightweight, anti-corrosion and easy-forming characteristics (Jones 1975). It is suitable for the non-linear and thermal-insulated architecture. However, there are little statically experimental studies on such curved panels (Bozhevolnaya and Kildegaard 1997, Frostig 1999, Keller et al. 2008), especially for the concentrated loading case, in which the local effects might be very obvious.

This paper conducts a series of three-point flexural tests to study the mechanical behavior of such panels, including the influences of different geometrical or physical parameters on the load capacity and failure modes.

EXPERIMENTAL PROGRAM

Material Properties

In this study, the glass fiber sheets were HITECH-G430S (Unidirectional fabric, 430 g/m²), which were produced by Nanjing Hitech Composites Co., Ltd. The resin system was SWANCOR 2511-1 A/BS epoxy resin and was produced by Swancor (Tianjin) Wind Blade Materials Co., Ltd. The PU foam was closed-cell and was produced by Kezhao New Materials Co., Ltd. The specimens were prepared using vacuum-assisted resin transfer molding (VARTM) process. The thickness of one single layer of FRP after solidification was approximately 0.45 mm, and the fiber mass fraction was approximately 68%. The material properties of GFRP (Glass Fibre-Reinforced Polymer) face sheet and PU foam core are shown in Table 1 and Table 2 according to Chinese standards GB/T 1447-2005 (FRP tension), GB/T 1448-2005 (FRP compression), GB/T 3355-2005 (FRP shear), GB/T 1452-2005 (PU tension), GB/T 1453-2005 (PU compression) and GB/T 1455-2005 (PU shear), respectively. The tension strength of GFRP face sheet in the 0° direction has not been obtained yet for the clamped failure of the coupon at the end of the tension process.

Specimens

The specimens in this study include ten curved sandwich panels and one flat sandwich panel as Table 3 shows. In the specimen designations such as D1-30-20-A, the first part represents the density of PU foam core, as shown in Table 2, and the second part means the inclined degree $\alpha$ as shown in Figure 1, and the third part represents the thickness of the PU foam core, and the last part means the stacking sequence of FRP face sheet, in which the $0^\circ$ direction means that the fiber is parallel to the longitudinal direction of the specimen. The thickness of face sheet can be calculated from the thickness of a single layer. The details of each specimen are shown in Table 3.

Setup and Instrumentation

![Figure 1 Experimental setup and instruments for FRP sandwich panels with PU foam](image)

The typical test setups for FRP sandwich panels with PU foam core are shown in Figure 1. The loading was controlled by the displacement magnitude, and the loading rate was approximately 1 mm/min.
EXPERIMENTAL RESULTS

Experimental Observation and Failure Modes

The specimens D1-30-20-A, D3-60-20-A, D3-30-15-A, D3-30-20-C and D3-30-20-D showed similar mechanical behaviors. The PU foam core under the loading roller didn’t exhibit significant deformation during the loading process. When the maximum load was reached, shear failure suddenly appeared in the core and the load sharply decreased. The failure of this specimen was sudden and brittle, as shown in Figure 2(a).

The specimens D3-00-20-A, D3-30-20-A and D4-30-20-A exhibited similar mechanical behaviors and failure modes. The transversely compressive deformations of the PU foam core under the loading roller were not significant during the initial loading stages, but the indentations took place and rapidly developed when closing to the maximum load. When the specimens reached their maximum load, as Figure 2(b) showed, the face sheets under the loading roller yielded and the capacity decreased. For the specimen D3-00-20-A, the plastic hinge at the mid-span formed and the force transferring route changed from beam system into catenary system, and the lower face sheet started to take tension force. For the other two specimens, the core immediately showed shear failure after the face yielded and the capacity suddenly decreased.

The specimen D3-30-20-B showed no significant local deformation under the loading roller during the initial loading process. When the load reached 0.6\(P_{\text{max}}\) (the maximum load), the indentation formed and gradually developed. When the maximum load was reached, as Figure 2(c) showed, the upper face sheet close to the loading roller wrinkled and the capacity decreased a little bit. The core shear failure finally took place and the load sharply decreased when the loading process continued. The specimen D5-30-20-A also showed face wrinkling followed by core shear failure, but little indentation was observed during the load stages.

The specimen D2-30-20-A exhibited little indentation until the load reached 0.9\(P_{\text{max}}\). When the load reached approximately 0.9\(P_{\text{max}}\), as the Figure 2(d) showed, the indentation quickly developed and the load increased gradually. After large deformation of indentation, the core shear failure sharply took place.

Load-Displacement Relationships

The load-displacement curves are shown in Figure 3. The displacement is the value of the displacement transducer placed at the upper face sheet at the mid-span. The Figure 3(a) shows the comparison of relationships within different densities, indicating that the higher density provides higher bearing capacity and stiffness. The Figure 3(b) shows the comparison between the curved sandwich panels and the flat sandwich panel. It is obviously shown that the curved ones provide higher stiffness than the flat one. The Figure 3(c) shows the influences of different stacking sequences on the relationships, which indicates that more number of layers in 0° direction provides higher stiffness and changes the failure modes from indentation to pure core shear. The Figure 3(d) shows the comparison of different core thickness. It is found that the thinner core provides lower stiffness and leads the failure of pure core shear.

![Figure 2 Failure modes of the specimens](image-url)
The capacity of the specimen is effected by the density of the foam, the inclined degree, the stacking sequence and the core thickness. The details of bearing capacity are summarized in Table 4. It is found that the maximum load is controlled by the failure process. If the failure mode is core shear, the capacity can be predicted by considering shear failure of the foam core and the contribution of the GFRP face sheets. The failure modes are also summarized in Table 4. It is found that the indentation and the core shear are the two main failure modes when loaded in the mid-span with loading roller. The indentation can cause further failures such as face yield or face wrinkling. The core shear is usually the final failure mode if the loading process continues.

</tbody>
</table>

The following conclusions can be drawn from this study:

- The capacity of the specimen is affected by the density of the foam, the inclined degree, the stacking sequence, and the core thickness.
- The maximum load is controlled by the failure process. If the failure mode is core shear, the capacity can be predicted by considering shear failure of the foam core and the contribution of the GFRP face sheets.
- The indentation and core shear are the two main failure modes when loaded in the mid-span with loading roller.
- The indentation can cause further failures such as face yield or face wrinkling. The core shear is usually the final failure mode if the loading process continues.
A series of three-point flexural tests are conducted to study the mechanical behavior of FRP curved sandwich panels with PU foam core. The influences of different geometrical or physical parameters on the load capacities and failure modes are concerned in the paper.

The curved sandwich panels show higher stiffness than the flat panel, and display different failure processes from the flat one. The force transferring route of the flat sandwich panel has changed for the forming of the plastic hinge in the upper face sheet at the mid-span.

The indentation and core shear are the two main failure modes in the tests. The local effects can’t be ignored when concentrated load exerting on such panels.

ABSTRACT

FRP (Fibre-Reinforced Polymer) curved sandwich panel with PU (Polyurethane) foam core combines the advantages of FRP and PU foam, showing low density, high strength, convenient construction and excellent designability. So it is a kind of structural components suitable for the need of low cost and fast construction when build non-linear architectures. However, there are little researches on the mechanical behavior of FRP curved sandwich panels with foam core. This paper develops an approach to analyze the mechanical behavior of such panels based on high order sandwich panel theory. The theoretical result is validated to be very precise in comparison with that of finite element analysis (FEA). With this method, the differences between the plain and the curved sandwich panel are compared and some parameter studies are further conducted.

KEYWORDS

FRP, curved sandwich panel, high order theory, finite element analysis, parameter study.

INTRODUCTION

With the development of non-linear architecture, the aims for easy construction are drawing more and more attention. Additionally, the continuing high energy consumption in buildings calls for better thermal insulation capabilities. Fibre-Reinforced polymer (FRP) is suitable to construct the non-linear architecture for its high-strength, lightweight, anti-corrosion and easy-forming characteristics (Jones 1975). The curved FRP sandwich panel with polyurethane (PU) foam core can not only fit the need of the non-linear architecture, but also significantly improve the thermal performance for the excellent thermal insulation capabilities of PU foam core. Various models have been developed to study the mechanical behavior of FRP sandwich panels (Noor et al. 1996, Carrera and Brischetto 2009). The classical and first-order model neglect the transverse deformation of the core (Carrera and Brischetto 2009). Frostig and co-workers have developed closed-form high-order sandwich panel theory (HSAPT) to analyze the flat and curved sandwich panel with compressible core without any preliminary deformational restrictions (Frostig et al. 1992, Frostig 1999).

This paper develops a simple but accurate enough method based on HSAPT to analyze the mechanical behavior of FRP cylindrical sandwich panels with foam core. The comparison of this method with finite element analysis (FEA) is conducted to assess the accuracy of this method. Some parameter studies are further conducted.

HIGH-ORDER SANDWICH PANEL THEORY FOR FRP SANDWICH PANELS

Mechanical Properties of FRP Curved Laminate

According to the classical laminate theory, the in-plane resultants of cylindrical FRP laminate are written as:

\[
\begin{bmatrix}
N_x \\
N_y \\
N_{xy}
\end{bmatrix} = \begin{bmatrix}
A_{11} & A_{12} & A_{16} \\
A_{21} & A_{22} & A_{26} \\
A_{61} & A_{62} & A_{66}
\end{bmatrix} \begin{bmatrix}
\epsilon_x \\
\epsilon_y \\
\gamma_{xy}
\end{bmatrix} + \begin{bmatrix}
B_{11} & B_{12} & B_{16} \\
B_{21} & B_{22} & B_{26} \\
B_{61} & B_{62} & B_{66}
\end{bmatrix} \begin{bmatrix}
\kappa_x \\
\kappa_y \\
\kappa_{xy}
\end{bmatrix}
\]

\[
\begin{bmatrix}
M_x \\
M_y \\
M_{xy}
\end{bmatrix} = \begin{bmatrix}
D_{11} & D_{12} & D_{16} \\
D_{21} & D_{22} & D_{26} \\
D_{61} & D_{62} & D_{66}
\end{bmatrix} \begin{bmatrix}
\epsilon_x \\
\epsilon_y \\
\gamma_{xy}
\end{bmatrix}
\]

(1)
where $A_{ij}, B_{ij}$ and $D_{ij}$ ($i, j=1,2,6$) are the stretching, coupling and bending stiffnesses, respectively. The strain and curvature matrices are written as follows:

\[
\begin{align*}
\hat{e}^e &= \begin{bmatrix} \hat{e}^e_r \\ \hat{e}^e_\varphi \\ \hat{e}^e_z \end{bmatrix} = \begin{bmatrix} u_r(\varphi,z) + w_z(\varphi,z) \\ v_\varphi(\varphi,z) \\ \frac{1}{r} \left( u_\varphi(\varphi,z) + \frac{1}{r} v_r(\varphi,z) \right) \end{bmatrix}, \\
\hat{e}^\varphi &= \begin{bmatrix} \hat{e}^\varphi_r \\ \hat{e}^\varphi_\varphi \\ \hat{e}^\varphi_z \end{bmatrix} = \begin{bmatrix} w_z(\varphi,z) - u_r(\varphi,z) \\ 2w_\varphi(\varphi,z) - u_\varphi(\varphi,z) \\ \frac{1}{r} \left( w_\varphi(\varphi,z) - \frac{1}{r} v_r(\varphi,z) \right) \end{bmatrix}.
\end{align*}
\]

(2)

where $u$, $v$ and $w$ are the displacements in the circumferential, the $Z$ and the radial directions, respectively.

**Mathematical Formulation**

The derivation of the mathematical formulation refers to the reference (Frostig 1999). The geometry and internal resultants and stresses are shown in Figure 1. The field equations are derived as follows.

For the FRP face sheets, the equations are:

\[
N_{r,\varphi} + \frac{M_{r,\varphi}}{r_i} - br_r(1 - \frac{d}{2r_i})\tau_{r,\varphi}(r = r_\text{in}, \varphi) = -n_r r_i + m_i
\]

(3)

\[
N_{b,\varphi} + \frac{M_{b,\varphi}}{r_b} + br_r(1 + \frac{d}{2r_b})\tau_{r,\varphi}(r = r_\text{out}, \varphi) = -n_r r_b + m_b
\]

(4)

\[
\frac{M_{r,\varphi}}{r_i} - N_r - br_r \sigma_{r,\varphi}(r = r_\text{in}, \varphi) + \frac{bd_r r_i}{2r_i} \tau_{r,\varphi}(r = r_\text{in}, \varphi) = -q_r r_i + m_{r,\varphi}
\]

(5)

\[
\frac{M_{b,\varphi}}{r_b} - N_b + br_r \sigma_{r,\varphi}(r = r_\text{out}, \varphi) + \frac{bd_r r_b}{2r_b} \tau_{r,\varphi}(r = r_\text{out}, \varphi) = -q_r r_b + m_{b,\varphi}
\]

(6)

where $N_j$ and $M_j$ ($j=t$ (i.e. top), $b$ (i.e. bottom)) are the in-plane resultants at the FRP face sheets, and $\sigma_{r,\varphi}(r=r_\text{in}, \varphi)$ and $\tau_{r,\varphi}(r=r_\text{in}, \varphi)$ ($j=t, b$) are the peeling and shear stresses in the interfaces, respectively.

For the foam core, the equations are:

\[
(r \tau_{r,\varphi}(r, \varphi))_r + \tau_{r,\varphi}(r, \varphi) = 0, \quad \tau_{r,\varphi}(r, \varphi) + (r \sigma_{r,\varphi}(r, \varphi))_r = 0
\]

(7)

Through the combination of kinematic relation, stresses fields, compatibility conditions and constitutive relations, the governing equation that only related to the core is derived as:

Figure 1 The geometry, the internal resultants and stresses of cylindrically curved FRP sandwich panel
FRP lamina and symmetric laminate

Because of the plane stress condition for HSAPT, the assumptions \(N_{y}^{f} = 0\) and \(N_{x}^{f} = 0\) are introduced, the load \(N_{f}^{o}\) is derived as Eq. 9 shows. The moment \(M_{f}^{o}\) can be similarly derived as follows.

\[
N_{f}^{o} = \left( A_{1} - \frac{2A_{1}A_{2}A_{6} - A_{2}^{2}A_{6} - A_{6}^{2}A_{12}}{A_{2}^{2} - A_{12}^{2}A_{6}} \right) \varepsilon_{o}^{0} \cdot M_{f}^{o} = \left( D_{11} - \frac{2D_{12}D_{26}D_{26} - D_{12}^{2}D_{66} - D_{26}^{2}D_{12}}{D_{11}^{2} - D_{26}^{2}D_{12}} \right) \kappa_{f}^{o} = (E)_{eq} \kappa_{f}
\]

Through the substitution of the Eq. 9 in the Eqs. 3-6, the four out of the five governing equations are derived as Eqs. 10-13 show. The fifth equation is listed as the above Eq. 8 shows.

\[
\left( \frac{(EA)_{eq}}{r_{i}} + \frac{(EI)_{eq}}{r_{i}^{3}} \right) u_{\phi,pp} + \frac{(EA)_{eq}}{r_{i}^{3}} w_{\phi,pp} - b r_{c} \left( 1 - \frac{d_{j}}{2r_{i}} \right) r_{i} = -n_{i} r_{i} + m_{i}
\]

\[
\left( \frac{(EA)_{eq}}{r_{b}} + \frac{(EI)_{eq}}{r_{b}^{3}} \right) u_{\phi,pp} + \frac{(EA)_{eq}}{r_{b}^{3}} w_{\phi,pp} + b r_{c} \left( 1 + \frac{d_{j}}{2r_{b}} \right) r_{b} = -n_{b} r_{b} + m_{b}
\]

\[
- \frac{(EA)_{eq}}{r_{c}} \frac{u_{\phi,pp}}{r_{c}} + \frac{(EI)_{eq}}{r_{c}^{2}} \frac{w_{\phi,pp}}{r_{c}^{2}} = \left( \frac{EA_{eq}}{r_{c}} \frac{w_{\phi,pp}}{r_{c}^{2}} - \frac{(EI)_{eq}}{r_{c}^{2}} \frac{w_{\phi,pp}}{r_{c}^{2}} \right) \varepsilon_{o}^{0} = -q_{c} r_{c} + m_{c,o}
\]

\[
- \frac{(EA)_{eq}}{r_{c}} \frac{u_{\phi,pp}}{r_{c}} + \frac{(EI)_{eq}}{r_{c}^{2}} \frac{w_{\phi,pp}}{r_{c}^{2}} = \left( \frac{EA_{eq}}{r_{c}} \frac{w_{\phi,pp}}{r_{c}^{2}} - \frac{(EI)_{eq}}{r_{c}^{2}} \frac{w_{\phi,pp}}{r_{c}^{2}} \right) \varepsilon_{o}^{0} = -q_{c} r_{c} + m_{c,o}
\]

\[
\kappa_{o,j}^{eq} = \kappa_{o,j}^{x} = 0
\]

Thus the in-plane resultants are written as:

\[
N_{f}^{o} = \left( A_{1} - \frac{A_{2}^{2}}{A_{12}} \right) \varepsilon_{o}^{0} + B_{1} \varepsilon_{o}^{0} - A_{12} \varepsilon_{o}^{0} = \left( A_{1} \varepsilon_{o}^{0} + B_{1} \varepsilon_{o}^{0} \right) \kappa_{f}^{eq} = \left( D_{11} - \frac{B_{12} B_{26}}{B_{16}} \right) \kappa_{f}^{eq} = (E)_{eq} \kappa_{f}
\]

The expressions for the governing equations are the same as the FRP lamina and symmetric laminates.

**Antisymmetric angle-ply laminates**

Since the variables \(u, w\) for HSAPT are only functions of \(\phi\), which means the coupling effects of FRP laminates are hard to be considered, the elements in Eq. 2 are in the forms:

\[
K_{o,j}^{eq} = 0, \quad \kappa_{o,j}^{eq} = 0
\]

**Asymmetric laminates**
The other cases except for the above types are usually denoted as asymmetric laminates. After some mathematical manipulations, the in-plane resultants are derived as follows with the plane stress assumption.

\[ N_j^\sigma = \left( A_1 - \frac{A_4 A_6 A_{26} - A_6^2 A_{26}}{A_{26}^2 - A_{26} A_{66}} A_2 A_6 A_{26} - A_6^2 A_{26} \right) c_{\sigma j}^\sigma + \left( B_1 - \frac{A_4 B_6 A_{26} - A_6^2 B_{26}}{A_{26}^2 - A_{26} A_{66}} A_2 B_6 A_{26} - A_6^2 B_{26} \right) \kappa_{\sigma j}^\sigma \]

\[ M_j^\sigma = \left( B_1 - \frac{A_4 B_6 B_{26} - B_6^2 B_{26}}{B_{26}^2 - B_{26} B_{66}} A_2 B_6 B_{26} - B_6^2 B_{26} \right) c_{\sigma j}^\sigma + \left( D_1 - \frac{A_4 D_6 B_{26} - B_6^2 D_{26}}{B_{26}^2 - B_{26} B_{66}} A_2 D_6 B_{26} - B_6^2 D_{26} \right) \kappa_{\sigma j}^\sigma \]  \hspace{1cm} (17)

Similarly, through the substitution of Eqs. 2 and 17 in Eqs. 10-13, the four out of the five governing equations can be derived. The fifth equation is still Eq. 8.

**FEA SIMULATION AND VALIDATION**

The specimens refer to the reference (Frostig 1999) as Figure 2 shows. The material properties are listed in Table 1 (Keller et al. 2010), where x, y and z correspond to the circumferential, the Z and the radial directions, respectively. The face sheets of symmetric laminate with the stacking sequence \([0/90/0]\), each layer of 0.5 mm, are first studied. The theoretical results are solved using software Maple and the finite element analysis (FEA) is conducted using ANSYS. The 20-node hexahedral solid element (solid 186) is used to simulate the PU foam and 8-node quadrilateral shell element (shell 99) is used to simulate the FRP face sheets.

Figure 3 shows that the HSAPT for FRP sandwich panels agrees well with the FEA. Figure 3(a) shows the radial displacements of the FRP face sheets. The largest error takes place at the mid-span, and is 1.61% for the upper face sheet (5.5000 mm with HSAPT and 5.4127 mm with FEA) and 1.11% for the lower face sheet (5.3206 mm with HSAPT and 5.3127 mm with FEA).
with HSAPT and 5.2624 mm with FEA). Figure 3(b) shows that the peeling stresses have stress concentration in the support vicinity. The simulation results of different stacking sequences of FRP face sheets are listed in Table 2. It is clearly shown that this method has enough accuracy.

**PARAMETER STUDY**

The inclined degree is changed from 0 to 90, namely, from flat panel to semi-circle panel. The method developed in this paper is also suitable to the flat FRP sandwich panel with foam core. The results for uniform load case listed in Figure 4. It is clearly seen that with the increase of the inclined degree, the mechanical parameters under uniform load all decrease quickly before about 30 degree, and decrease gradually after that until 90 degree. In comparison with the curved sandwich panels, the flat panel has the largest deflection, peeling stresses and shear stresses in the interfaces under the same load and boundary conditions. Figures 4(b) indicates that the local effects are located in the vicinity of the support, and decrease when the inclined degree increases.

**CONCLUSIONS**

The main conclusions are as follows:

(1) Based on HSAPT, an analytical method is put forward to analyze mechanical behaviors of the FRP cylindrically curved sandwich panels with foam core.

(2) This method is validated to be accurate enough compared to the results of the FEA. The method is suitable for different stacking sequences for the FRP face sheets, but the coupling effects are not calculated.

(3) The flat sandwich panel has the much larger deformation, peeling stresses and shear stresses compared to the curved panels under the same load and boundary conditions.

ABSTRACT

The use of composite sandwich panels as structural elements is becoming increasingly widespread due to their high strength-to-weight ratios and favourability for pre-fabricated construction methods. This study analyses the effect of foam core density on the flexural behaviour of sandwich panels with novel bio-composite unidirectional flax fibre-reinforced polymer skins. Nine 1000x100 mm² sandwich panels with symmetrical skins and a 50 mm thick core were fabricated and tested in four-point loading. This experimental program compares the effect of three polyisocyanurate foam cores with varying densities when used in conjunction with three-layers of flax-FRP for each skin.

INTRODUCTION

The recent movement towards sustainable and environmentally friendly building practices has brought the development of alternative building materials and methods to the forefront of current research. As a result, the popularity of highly efficient buildings and pre-fabricated modular construction has risen considerably to meet new sustainability design criteria. Sandwich panels are an example of highly efficient systems that can be optimized for rapid-construction for the cladding of buildings or lightweight decking.

Sandwich panels are composite systems comprised of two stiff skins on opposite faces of a core material. The core material is often comprised of lightweight foam polymer, balsa wood, or aluminium honeycomb structure. Structural Insulated Panels (SIPs), a denomination of sandwich panels, are typically selected based on insulating properties. The most common foam cores are closed-formed cell structures such that they are impermeable to water and are isotropic, including polyurethane (PUR), polyvinylchloride (PVC) and polyisocyanurate (PIR) (Carlsson, 2011). As a result, sandwich panel systems boast a high strength-to-weight ratio.

Although typical skin materials include concrete, sheet metal and oriented strand board, fibre-reinforced polymers (FRP) have been implemented as the skin materials in SIPs and have shown promise in providing high structural capacity. Glass fibre-reinforced polymer (GFRP) skins are the most common type of FRP skin; however, they rely heavily on synthetic materials. Mak et al (2015) demonstrated the promise of natural flax fibres as a more sustainable alternative to commercially established GFRP, demonstrating that three layers of unidirectional flax fibres are equivalent in strength and stiffness to a single layer of GFRP.

Mathieson and Fam (2008) investigated the static behaviour of sandwich panels with GFRP skins and soft PUR foam cores and found that the core material governs in design due to significant shear deformations comprising up to 93% of the total deflection. Sharaf et al. (2010) investigated the effects of core density on one way bending of sandwich panels using two PUR foam cores and GFRP skins. It was found that increasing the density of the core material significantly increased the stiffness and strength of the composite system, while reducing the degree of core shear deformations. The governing failure mode of thin-skinned sandwich panels is often due to inward wrinkling of the skins, shear failure of the foam core or debonding at the core-skin interfaces. Sharaf et al. (2010) found lower density foam cores suffer from localized inward wrinkling of the compression GFRP skin. Mak et al.
(2015) showed that this failure type was consistent in sandwich panels comprised of three layers of unidirectional flax fibre-reinforced polymer (FFRP) skins, and that the ultimate capacity of three-layered FFRP skinned sandwich panels matches closely to that of identical GFRP sandwich panels.

PIR foam cores were used in this study due to low thermal conductivity for cladding applications. Applications involve spray foam and rigid foam boards. Spray foam cores were investigated by Shawkat et al. (2008); however, panels demonstrated poor quality control. Mak et al. (2015) studied the performance of sandwich panels with rigid foam boards using different manufacturing methods. A reduced ultimate strength was reported with the use of vacuum bag moulding as opposed to wet layup moulding using rigid foam.

This study investigates the effect of PIR foam core density on the flexural behaviour of FFRP sandwich panels subjected to four-point bending. Sandwich panels with skins comprised of three-layered unidirectional FFRP were constructed using three separate PIR foam cores of increasing density. The panels were constructed using a commercially available epoxy. The impact on strength, stiffness, and failure mode with changes in core density are examined.

MATERIAL SPECIFICATIONS AND TESTING

Materials

This section highlights the properties for all materials used in the fabrication of the test specimens.

Flax Fibres: Unidirectional flax fibre fabric was used with a reported tensile strength and modulus of 500 MPa and 50 GPa respectively, and an ultimate elongation of 1.5%. The dry density of the fibres is 1.28 g/cm³ (Composites Evolution Ltd. 2012). Mak et al. (2015) found the tensile and compressive strengths of four layers of unidirectional flax fibres with Tyfo S epoxy to be 150 MPa and 77 MPa respectively, and the tensile and compressive moduli to be 8.7 MPa and 4.2 MPa respectively.

Epoxy: Tyfo S, a two-component high elongation epoxy resin was used as the saturating resin. The reported tensile strength and modulus are 72.4 MPa and 3.18 GPa respectively, the compressive strength and modulus are 86.2 MPa and 3.2 GPa respectively, and the maximum elongation is 5%. These reported material properties are given after a 72 hours post cure at 60°C (Fyfe Co. LLC., 2012).

Foam: Three separate rigid, unfaced, closed cell polyisocyanurate foams were used: ELFOAM P200, P400, and P600 with respective densities of 32, 64, and 96 kg/m³. The P200 foam has a reported parallel and perpendicular shear strength of 151 kPa and 110 kPa, parallel and perpendicular shear modulus of 1.52 and 1.22 MPa, and an R-value of 1.06 m²°C/W (Elliott Company, 2012). The reported density is 32 kg/m³. The P400 foam has a reported parallel and perpendicular shear strength of 379 kPa and 344 kPa, parallel and perpendicular shear modulus of 5.86 and 5.17 MPa, and an R-value of 1.04 m²°C/W (Elliott Company, 2012). The reported density is 64 kg/m³. The P600 foam has a reported parallel and perpendicular shear strength of 585 kPa and 489 kPa, parallel and perpendicular shear modulus of 7.23 and 6.06 MPa, and an R-value of 0.97 m²°C/W (Elliott Company, 2012). These directions are representative of the direction of manufacturing. The reported density is 96 kg/m³. The density of the foam used in this study was calculated to be 92.7 kg/m³.

PIR Foam Core Tests

Compression tests

Five coupons were tested for each foam density according to ASTM C365 (ASTM 2011). Each coupon was cut into a 50-by-50-by-50 mm³ cube. The coupons were placed between two steel compression plates in an Instron 8802 testing machine. The compression tests were conducted at a rate of 1.0 mm/min until 80% strain was reached. A linear potentiometer (LP) was used to measure the total displacement between the compression plates and related to the strain in the sample. For each density, the initial response of the PIR foam was linear until reaching a plastic plateau after initial crushing, followed by strain hardening. The response of each density can be seen in Table 1 and Figure 1.

Tension tests

Five coupons were tested for each foam density according to ASTM C297 (ASTM 2016). Each coupon was cut into a 50-by-50-by-50 mm³ cube. The coupons were bonded to steel T-sections with epoxy resin to be gripped using an Instron 8802 testing machine. The tension tests were conducted at a rate of 0.5 mm/min until failure. For
each density, the response of the PIR foam was linear until failure. Strain in the sample was related to the displacement between the steel grips. The response of each density can be seen in Table 1 and Figure 1.

Fabrication of Sandwich Panels

Nine sandwich panels were fabricated using the wet lay-up method for manufacturing composite materials. Rigid sheets of 1050x350 mm² of each foam density were set on plastic sheeting and dabbed with a damp towel to remove any particles that may impact the core-skin bond. The foam was evenly wetted with epoxy resin. A sheet of flax fibre was placed along the foam sheet and additional epoxy resin was added until the installed fibres were saturated. The processes was repeated until three saturated layers were in place. A sheet of plastic was placed over the completed side and the panel was flipped over to apply three layers to the opposite side. Finally, the excess epoxy resin and air was worked out of the skin. A large plastic panel was placed on the sandwich panel. Steel plates were then placed on top of the large plastic panel during the curing process to ensure smooth skins of even thickness. Each completed sandwich panel was then cut using a circular saw into three 1000x100 mm² repetitions for testing, denoted by A, B and C. Each type of specimen was given a unique title to reflect the comprising materials. For instance, F64 refers to the three repetitions of flax skinned (F) panels with a 64 kg/m³ foam core. All specimens were allowed to cure at room temperature for a minimum of a month prior to cutting and testing.

Test Setup and Instrumentation

The specimens were tested in a Lab Integration universal testing machine in simply supported four-point loading at a rate of 2 mm/min, as shown in Figure 2. A 3 mm thick rubber pad was placed between steel plates at the end supports and loading points in order accommodate small rotations and minor various in skin thickness. The total span of each specimen was 900 mm, including two 375 mm long shear spans outside of the 150 mm constant moment region at mid-span. One electrical resistance strain gauge was adhered to each skin at mid-span in order to measure longitudinal skin strains. Three linear potentiometers (LPs) were placed at mid-span against aluminium extenders attached to opposite sides of the tension skin in order to measure deflections and rotations.
EXPERIMENTAL RESULTS AND DISCUSSION

Flexural Behaviour

The load-deflection plots for each sample repetition for each foam core density are seen in Figure 3. The load-deflection curves have two components: an initial linear response, followed by a non-linear, more ductile response until failure. No significant rotations were seen at mid-span and were therefore considered negligible. Figure 3 shows the load-strain response in both the compression and tension skins in the longitudinal direction, where compressive strains are negative. A summary of the test results is shown in Table 2.

Failure Modes

The primary failure mode for all repetitions of 32 and 64 kg/m³ density foam core samples was inward wrinkling of the compression skin in the shear span near the loading points. This failure mode is a result of localized compression failure of the foam while bracing the skin. The failure modes observed can be seen in Figure 4. The compressive yield stresses of each foam density were compared to the ultimate stress applied to the panels at each loading point. This assumes ideal load transfer. The 32, 64 and 96 kg/m³ PIR failed at 87%, 72%, and 65% of their respective compressive yield stresses. This further explains the shift in failure mode away from inward skin wrinkling in samples with high density cores. Failure before the ultimate compressive capacity of the core is attributed to additional stresses due to bending.

The increase of density to 96 kg/m³ demonstrated a shift in the governing failure mode to core shear failure in the shear span. This resulted in an increased shear transfer between the core and skin, as well as more effective bracing of the skins. As a result, the shear capacity of the core material became the limiting factor in terms of ultimate strength for two of the three repetitions, despite one of those repetitions reaching a higher ultimate load. The third repetition showed crushing of the compression skin in the shear span, followed by debonding of the shear span skin. The compressive strains of the FRP at failure matches closely to the ultimate compressive strain of 0.0153 for four-layered FFRP skins (Mak and Fam 2015), therefore failure due to skin compression is expected.

![Figure 4](image1.png)

Three failure modes are inward skin wrinkling in the shear span (left), skin crushing in the shear span (centre), and primary core shear failure in the shear span followed by secondary debonding of the skin (right)

![Figure 5](image2.png)

The effect of PIR foam core density on the ultimate strength (left) and initial stiffness (right) of sandwich panels with three layers of unidirectional FFRP skins.
Effect of Foam Core Density

Figure 5 shows the average increase in strength and stiffness observed by increasing the density of the foam core. Taking the lowest core density as a baseline, doubling the foam core density from 32 kg/m$^3$ to 64 kg/m$^3$ resulted in increases of 82% and 65% for ultimate strength and initial stiffness respectively. Tripling the core density from 32 kg/m$^3$ to 96 kg/m$^3$ resulted in increases of 213% and 150% for ultimate strength and initial stiffness respectively. The stiffness of each sample was taken as that seen in the initial linear response.

CONCLUSION

This study examined the effect of PIR foam core density in sandwich panels with FRP skins comprised of three layers of unidirectional flax fibres in four-point bending. The following conclusions were drawn:

1. Increasing the density of the PIR foam core resulted in significant increases in ultimate capacity. Doubling the density from 32 kg/m$^3$ to 64 kg/m$^3$ and tripling the density from 32 kg/m$^3$ to 96 kg/m$^3$ saw increases in strength of 82% and 213%, respectively.

2. Increasing the density of the PIR foam core resulted in significant increases in stiffness. Doubling the density from 32 kg/m$^3$ to 64 kg/m$^3$ and tripling the density from 32 kg/m$^3$ to 96 kg/m$^3$ saw increases in stiffness of 65% and 150%, respectively.

3. The 32 and 64 kg/m$^3$ densities saw inward skin wrinkling in one of the two shear spans as the primary failure mode. For the 96 kg/m$^3$ density core, this failure mode transitioned to primarily core shear failure, followed by secondary debonding of the skin in one of the two shear spans.

4. The 96 kg/m$^3$ core’s shear modulus provided adequate skin bracing and shear transfer to allow the FFRP skins to approach their expected ultimate compressive capacity.

FRP SANDWICH STRUCTURES: CASE STUDIES IN AUSTRALIA

T. Aravinthan and A. Manalo
Centre for Future Materials (CFM), School of Civil Engineering and Surveying, University of Southern Queensland, Australia.

ABSTRACT

The application of fibre reinforced polymer (FRP) composites in civil infrastructure has substantially increased around the world in the last two decades. Breakthrough research and developments carried out in Australia on FRP sandwich panels over the years have paved way to diverse applications including new structures and structural rehabilitation. This paper highlights some of the innovative applications of FRP sandwich structures in civil infrastructure in Australia. Selected case studies include a) composite bridge decks and girders, b) transoms in railway bridges, c) replacement sleepers in railway turnouts and d) innovative sleepers in mainlines. The challenges faced in applying this emerging technology in civil construction will be discussed including the need for appropriate education and training of engineers. An overview on the future potential of FRP sandwich structures in the construction industry will be also discussed.

KEYWORDS

Sandwich panel, bridge decks, railway sleepers, composite structures, technological developments, infrastructure applications.

INTRODUCTION

Fibre composite sandwich systems as primary load-bearing elements have been increasingly used in civil infrastructure in the last decade. A structural sandwich is a special form of a laminated composite fabricated by attaching two thin but stiff skins to the lightweight but thick core (ASTM C274-99). Because of this special feature, the sectional area is increased and consequently an increase in its flexural rigidity. The strength of this type of construction results from the combination of properties from the skin, core and interface. In a sandwich structure, the strong and stiff skins carry most of the in-plane and bending loads while the core mainly bears the transverse shear and normal loads (He and Hu 2008). Fibre composites are now commonly used for the top and bottom skins due to its high mechanical performance and low density. On the other hand, the core provides a sandwich construction with high flexural stiffness and strength with a relatively lightweight structure (Galletti et al. 2008). The interaction of the inherent properties of these constituent materials makes composite sandwich construction an efficient structural system.

Over the last few years, the development in fibre reinforced polymer (FRP) composite sandwich structures has been very exciting in volumes as well as in applications. The evolution of sandwich structures with enhanced material systems (skin and core) provided an opportunity to expand the application of this material in civil infrastructure. At present, there is a strong interest in the development and applications of fibre composite sandwich structures for civil and building material systems. Some examples of structural applications of sandwich composites include the first balsa cored composite bridge deck installed in Louisiana (SAMPE 2010), web for an innovative hybrid box beam section (Canning et al. 1999) and the function integrated GFRP sandwich roof structure (Keller et al. 2007). In these applications, sandwich composites were adopted because of their lightweight which facilitates handling during assembly, and reduces installation and transportation costs. They also offer corrosion resistant structures requiring less maintenance. In Australia, fibre composite sandwich structures are now being used as structural panels, building components in residential and industrial buildings, and as bridge decks in a number of infrastructure projects. This paper presents an overview of the recent developments and initiatives on fibre composite sandwich structures, which have been evolving and have become a viable construction material in civil engineering and construction. The on-going research, development and applications of a novel composite sandwich panel made up of glass fibre reinforced polymer skins and a modified phenolic
core material at the Centre for Future Materials (CFM) at the University of Southern Queensland (USQ) are also highlighted.

THE NOVEL SANDWICH PANEL

A novel sandwich panel comprises a proprietary phenolic core material sandwiched between two high strength glass fibre reinforced skins as shown in Figure 1. In the production of the panel, the dry fibres for the top and bottom skins are infused with resin at the same time and co-cured with the phenolic core. The solid phenolic core has been purposely designed to have high compressive and shear strength to carry the concentrated loads typical for bridges and other structural elements. The sandwich panel is strong, light weight (similar to hardwood), corrosion proof, fire and termite resistant and very durable. The standard deck panel is 1200mm wide and has a thickness of 30mm. The panel is produced using a continuous process and can be cut to any length. The panels can be cut and drilled using standard wood working practices. A major advantage of the novel sandwich panel technology is its environmental sustainability. It uses patented plant-based polymer technology (approximately 50% bio-content) that permanently stores large volumes of atmospheric carbon resulting in the panel to have low embodied energy. Generally they only use 1/7th of the energy required by conventional materials such as concrete, steel and aluminium.

Figure 1 The composite sandwich panel

CASE STUDIES USING SANDWICH COMPOSITES

FRP sandwich panels have been utilised effectively in Australia in diverse applications. In this section, selected case studies are presented wherein these panels have been engineered to meet the needs of civil infrastructure.

Deck Panels for Small Bridges

Pedestrian bridges and walkway structures with fibre composites sandwich bridge decks (Figure 2) are now common all across Australia. Due to their unique characteristics to withstand the harshest environments while providing a low maintenance, fibre composite sandwich structure in combination with pultruded FRP sections are now the preferred materials in the construction of bridges and walkways near to costal, marine, and environmentally sensitive areas such as tidal flood plains, protected mangrove swamps and corrosive mining facilities. The fabricated deck sections utilizing the novel sandwich panel allow assembly of bridges to be undertaken off site in the factory and then transported to site for very quick installation. This was extremely important where the bridges spanned busy roads that would have required prolonged closure to allow traditional construction methods. Similarly, the sandwich panel can be glued together in several layers to support different loading conditions and for decking solutions that require long spans.

Composite Bridge Beams

Timber bridges are a significant asset in Queensland’s bridge inventory. The task of managing these bridges is becoming increasingly challenging with an ageing timber bridge stock, depletion of the supply of suitable replacement timber elements combined with escalating prices, increasing traffic loads and limited financial resources. In order to address these urgent and complex issues, a collaborative research project was initiated in 2006 to develop commercially viable fibre composite bridge beams (Figure 3). The composite bridge beam incorporates the novel sandwich panel to provide the general shape, shear strength and structural core of the girder while the hybrid modules provide additional flexural strength and stiffness. The steel reinforcing bars of the hybrid elements ensure that the beams have a ductile failure mode which is highly desirable in bridge girders. Selected
cutting and drilling is permitted to ensure the girders are ‘sized’ appropriately for the location in which they are to be installed.

Figure 2 Completed structures with sandwich panel decking

Figure 3 Composite sandwich bridge beams

Transoms

The CFM at USQ, in collaboration with the different railway industries in Australia, has been involved in a number of research and development projects involving innovative composite railway sleepers. These sleepers were developed for areas where railway owners continue to use large numbers of timber sleepers for maintenance including existing timber lines, turnouts and transoms.

Transoms (bridge ties) are large sleepers used on railway bridges to transfer the loads from the rails to the bridge girders. In Australia the rails and the support beams are generally off-set by approximately 250mm which creates significant bending moments and shear forces in the transom. For this type of application, a hybrid polymer sleeper which has sufficient bending and shear strength as well as exhibits a ductile behaviour is developed using the novel sandwich panel as the main structural components. This is achieved by including some steel reinforcement bars at strategically chosen locations within the sleeper. This does not affect the electrical insulation properties of the sleeper and creates a very reliable structural element that gives ample warning of failure. Figure 4 shows the typical cross section of the composite railway transom (Figure 4) wherein the FRP sandwich panels were combined with steel bars similar to the bridge beam concept in Figure 3. In November 2007 the Australian Rail Track Corporation (ARTC) installed twenty two of these transoms on a railway bridge in the Hunter Valley, Australia and to date they have been performing extremely well.

Turnout Sleepers

Turnout sleepers (switch ties) are special sleepers installed in a railway turnout and with varying lengths (up to 4-5m) and fastening locations (Manalo and Aravinthan 2012). A railway turnout enables a train to be guided from one track to another. Because of diminishing availability of long hardwood sleepers, composite turnout sleepers are now being developed to provide an alternative solution to replace deteriorating timber turnout sleepers. This new reinforced polymer sleeper is manufactured using a proprietary casting technique. The sleeper has a prismatic rectangular shape (Figure 5 – left) and contains long glass reinforcement fibres along the length and depth of the sleepers. By strategically concentrating the fibres in locations where they are most effective in carrying the bending moment and shear forces, the total amount of fibres used is significantly less. This economical use of materials
combined with the fast production cycle has resulted in a sleeper which is significantly more cost effective than the alternatives.

Timber Replacement Sleepers

The timber replacement sleepers was specifically designed to conform to the loading conditions for mainline applications in which the sleeper is only loaded in two distinct locations (at the rails) and does not need the same strength along its length. This composite sleeper requires significantly less volume of polymer material while still complying with all strength and stiffness requirements of a timber sleeper is developed and investigated (Figure 5 - right). The shape of the composite sleeper uses only 1/3 the material of a standard rectangular sleeper resulting in a polymer sleeper which is only marginally more expensive than a timber sleeper. The sleepers can be drilled on site similar to timber sleepers, and are available with resilient fasteners or standard rail screws. The innovative casting process creates a very strong layer in the rail seat area and allows for this area to be shaped similar to concrete sleepers which remove the need for steel rail plates. In addition to reducing the amount of polymer material in the sleeper, the novel shape also offers significantly increased resistance against lateral movement (particularly important in curved track). This new sleeper is currently being trialed in Australia by Queensland Rail and in the USA by Union Pacific.

Housing and Construction Applications

The novel sandwich panel has proven to have mechanical properties suitable for housing and construction. In the construction industry the panel has major advantages in wet areas and balcony construction (Figure 6 - left). The panel itself has been classified as a Grade 1 waterproof membrane thus, tiling can start within hours of installation. Recent fire testing has given the panel the top Class 1 rating (Building Code of Australia) which means that the sandwich panel can also be used for walls, roofs, floors and fire doors.

Sandwich Waler

On the coastline of Australia, boardwalks, jetties, pontoons, and marine structures operate in a very corrosive environment. This results in serious durability problems for steel and reinforced concrete. Hardwood has traditionally been used to overcome some of these problems. However, when exposed to aggressive marine environments, timber waler would require replacement every 10 to 15 years. The composite waler made from glue-laminated sandwich structure is a viable substitute for this application because of its excellent corrosion resistance.
and durability properties. The flexural test (Figure 6 - right) indicated that the strength and stiffness of a sandwich waler are suitable for this application. The presence of vertical fibre composite skins in the sandwich waler resulted in a higher resistance to mechanical connections than that of hardwood timber.

Figure 6 Sandwich panel for flooring (left) and composite waler (right)

CHALLENGES AND FUTURE DEVELOPMENTS

A number of issues contributing to the slow uptake of composite sandwich structures in civil infrastructure have been well documented. These important aspects have to be addressed in order to advance their use of sandwich structures in civil engineering applications.

Core Material Development

The core of the sandwich structures for building and construction needs to be reasonably strong to withstand high concentrated and impact loads. Moreover, a thicker composite sandwich panel is usually used in structural than in industrial applications where the shear strength of the core is a critical parameter to efficiently transfer the shear between the top and bottom skins. In fact, Styles et al. (2007) indicated that the shear cracking of the core is the dominant failure mode for a sandwich structure with a thick core. Thus, it is anticipated that the evolution of composite sandwich structure with lightweight, high-strength core and with good capacity for mechanical connections could provide wider opportunity to increase the acceptance and utilisation of this type of construction in civil infrastructure. However, the method of enhancement of the core structure should not involve a complex manufacturing process and increase the cost of production.

Innovative Applications

The growth of composite sandwich construction in civil infrastructure can be further realised by developing innovative structures which exploit its many advantages. Fibre composite sandwich structures will generally feasible in infrastructure when the need for corrosion resistance, high strength, reduced weight, or fast installation is a driver for the system. As seen by the recent development of innovative composite sandwich bridge decks, this effort is driven by the need to replace the heavy weight and corrosion prone reinforced concrete decks and the opportunity to upgrade the load carrying capacity of the existing bridge. Such composite structures are needed in order to address the need in the construction industry for more durable and cost-effective infrastructure. Moreover, typical infrastructure prototypes need to be developed to demonstrate its practical application, increase its acceptance and to build a market volume.

Design Guidelines

The limited understanding by engineers of the overall behaviour of composite sandwich structures is commonly claimed to place them at a disadvantage when considered against traditional construction and building materials. This problem, combined with the lack appropriate design codes and standards, is recognised as a significant barrier to broad utilisation of these materials in civil engineering. Bakis et al. (2002) pointed out that without an established design method and data, it is unlikely that structures utilising fibre composites will be used beyond the scope of research and demonstration projects. Thus, design guidelines for composite sandwich panels should therefore be developed so that it could gain wider acceptance in civil infrastructure.

Structural Health Monitoring

Primary load-bearing FRP sandwich systems are a relatively new technology in civil engineering applications. As a result, their performance history is relatively short compared to more conventional construction systems utilising hardwood, concrete or steel. Thus, short and long-term investigations of their structural (health and) behaviour are essential to develop the market and increase confidence in using these new technologies. The information that will
be obtained from this long-term monitoring and performance evaluation would be helpful in developing design specifications for FRP sandwich systems in civil engineering and construction.

**Education and Training for Civil Engineers**

Several successful R&D projects completed leading to several applications are a testimony that FRP sandwich composites are viable alternative in civil infrastructure. However, there is still a lack of practicing engineers who are trained to design and use fibre composite materials. To fill this gap, courses in fibre composites needs to be developed. USQ has taken the initial steps by developing the first online course on engineered fibre composites with the focus on civil and structural engineers (Aravinthan 2012). This provides a flexible learning environment for practicing engineers who can continue to develop their professional skills in FRP sandwich technologies. Such education and training, especially the young engineers will be a key factor to embrace sandwich composites as an alternative system in civil infrastructure.

**CONCLUSIONS**

This paper has presented recent developments and applications of sandwich composites into civil infrastructure in Australia. Based on this experiences, the following conclusions can be drawn:

- A novel sandwich panel comprises a proprietary and high strength phenolic core material sandwiched between two high strength glass fibre reinforced skins was developed as an answer to minimize the carbon footprint of the construction industry.
- Composite sandwich structure have numerous potential advantages in structural engineering and construction such as high strength, better quality control, easier and faster to install, and reduced energy in transportation.
- Several new and innovative applications have shown that the construction of a more durable and cost-effective infrastructure is possible using FRP sandwich structures. FRP sandwich systems have been successfully used for bridge decks, bridge beams, railway sleepers, and floating structures.

A number of barriers that need to be overcome for the continued growth and wide acceptance FRP sandwich structures are also presented and potential solutions have been identified for this advanced composites technology to become more competitive construction material and harness its potential in civil infrastructure.

**ACKNOWLEDGMENTS**

The authors would like to acknowledge all the industry partners who have been involved in the research and development of diverse application of this technology that has paved way the research and development on the sandwich panel to real-life applications in civil infrastructure.

ABSTRACT

This paper presents the results of an experimental investigation on the flexural behaviour of sandwich composites under elevated temperature. Sandwich beams made up of glass fiber reinforced polymer (GFRP) composite skins and solid phenolic foam core were tested under 3-point static bending at room temperature and up to 180°C. The results showed that behaviour of the sandwich beams is governed by the GFRP skin up to 80°C while the phenolic core played a major part on the overall behaviour beyond this temperature. The failure of the sandwich beams is initiated by compressive failure of the top skin up to 80°C, while cohesive bond failure and disintegration of the core was observed at higher temperature. Besides, the sandwich beam retained more than 80% of their strength and stiffness at 80°C and this decreases to only 19% at 180°C. Based on these results, the composite sandwich beams can fulfil requirements for civil infrastructure exposed to a service temperature of up to 80°C.

Sandwich composites, temperature, phenolic core, flexure.

INTRODUCTION

Fiber reinforced-polymer (FRP) sandwich systems have been successfully applied in civil engineering and construction including structural roofs, walls, bridge beams, bridge decks, and railway sleepers. Still, engineers and asset owners remain cautious about accepting them in civil infrastructure out of concern about its structural performance in applications exposed to elevated temperatures. For example, Sirimanna et al. (2011) measured temperature as high as 61°C for composite sandwich bridge decks exposed to Australian weather conditions. In such conditions, the main concern is the reduction of the sandwich composite’s mechanical load-bearing capacity due to material degradation. Taher et al. (2013) mentioned that the main reason for this concern is the limited and incomplete information about the temperature dependence of sandwich composites. There is a crucial need for research in this area if FRP sandwich systems are to gain acceptance and be used safely for mainstream applications.

To date, there has been limited research and development activities investigating the effect of elevated temperatures on the structural behavior of FRP sandwich composites. Moreover, temperature-related research on polymeric foam cores normally used in FRP sandwich systems is limited as such systems are relatively new in civil engineering applications. Zhang et al. (2015) were probably the first to analytically and experimentally study the influence of elevated temperature on the stability of foam-cored sandwich structures, although the temperature range was only from room temperature up to 90°C. Moreover, skin temperature receives scant attention in all of the existing studies despite the fact that it is significant when the FRP sandwich structure is exposed to elevated temperatures.

Recently, a sandwich composite consisting of glass fiber reinforced polymer (GFRP) composite skins and a solid phenolic foam core has been developed. Extensive characterization of the mechanical properties of this sandwich (Manalo et al. 2010; Manalo 2013) showed that they have strength and stiffness suitable for civil engineering and construction. While the phenolic foam is known to have excellent fire resistance, flame resistance, and high thermal stability (Song et al. 2014) and the GFRP composites have high mechanical properties, no studies have shown that the mechanical properties of a sandwich composite system made from these materials will achieve the required structural performance at elevated in-service temperatures. This paper presents the results of an experimental
investigation of the behavior of this new FRP sandwich system when subjected to the combined simultaneous action of thermal and mechanical loads.

**EXPERIMENTAL PROGRAM**

**Material Properties**

The sandwich panel was manufactured in a single continuous operation, which consists of sandwiching a phenolic-based core between two high-strength GFRP skins. The GFRP skins were comprised of 2 plies of bi-axial (0/90) stitched E-CR glass fabric with a chopped strand mat infused with toughened phenol-formaldehyde resin and had a fiber fraction of 45% by weight. The phenolic core material was a toughened phenol-formaldehyde resin of proprietary formulation owned by LOC Composites Pty Ltd (Australia). Based on the results of the dynamic mechanical analysis (DMA) test, the $T_g$ values measured at the onset of the storage modulus curves are 93°C and 95°C for the GFRP skin and phenolic core, respectively. The mechanical properties of the GFRP skins and the phenolic core are reported in Table 1.

**Specimen Details**

The beam specimens (50 mm in width and 220 mm in length) were cut directly from the manufactured sandwich panels. The top and bottom skins had a nominal thickness of 2.5 mm, while the core thickness was 15 mm (Fig. 1a). Although the beam length was limited by the temperature chamber’s internal clearance, the span of 200 mm (shear span-to-depth ratio of 5) was adequate to initiate skin flexural failure (Manalo 2013). Five replicates for each level of temperature were prepared and tested.

**Test Set-up**

The flexural behavior of the sandwich beams was evaluated with a 3-point static bending test (Figs. 1b and 1c) according to ASTM C393 (2000). Nine temperature cases (RT, 35°C, 50°C, 65°C, 80°C, 100°C, 120°C, 150°C, and 180°C) were considered, where RT represents the control specimens tested at room temperature or at 21°C. The required elevated temperature was achieved with an Instron 3119 environmental chamber mounted on a 100kN servo-hydraulic MTS machine. Prior to testing, the specimens were placed in the environmental chamber at the required test temperature setting for 30 minutes. In addition to the soaking period of 30 minutes in the environmental chamber, the sandwich beams are conditioned in an oven set at the desired temperature while the testing of specimens for a lower test temperature is being conducted. A set of 5 specimens were tested for each temperature range and were loaded at a rate of 3 mm/min.
RESULTS AND DISCUSSIONS

Load-deflection Behavior

Figure 2 shows the typical load–deflection behavior of the sandwich beams at elevated temperature. As can be seen from the graph, almost linear load–deflection behavior was observed up to failure for sandwich beams tested at RT and up to 80°C. At 100°C to 180°C, a reduction in the stiffness and failure load was observed. The load–deflection behavior of the sandwich beams tested under these temperatures is characterized by an initial linear elastic phase, followed by a nonlinear phase until a maximum value was reached. After this, only a small increase in load but with a significant increase in deflection until failure occurred. The nonlinear behavior of these beams resulted from the low, steady decrease in the phenolic core’s mechanical properties between these temperature ranges. Garrido et al. (2015) observed similar behavior for PET foam, which exhibited reduced stiffness and increasing nonlinear behavior at higher temperatures. The significantly low load capacity of the sandwich beams at 150°C and 180°C is due to the strong degradation of the phenolic core. Surprisingly, a slightly higher slope at the linear elastic portion of the load-deflection curve was observed for sandwich beams tested at 180°C than 150°C. This can be due to the evaporation of moisture in the matrix, making the laminate brittle and regaining some of its stiffness. Lauobi et al. (2014) reported a similar observation and evaporation of moisture from glass-fiber unsaturated polymer composites at higher temperature.

Failure Behavior

Figure 3 shows the typical failure behavior of the sandwich beams at elevated temperature. Compressive failure of the top skin was observed in the sandwich beams tested at RT and up to 80°C. This was followed immediately by core shear and interlaminar shear failure of the bottom GFRP skin, which extended up to the edge of the beam. Figures 3a and 3b clearly show the delamination between the plies of bottom skin and fibers still attached to the phenolic core. The initiation of compressive failure of the skins was also observed in the sandwich beams tested at 100°C and 120°C. The core experienced cohesive bond failure, followed by more progressive failure behavior than in the specimens tested at up to 80°C. This failure was confined to the area between the loading point and support, as shown in Figure 3c. No loss of bond was observed in the specimens tested at 150°C and 180°C, but the core disintegrated, resulting in shear failure. The disintegration of the core is characterized by micro cracks along the length of the beam which eventually grow in number and start to interact with each other forming a shear crack. Core indentation occurred under the loading point, which clearly indicates softening of the phenolic core at elevated temperature. These observed failure behaviors differ from those observed by Goodrich and Lattimer (2012), in which they indicated that sandwich composites with foam cores at elevated temperature normally fail.
by face-sheet debonding. The observed failure of sandwich panels in this study suggests the high quality of bond between the GFRP skins and phenolic core, thereby preventing debonding failure of the top and bottom skins.

Effect of Elevated Temperature on Sandwich Beams’ Properties

Figure 4a shows the maximum bending stress (BS) and the overall bending stiffness (OBS) of the sandwich beams. When the maximum BS and OBS were calculated, the sandwich beams were assumed to have a homogenous rectangular cross section. It is important to note that shear deformation of the phenolic core was not considered in the analysis of the sandwich beam. This assumption is reasonable as it was found in the earlier investigation that the behavior of this sandwich beam with an a/d of 5 is governed by flexure and with only minor contribution by shear (Manalo 2013). Moreover, the results of the investigation by Manalo et al. (2010) showed that the contribution of shear in the total deflection of the sandwich beam is only around 5% due to the high shear modulus and strength of the phenolic core.

It can be clearly see from Figure 4a that both the BS and OBS of the sandwich beams decreased with increasing temperature. The maximum BS was affected more by the high temperature than the OBS. This is because the OBS was measured at the linear region of the load–deflection curve, while the BM was based on the point of maximum load. Moreover, the thermal degradation of the phenolic core resulted in reduced load transfer between the top and bottom skins. It can also be seen that there were no significant changes in the sandwich beam’s OBS up to 80°C. In this case, the value of 1.11 kN/mm at RT dropped only to 1.03 kN/mm at 80°C. The OBS decreased rapidly at temperatures in excess of 80°C. The strength of almost 135 MPa decreased to 99 MPa at 80°C and to only 25 MPa at 180°C. In the case of sandwich beams under bending, the top and bottom skins are subjected to compressive and tensile stresses, respectively, while the core resists shear. Gu and Asaro (2009) indicated that sandwich composites will experience a significant reduction in strength and stiffness once the skin has completely degraded due to the core's low bending stiffness. This study determined that the GFRP skins contributed significantly to the overall flexural behavior of the sandwich beams up 80°C, but the phenolic core played a major role at higher temperatures. Zhang et al. (2015) indicated that this is because the shear modulus of foam-core materials decreases at elevated temperature.

The OBS of the sandwich beam [SW (OBS)] at different levels of temperature under 3-point static bending was normalized by dividing the values by the overall bending stiffness of the specimens obtained at room temperature (Figure 4b). In this figure, the normalized storage moduli of the skin [Skin (DMA)] and the phenolic core [Core

1315
(DMA)] from the DMA tests was also reported for comparison. It can be seen from that the normalized bending stiffness of the SW (OBS) and the Skin (DMA) followed the same trend up to 120°C, but began deviating beyond this temperature. The increase in the storage modulus of the Skin (DMA) at a temperature around 130°C is due to the evaporation of moisture in the matrix, making the laminate brittle. The decreasing effective bending stiffness of the sandwich beam with increasing temperature is due to the phenolic core’s thermal degradation. Still, SW retained 84% of its stiffness at 100°C and 69% at 120°C. In comparison, Zhang et al. (2015) reported that only about 5% of the bending stiffness and 8% of the yield strength were lost with a sandwich beam with a PVC foam core at 90°C. This is expected as the aluminum alloy used for the face sheet had high heat conductivity, and its stiffness and strength were not affected up to 90°C. This indicates that the strength of sandwich beams at temperatures lower than the $T_g$ of the constituent materials will be governed by the GFRP skin’s strength. This is supported by the observed failure behavior, in which the the sandwich beam failed due to compressive failure of the top skin, followed by core shear. Compressive rather than tensile failure was expected as the GFRP skin had greater tensile than compressive strength, as shown in Table 1. Similarly, Feih et al. (2007) indicated that FRPs were more stable in tension than in compression at high temperature. In their study, they observed that the compressive strength of woven glass/vinyl ester laminate decreased by 80% when subjected to temperatures between 50°C and 120°C, but that the tensile strength only decreased by 15%. The large discrepancy between the behavior of sandwich beam and the skin at 150°C and 180°C could be attributed to the disintegration of the phenolic core, as shown in Figure 3d, thereby reducing the load transfer between the top and bottom skins.

CONCLUSIONS

This study investigated the flexural behavior of sandwich composites consisting of GFRP skins and a phenolic core at elevated in-service temperature. Based on the results of this study, the following conclusions have been drawn:

- The bending strength and stiffness of the sandwich beams decreased with increasing temperature, with the bending strength was affected more than the stiffness.
- The flexural behavior of the sandwich beams is governed by the GFRP skin up to 80°C, while the phenolic core played a major part in the overall behavior beyond this temperature. The failure of the sandwich beams was initiated by the compressive failure of the skin up to 80°C, while cohesive bond failure and disintegration of the phenolic core were observed at higher temperatures.
- The sandwich beam retained more than 80% of their strength and stiffness at 80°C and this decreases to only 19% at 180°C. Based on these results, the composite sandwich beams can fulfil requirements for civil infrastructure exposed to a service temperature of up to 80°C. This indicates that FRP sandwich systems made from these materials can be used for civil-engineering structures with in-service temperatures of up to 70°C.
- The full composite action between the skins and the core was lost due to the disintegration of the phenolic core at higher temperatures, which should be accounted in the prediction of the strength and stiffness of the sandwich beams under elevated temperature.

ACKNOWLEDGMENTS

STRUCTURAL CONCEPT AND DESIGN OF A GFRP-POLYURETHANE SANDWICH ROOF STRUCTURE

S. Yanes-Armas and T. Keller

1 Composite Construction Laboratory (CCLab), Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland
Email: sonia.yanesarmas@epfl.ch

ABSTRACT

This work presents the concept and structural design of a 1000-m² glass fiber-reinforced polymer (GFRP) sandwich roof replacing a timber roof over an indoor swimming pool. The advantages offered by the lightweight, multifunctional GFRP-polyurethane (PUR) sandwich construction for the roof replacement are described. The roof structure was designed for two potential construction scenarios (with and without including a green rooftop), whose pertinent dead loads on the roof significantly differed. The resulting designs for both cases, considering long-term effects and applying two design recommendations (Eurocomp and BÜV) are compared and discussed.

INTRODUCTION

Within the framework of renovation works, the existing timber roof of the CLP building in Switzerland is replaced by a glass fiber-reinforced polymer (GFRP) sandwich roof. The top floor of the CLP building accommodates two main uses, namely an indoor swimming pool and a reception zone (see plan view in Figure 1(a)). The almost entire top floor is currently covered by an approximately 1000-m² area (up to 54-m length by up to 23-m width) flat green timber roof with triangular openings for zenithal daylighting. Based on architectural and aesthetic considerations, the new roof aims to provide the swimming bath’s inside space with architectural spatial effects while maintaining illumination through natural light and virtually preserving the nearly trapezoidal perimeter geometry of the original timber roof. Furthermore, the new roof structure has to be borne by the underlying vertical structure within its limited load-bearing capacity, therefore preventing the need for structural reinforcement. The existing structure consists of prefabricated steel/concrete columns around the swimming pool and along the North and East facades delimiting the reception zone, as well of reinforced concrete core walls which allocate the technical building equipment and create the spatial division between the two building uses, see Figure 1(a). Besides, demanding serviceability and durability requirements, in particular the high operating temperature and relative humidity in the swimming pool environment, had to be met.

Figure 1 (a) Plan view of CLP Building, dimensions in [m]; (b) panel arrangement of CLP sandwich roof

Following the architectural concept, double-curved enclosure shapes enabling the introduction of natural light across the arising openings are designed for the swimming pool area, as shown in Figure 2. On the other hand, for
the lobby area, with lower aesthetic requirements, a flat roof solution is used. Considering the double-curved geometry, the roof is conceived in lightweight GFRP sandwich construction, which allows both for complying with the aforementioned constraints and building the designed complex shapes. Moreover, the merging of aesthetic architectural functions (roof shape, daylighting and surface appearance), static functions (vertical load transfer and bracing of the existing base-hinged columns) and building physical functions (thermal insulation provided by the selected core material) into the sandwich single components will contribute to reduce and accelerate on-site works, thus shortening the closure time of the building.

![Figure 2 Rendering of CLP sandwich roof (a) exterior and (b) interior views](image)

The roof is envisaged to be prefabricated using the vacuum assisted resin infusion process in the form of ten primary components, see Figure 1(b). Each wave form is comprised within one panel, and the impact of the complex shapes on the manufacturing cost is decreased by the repeated use of one (expensive) mold for elements 3–5 in Figure 1(b). The resulting panels, generally 5.00-m-wide and with a length equal to the roof’s width, are transportable by road to the site, and their installation can be done almost simultaneously with the dismantling of the existing timber roof. Worksite construction comprises the execution of the panel-to-panel joints, which are vacuum infused. In order to fulfill urban planning specifications, the installation of a green rooftop may be required; an extensive sedum roof (shallower and lighter) is selected against an intensive green roof.

### STRUCTURAL CONCEPT AND MATERIALS

The plan view of the roof structure, indicating the supports location, and a longitudinal cross section are shown in Figure 3. The geometry of the sandwich roof consists of three identical double-curved wave shapes with a 1.25-m rise and 8.80-m span above the swimming bath (see axes D–F in Figure 3). The roof is nearly flat elsewhere and has pre-cambered, 1.70-m-long wing-shaped overhangs along the perimeter facades. The sandwich structure has a variable 300–600 mm thickness (tapering off to 90 mm at the overhangs ends) so as to guarantee the minimum slope required for rainwater evacuation. This option was selected against an inclined roof of constant thickness due to two reasons: (i) to keep horizontal the roof’s bottom surface – this was essential to simplify the use of the existing underlying structure as supports; (ii) to have horizontal cornice lines. The roof structure mainly spans transversely to the building’s longitudinal direction, i.e., in the East-West or X direction, with an 8.80-m maximum span located over the swimming bath and given by the spacing of the existing columns around it (see axes 2-3 in Figure 3(b)). The transverse span (in the North-South or Y direction) is of 5.00 m and determines the roof division for manufacturing purposes – panels 2–8 in Figure 1(b) have a constant 5.00-m width.

The sandwich structure is composed of GFRP face sheets and a polyurethane (PUR) foam core. The GFRP face sheets consist of E-glass fibers and a fire- and flame-retardant epoxy resin. Based on the manufacturing process, a total fiber volume fraction of 55% is considered. Unbalanced cross-ply laminates, with 2/3 and 1/3 of the total UD layers directed in the main (X) and transverse (Y) span directions, were selected. The core globally consists of a PUR foam of 60-kg/m³ density, which also provides the thermal insulation required for building physical performance. The PUR foam core is locally reinforced by vertical GFRP webs or ribs. In each sandwich panel, one internal main web (beam) running parallel to the main span direction and aligned with the supports contributes to increase the shear stiffness and strength of the non-reinforced PUR foam core. Internal secondary webs are added in the transverse span direction, crossing the main ones at the supports, to avoid potential punching failure of the sandwich structure at the location of the concentrated reaction forces. Besides, external webs laterally envelope the panels, conforming double webs once adjacent panels are connected. The arrangement of webs is depicted in Figure 3(b). The same total fiber volume fraction as for the face sheets is used for the webs; however, balanced cross-ply laminates, with 1/2 and 1/2 of the fibers directed along the web’s length and height, respectively, are selected instead. The main mechanical properties of the GFRP laminates, both for the face sheets and for the webs, and of the PUR foam are listed in Tables 1 and 2.

STRUCTURAL DESIGN

The sandwich roof was designed for two potential construction scenarios: (i) A roof: the sandwich finishing surface provides the roof’s exterior appearance, i.e., no additional construction elements are added above; (ii) B roof: a sedum green roof of 170-kg/m$^2$-weight is installed on the top. The structural design was carried out according to the requirements of Swiss standards (SIA), namely SIA260 (2013) and SIA261 (2014), which are consistent with the corresponding Eurocodes. The partial safety factor concept, with partial factors applied both on the action and material sides (load and resistance factors, respectively), was used. The following actions were considered: permanent loads (self-weight of the sandwich structure and roof system) and snow; their associated load factors were determined from SIA260 (2013). Material resistance factors were obtained from Eurocomp (Clarke 1996) and from the German BÜV (2014), both in line with the Eurocodes philosophy, as neither the Swiss standards nor the Eurocodes provide such values for FRP and PUR foam materials.

The preliminary structural design, both for Eurocomp and BÜV design recommendations, was conducted based on the selected materials and the basic module depicted in Figure 4, representative of the sandwich roof structure. Only the design of the “beam” and “slab” elements are referred here. The longitudinal main web conjointly with 1.0-m width from the upper and bottom face sheets was considered as a wide flange beam, designated as “beam” in the following. The web and face sheet thicknesses were determined to verify the ultimate (ULS) and serviceability (SLS) limit states for the beam element, respectively. The resulting face sheet thickness were afterwards used to verify the slab’s ULS and SLS (constant thickness laminates are used as face sheets).
The resistance factor for FRP materials according to Eurocomp, $\gamma_m$, comprises at ULS three sub-factors ($\gamma_m = \gamma_m^1 \cdot \gamma_m^2 \cdot \gamma_m^3$) relating to the property source, manufacturing process, operating temperature and load duration. These factors are applied to the characteristic (5%-fractile) strength and stiffness values of the laminate and core properties to obtain the design values. The characteristic values can be obtained reducing by 0.8 the relevant average values (DIN 18820-2). For the verification of the SLS, the average stiffness properties are reduced by $\gamma_m = 1.30$ and creep is considered by a further stiffness reduction factor, $\chi$ (see Figure 4.13 in Eurocomp). These factors were also used for the PUR foam. In BÜV, the resistance factor, $\gamma_m$, depends on the design situation, material type (laminate, resin or foam) and manufacturing method. A material-specific value is formed increasing $\gamma_m$, both at ULS and SLS, by an additional modification factor, $A_{\text{mod}} \geq 1$; this is built-up from three sub-factors ($A_{\text{mod}} = A_1 \cdot A_2 \cdot A_3$) accounting for the load duration, environmental exposure and ambient temperature. Different $A_{\text{mod}}$ factors apply for strength (superscript $f$) and stiffness (superscripts $E$ or $G$). The two sets of factors used according to Eurocomp and BÜV are listed in Tables 3 and 4, respectively.

Design of Webs

The web thickness, $t_w$, was designed to verify ULS of shear and shear wrinkling, both for short- (variable and permanent) and long-term (permanent) loading. Shear buckling stress, providing a low bound for shear strength and therefore a $t_w$ value on the safe side, was also verified at long-term (i.e. the foam core, whose lateral support is reduced with time owing to creep, is neglected). An $h_w = 500 \text{ mm}$ web depth (value at the cross section where...
the shear force is maximum) was considered for all verifications. According to Eurocomp, the shear area, $A_s$, equals the web cross-sectional area ($A_s = t_w \cdot t_e$), whereas in BÜV this value is reduced by 1.5 to take into account the non-uniform distribution of shear stresses. A basic web shear strength of $t_w = 50$ MPa was used for the ULS shear verification. The wrinkling shear strength was verified according to $\tau_{wr,d} = 0.5 \sigma_{wrd}$ (Keller et al. 2008), with the design value of the uniaxial compression wrinkling strength, $\sigma_{wrd}$, given by Eq. (1) (BÜV 2014):

$$\sigma_{wrd} = 0.82 \sqrt{\frac{E_{L,d}}{G_{C,d}}}$$

where $E_{L,d}$ = design value of the laminate elastic modulus, $E_{C,d}$ = design value of the core through-thickness elastic modulus, $G_{C,d}$ = design value of the core through-thickness shear modulus. The critical shear buckling stress was calculated according to Eq. 2 for especially orthotropic materials (Clarke 1996):

$$\tau_{cr,d} = \left[4k \cdot (D_x \cdot D_y)^{1.25}\right]/(h_w^2 \cdot t_w)$$

where $k = 8$; $D_x$ = plate flexural rigidity in the $X$ direction, $D_y$ = plate flexural rigidity in the $Y$ direction. The resistance factors applied for Eurocomp design are identical for the three referred verifications, see Table 3. For BÜV design, resistance and modifications factors relating to local stability apply for $\tau_{wrd}$ and $\tau_{cr,d}$; besides, $\tau_{cr,d}$ depends on three material properties (see Eq. 1) for which different factors apply. As a result, the global $f_{M} \cdot A_{mod}$ values for $\tau_{cr,d}$ differ as follows: 2.08/2.75/1.3 and 2.47/3.54/2.04 for short- and long-term scenarios. Figure 5(a) shows the minimum $t_w$ required for each design case; the resulting thicknesses are encircled (those obtained from the shear buckling verification are not considered). Applying the Eurocomp factor set, the web is designed for shear, due to the slightly higher characteristic shear wrinkling strength ($\tau_{cr,d} = 52$ MPa) compared to the basic shear strength ($t_w = 50$ MPa) and the equal resistance factors applied in both cases at the design level. The long-term scenario is determining, both for $A$ and $B$ roofs, since the resistance factor is 2.5 times higher at long- than at short-term, whereas the ratio of the short-long-term loads is smaller (2.3 / 1.4 for $A$ / $B$ roofs). For the design according to BÜV, the governing design case is shear wrinkling, for which the greatest resistance factors apply and compensate for $\tau_{wr,k} > \tau_{wrd}$. The short-term scenario is decisive, as the aforementioned short-long-term loading ratio is not counteracted by the only 1.3 higher resistance factor at long-term. For $A$ roof, higher $t_w$ was obtained for BÜV (where a lower $A_e$ is considered) than for Eurocomp design (6 vs. 4 mm). On the other hand, similar $t_w$ values (11 mm) were obtained for $B$ roof with both recommendations in spite of the different governing design case.

![Figure 5 Design of beam: (a) web thickness and (b) minimum face sheet thickness](image)

**Design of Face Sheets**

The face sheets thickness, $t_f$, was determined so that the beam element verified the deflection at SLS. Timoshenko’s beam theory, the $t_f$ values obtained from the web’s design and the minimum web’s depth ($h_w = 420$ mm) were used to calculate the deflections. Rotationally free beam end conditions were considered for the short-term loads (assumption on the safe side) and partially restrained ends for the permanent loads (to take continuity into account). The deflection limits according to SIA260 (2013) were span/350 and span/300 for variable and permanent loads including creep, respectively. The minimum $t_f$ required for each design case is shown in Figure 5(b) and the resulting thicknesses are encircled. For $A$ roof, the short-term case is determinant, both for Eurocomp and BÜV designs, due to several reasons: the higher (~1.3 times) value of the variable load compared to the permanent load, the simply-supported end conditions and the more restrictive deflection limit applicable. For the $B$ roof, on the other hand, the significantly higher permanent loads (more than 2.5 times the variable load), resulting in also significantly higher long-term creep deflections, counteract the more favourable end conditions and deflection limits of the short-term verification; consequently, the long-term becomes the governing design case. Higher $t_f$ values were obtained for Eurocomp than for BÜV design (12 / 21 mm vs. 8 / 17 mm for $A$ / $B$ roofs, respectively).
in part due to the more restrictive Eurocomp \( y_w/\chi \) values for the face sheets compared to the pertinent \( y_M/A_{mod} \) values from BÜV. At ULS, the face sheets’ compressive stress was verified against wrinkling strength according to Eq. (1) (the face sheet elastic modulus in the main span direction, \( E_{L,x,d} \), is used). The results are given in Figure 6(a), which shows that the ULS of the face sheets is verified and that they are overdesigned in terms of strength (a maximum stress/strength ratio of 41\% was obtained).

Figure 6 Verification at ULS of (a) beam face sheets and (b) sandwich slab

Verifications of Sandwich Slab

ULS verifications of the sandwich slab concerned the shear strength of the core and the wrinkling strength of the compressed face sheets in the transverse (Y) span direction, the latter according to Eq. (1) with \( E_{L,y,d} \) for the laminate elastic modulus. Figure 6(b) summarizes the verifications and shows that ULS is fulfilled for both components: the maximum \( E_d/R_d \) values obtained (ratio of effect of actions to resistance) were \( V_d/V_{R,d} = 79\% \) for the core and \( \sigma_{u,d}/\sigma_{w,r,d} = 6\% \) for the face sheets, which are therefore largely overdesigned for ULS in the Y direction. All the deflection limits were met except for B roof design according to BÜV recommendations, with a resulting long-term deflection of approximately span/250. The addition of an intermediate transverse web parallel to the Y direction and reducing the slab span in X direction from 8.80 to 4.40 m is needed.

CONCLUSIONS

A lightweight sandwich roof consisting of GFRP face sheets and PUR foam core is designed to replace the existing timber roof of the CLP building. The new GFRP-PUR sandwich roof, integrating structural, building physical and architectural functions into large-scale, prefabricated and lightweight elements, allows for using the existing vertical structural members as supports within their limited load-bearing capacity and for reducing installation times. The roof dimensions and composition depend on the selected design recommendations (Eurocomp / BÜV); however, material consumption may be comparable (Eurocomp leads to thicker face sheets, whereas thicker webs or additional intermediate transverse webs are required by BÜV). The considered construction scenario (with / without green rooftop) significantly influences the final design. In particular, the considerably higher (3.4 times) permanent loads of the green roof lead to notably greater thicknesses of the web (1.8–2.8 times) and face sheet (1.8–2.1 times) laminates. As a result, the self-weight of the slab increases by up to 60\%. The substantial influence of high permanent loads on the roof solution highlights the relevance of considering long-term performance and creep effects in the design of FRP sandwich structures.

ABSTRACT

A concept of a nature-inspired pedestrian bridge which tries to merge architectural, structural and manufacturing aspects in an optimized way is presented. The 18.0-m-span bridge is designed as an overhead spatial frame of a complex double-curved shape, which is composed of twelve modules consisting of lightweight carbon fiber-reinforced polymer (CFRP) sandwich construction. The modules are fabricated with only one mould through vacuum assisted resin infusion. The aimed visible texture and black colour of the CFRP fabrics represents an essential architectonical element. The resulting benefits and required compromises of this multi-criteria approach are discussed.

KEYWORDS

CFRP, bridge, module, sandwich.

INTRODUCTION

The new 18.0-m-span TSCB (twin-shaped composite beam) pedestrian bridge connects the villages of Bissone and Melide on the eastern and western side of the lake of Lugano in Switzerland. The architectural and structural concept is inspired by natural microorganisms, e.g. radiolarians and diatoms, whose skeletons are structurally optimized lightweight constructions. The resulting bridge structure is conceived as an overhead spatial frame of 2.40-m height, as shown in Figures 1 and 2. The roof frame and walkway slab are in parallel, horizontal planes while the side frames are undulated and form three waves of 6-m length each, see Figures 3 and 4. This undulation results in an also undulating width of the roof frame and walkway slab along the bridge, which are staggered however by one half-wave length, i.e. in the cross sections with the largest width of the walkway slab the width of the roof frame is the smallest and vice versa. The width of the walkway thus varies between 1.36 and 3.36 m. The edges between the horizontal and the undulated side frames are double-curved. Furthermore, transverse stiffeners are located around the frame openings to increase the buckling resistance of the compressed frame struts.

Figure 1 Rendering of TSCB bridge

Following the aim of approaching the efficiency of natural structures, the components of the lightweight spatial frame are conceived in sandwich construction. Carbon fiber-reinforced polymer (CFRP-) materials were selected for the face sheets since the architectural concept aimed to have a black coloured bridge with a surface finish that shows the texture of the fabrics.
The geometry of the bridge was not only a result of the architectural and structural conception, but also optimized from the manufacturing point of view. The overall complex shape is conceived in a way that it can be built up from only one complex module of 3.0-m length, as shown in Figure 5, which requires only one (expensive) mould for manufacturing. The openings in the bottom frame are closed to form the walkway slab. Furthermore, the undulating joints between the upper and lower modules are located in vertical planes to reduce the geometrical complexity, see Figure 4; the overall bridge width is thus constant (4.20 m), see Figure 3. Vacuum assisted resin infusion was selected for the manufacturing with the mould being placed on the inner side to have the smooth surface there. All the joints are vacuum infused or adhesively-bonded in the factory; the whole bridge is thus prefabricated and transported to the site.

MATERIALS AND STRUCTURAL MODEL

The thickness of the roof and side frame sandwiches is 30 mm, and that of the walkway slab 40 mm. The CFRP face sheets are 0.75-mm thick and composed of three layers of fabrics (SAATI CC283, 49/51% in 0/90° direction) and an epoxy resin (Conchem LC 318/IN). Lightweight (280-g/m²) twill-weave fabrics were selected due to the required drapability. The three layers are rotated against each other by 30° (arranged at 0/30/60°) to form quasi-isotropic laminates since an anisotropic lay-up, that would better adapt to the stress fields, was inconceivable considering the complex geometry. The 3-layer laminates are thus asymmetric, the resulting through-thickness stresses in the core are however insignificant. The laminate lay-up is doubled to 6 layers (in a symmetric
1326

arrangement) in the walkway slab and, in the curved edge regions marked in yellow in Figure 6, it is increased to
6 or 12 layers. The laminates are UV-protected by a transparent coating. The core material is an orthotropic
polyethylene terephthalate (PET) foam of 135-kg/m³ density (Airex T92.130). The foam is placed with the
extrusion direction and weldline planes perpendicular to the face sheets (in "end-grain" direction). The foam is
substituted by an isotropic solid polyurethane (PUR) material (SikaBlock M930) in the support cross beams (blue
region in Figure 6) and the double-curved curved edge regions.

The laminate properties and joint strengths were obtained from testing, the core properties from the manufacturer.
The main properties of the CFRP laminates and PET foam at room temperature are given in Tables 1 and 2. Due
to the black colour, the surface temperature could locally increase up to 84°C, as corresponding measurements on
CFRP sandwich samples protected with a transparent UV-coating and exposed to a normal irradiation of
1000 W/m² (as present in Bissone) have shown. The maximum allowable service temperature, however, was
defined as the onset value of the glass transition temperatures, \( T_{g,\text{onset}} \) (according to dynamic mechanical analysis,
DMA), of the resin or foam minus 10°C. Surfaces which would exceed this temperature are painted with a light
colour to limit the temperature increase to the allowable temperature.

The replacement of the PET foam in the strongly curved edge regions by the solid PUR material was necessary
since the foam could not be placed in end-grain direction. A deviation of this direction, however, was linked with
a drop of the properties due to the material orthotropy. Several core materials were evaluated to solve this problem,
as it is shown by a comparison of some significant properties listed in Table 3. A comparable high-density (almost)
isotropic polyurethane foam (PUR 145) has a better tensile strength than the selected PET foam transverse to its
extrusion direction (index \( \perp \)), however, the properties parallel to the PET foam extrusion direction (index \( \| \)) were
much lower. Orthotropic Balsa wood, on the other hand, has much better properties in grain direction than the PET
foam in extrusion direction. However, the tensile strength in the critical transverse direction is lower. It was thus
not possible to find only one lightweight material (at a reasonable cost) that would fulfil all the requirements and
the selected two-material solution resulted as being the best one.

\(^1\)\(^-\)\(^-\) = parallel-transverse to extrusion/grain direction
The spatial frame is supported by two elastomer bearings on each side, the support conditions are those of a simple beam. In addition, all supports are secured against uplift since wind uplift forces may be higher than the dead load. The spatial frame was modelled in a finite element software using shell elements; half of the bridge was considered using a symmetry condition, as shown in Figure 6. The geometry was simplified, i.e. the curved edges in the cross section were modelled as sharp corners; detailed verifications demonstrated that this simplification is on the safe side.

**STRUCTURAL VERIFICATIONS**

The structural verifications are based on Swiss standards (SIA), which are in line with Eurocode standards. The ultimate limit (ULS) and serviceability limit (SLS) states were verified using the partial safety factor concept, i.e. applying load factors on the action and resistance factors on the material side. The actions, their combinations and associated load factors were determined according to SIA260 (2013) and SIA261 (2014). Actions taken into account were dead and live loads, snow, wind and temperature. Since resistance factors for FRP materials are defined neither in the Swiss standards nor in the Eurocodes, resistance factors from Eurocomp (Clarke 1996) were adopted, as it is in accordance with the Eurocode design philosophy.

**Resistance Factors**

The resistance factor, $\gamma_R$, according to Eurocomp is composed of three sub-factors, $\gamma_R = \gamma_{M1} \cdot \gamma_{M2} \cdot \gamma_{M3}$, which take the property source, manufacturing method, load duration and operating temperature into account. The sub-factors at ULS were selected as follows: $\gamma_{M1} = 1.15$ (properties derived from tests), $\gamma_{M2} = 1.20$ (vacuum infusion process, fully post-cured), $\gamma_{M3} = 1.20$ or 3.00 for short-term or permanent actions, resulting in $\gamma_R = 1.70$ or 4.10 for short-term or permanent actions. These factors were applied to the characteristic, i.e. 5%-fractile strength and stiffness values of the laminate and core materials in order to obtain the design values. The core and laminate stiffness values were used to calculate the wrinkling resistance of the laminates. For the verification of adhesively-bonded joints, a fourth factor, $\gamma_{M4}$, is applied. The four factors in this case are $\gamma_{M1} = 1.25$ (properties derived from tests), $\gamma_{M2} = 1.50$ (manual application, no adhesive thickness control), $\gamma_{M3} = 1.00$ or 1.50 for short-term or permanent actions, $\gamma_{M4} = 2.00$ (service conditions outside the adhesive test conditions), resulting in $\gamma_R = 3.75$ or 5.60 for short-term or permanent actions.

At SLS, the average stiffness values were reduced by $\gamma_{R} = 1.30$ and creep was considered by a further stiffness reduction factor of 0.41 (Eurocomp, Figure 4.13, CSM/WR worst case at a 50-years' time). Furthermore, a strain limit of 0.2% was taken into account at SLS.

**Ultimate Limit State**

The laminate tensile and compressive resistances were verified, the latter according to the following wrinkling equation (Wiedemann 1996):

$$ f_{w,d} = C_w \cdot \sqrt{E_{L,\|d} \cdot E_{C,\perp,d} \cdot G_{C,\perp,d}} $$

(1)

with $f_{w,d}$ = design value of the wrinkling resistance, $C_w = 0.5$ (Keller et al. 2008), $E_{L,\|d}$ = design value of the laminate elastic modulus, $E_{C,\perp,d}$ = design value of the core elastic modulus, $G_{C,\perp,d}$ = design value of the core shear modulus. Further verifications concerned the core shear stresses and the through-thickness stresses resulting in the curved regions, including laminate-core delamination.

For the stability verification of the compressed frame struts an initial deformation of 1/300 of the buckling length was assumed and a subsequent second order verification was performed.

**Serviceability Limit State**

SLS verifications concerned the deflections, vibrations (eigenfrequencies) and the above mentioned 0.2%-strain limit. The deflections were verified for permanent loads including creep and the live loads. The corresponding deflections limits according to SIA260 (2013) were span/700 and span/600 respectively, in both the longitudinal and transverse directions. Based on the sandwich composition resulting from the ULS verification, all the deflection limits were met with the exception of the deflection of the walkway slab at the largest width. The resulting deflection of span/300 however was assessed as being admissible.
Concerning vibrations, the eigenfrequencies of pedestrian bridges have to exceed 4.5 Hz for vertical and 1.3 Hz for horizontal (transverse) vibrations according to SIA260 (2013). The eigenmodes and eigenfrequencies were calculated taking the dead load and 10% of the live load into account. The resulting first and second eigenmodes are a lateral and a vertical vibration respectively, see Figures 7 and 8, at eigenfrequencies that exceed the limit values.

Figure 7 First eigenmode, lateral oscillation, 3.42 Hz eigenfrequency

Figure 8 Second eigenmode, vertical oscillation, 4.64 Hz eigenfrequency

CONCLUSIONS

The intention of the new TSCB bridge is to create a bridge that meets architectural, structural and manufacturing requirements in an optimized way. The complex shape of the spatial frame can be built up of only one single module which can be manufactured in series. The overhead spatial frame has a large static height that offers a high stiffness and thus allows the laminate and core strengths to be fully used, which in most cases of FRP bridges is not possible due to deflection constraints. The complex, i.e. double-curved shape however also presents some disadvantages. The strength of the expensive carbon fibers cannot be fully used due to the required isotropic lay-up and orthotropic core materials are not ideal since their transverse direction is also stressed. Moreover, the small walkway width at mid-span results in high stresses in this cross section.

Without the architectural intention of exhibiting a black fabric texture and a slight increase of the frame static height and walkway core thickness, the bridge may be conceived at lower cost by using glass fibers. In fact, due to the temperature constraints, significant areas, in particular on the exterior side, need to be painted in a light colour. The selected sandwich construction, however, is an advantageous way to provide the required stiffness to prevent buckling in compressed parts and limit deflections in the walkway slab. Lightweight construction is thus maintained and the use of expensive CFRP materials is minimized. Furthermore, from the architectural point of view, the project demonstrates the liberty in the formal expression and plasticity offered by FRP composite materials.

ABSTRACT:
Innovative Fiber Reinforced Polymer (FRP) composite sandwich beams which composed of FRP sheets and Wood-Plastic Composite (WPC) core were manufactured using vacuum infusion molding process. The flexural behaviors of the FRP composite sandwich beams with three different depths ($h = 40$ mm, $85$ mm and $125$ mm) were investigated by four point bending tests. The failure modes obtained from the tests include the crushing of the upper FRP sheet and the tensile failure of the bottom FRP sheet of the FRP composite sandwich beam, and debonding failure between FRP sheets and WPC core was found. The ultimate moment of FRP composite sandwich beams increased by 1.9 times, 14.0 times and 26.9 times compared with those WPC beams, respectively. The results showed that the presence of FRP skins increases the load carrying capacity and result in a more ductile failure behavior.

INTRODUCTION
Wood-Polymer Composite (WPC) materials are becoming popular because of the properties such as resistance against biological deterioration and versatility in processing. They are considered environmentally friendly materials due to the usage of recycled thermoplastics in their compositions and processing residue fillers such as sawdust, rice hulls, or peanut shells. The main part of WPCs is the filler to decrease the cost of the product and increase the stiffness (Clemons 2008). To advance WPCs as a load bearing material, the mechanical properties must be convincingly improved. The published research works investigating the mechanical properties of WPCs were mainly dealing with: compatibilization of wood particles and polymer surfaces (Yang et al. 2007), type and geometry of wood (Bouaffif et al. 2009; Migneault et al. 2008), the effect of processing parameters (Yeh and Gupta 2008; Balasuriya et al. 2001), impact modifier (Oksman and Clemons 1998) and hybridization with short reinforcement fibers (Rizvi and Semeralul 2008; Deng and Tang 2010).

Despite improving the material properties, it is unlikely that WPCs will replace load-bearing members, such as beams or columns, used in building and transportation structures. The limited use is mainly because of the low strength and time-dependent deformation of WPCs compared with traditional structural materials such as steel and concrete. The research conducted by Klyosov (2007) shows that the strength is low because of the poor interfacial bond between wood and polymer. Several studies attempt to improve the compatibility between the wood and polymer interface using various additives. But Lu et al. (2005) shows that using coupling agents alone might not be enough to achieve significant improvement in the mechanical properties of WPCs. The increase in deformation of WPCs over time under sustained load can be attributed to its viscoelastic properties.

One way to increase the mechanical properties of WPCs is to reinforce the surface with some other material with higher mechanical properties such as fiber reinforced polymer (FRP). The study (Dura 2005) conducted quasi-static flexural tests on extruded WPC beams with hollow cross-section reinforced on the top and bottom flanges with one-layer of E-glass FRP. The peak load for the reinforced members increased 2.4 times compared with the unreinforced member, whereas the modulus of elasticity increased by a factor of 1.73. One study conducted by Manalo et al. (2010) involved experimental investigation onto the flexural behavior of glue-laminated fiber
composite sandwich beams with a view of using this material for structural beams. The results shows that the composite sandwich beams in the edgewise position failed with 25% higher bending strength but have 7% lower bending stiffness than beams in the flatwise position. Moreover, Lopez-Anido and Xu (2002) developed a structural system based on the concept of sandwich construction with strong and stiff FRP composite skins bonded to an inner glulam panel. These examples show that the concept of composite sandwich panels to form a structural beam is highly practical.

This paper presents the results of an experimental investigation on the behavior of FRP composite sandwich beams with WPC core. The composite sandwich beams are fabricated by vacuum infusion molding process (VIMP) and subject to static 4-point bending test to determine their flexural properties. The load–deflection behavior, strength and failure mechanisms of the FRP composite sandwich beams are reported. The effects of the number of core layers on the strength and stiffness of FRP composite sandwich beams are also discussed.

EXPERIMENTAL PROGRAM
Material and specimens

Alkali-free glass fiber, wood-plastic composite, and unsaturated resin were selected to manufacture the composite sandwich beams with different sections. Figure 1 shows the manufacturing of FRP composite sandwich beam specimens. Each WPC core was wrapped with one layer of a bidirectional fabric (0/90°) with 800 g/m² of areal density, which was called sandwich panel element. Two or three sandwich panel elements were assembled together, and then the glass bidirectional fabric was covered on it by vacuum infusion molding process to manufacture a complete GFRP composite sandwich beam. The descriptions of the test specimens are listed in Table 1.

Test set-up, measurements and procedure

The 4-point static bending test on composite sandwich beams was performed in accordance with the ASTM C393-00 standard (2000). The distance between two loading points was 300mm and the length of the shear span was 450mm. A loading speed of 2 mm/min was employed. The actual test set-up and instrumentation for the static flexural test of composite sandwiches are shown in Figure 2. Before each test, the loading pins were set to almost touch the top surface of the composite sandwich specimen. The applied load, displacement and strains were recorded. The failure behaviors were also monitored and recorded.

EXPERIMENTAL RESULTS

Failure behavior

Experimental investigation showed that the GFRP composite sandwich beams exhibited some failure behaviors. These failure modes of the composite sandwich beams are shown in Figure 3.

Figure 2 Test set-up and measurement of flexural test

Figure 3 Failure of composite sandwich beams.

Specimen WPC failed in tension on the bottom, leaving an irregular fracture surface in the middle region of the specimen. The cracks of the compressive GFRP sheets were observed in specimen 1W-FRP. These cracks were also observed on the upper GFRP sheets for specimen 2W-FRP and 3W-FRP. When these cracks appeared, a significant drop in the load was observed. These cracks originated at the upper GFRP sheets and progressed with the application of load, but these cracks did not cause immediate failure. As these cracks developed, the damage
on the specimen increased, thereby, increasing the deflection. The specimen continued to carry load even after compressive failure of the upper GFRP sheets as shown by the cracks which developed near the loading point. The continuous application of load caused the fracture of the upper GFRP sheets. Splitting of the tensile GFRP sheets were also then observed. Final failure of the GFRP sandwich beams was due to tensile failure of the GFRP sheet on the bottommost. And the results of the experimental investigation with 3W-FRP also showed slipping occurred on the WPCs. The results show that the GFRP composite sandwich beams should improve the interfacial bonding properties.

**Load–deflection curve**

The load and mid-span deflection behavior of all specimens under 4-point static bending is shown in Figure 4. The figure shows that the deflection of specimen WPC increased almost linearly with load up to final failure, with an applied load of 1.8kN and a mid-span deflection of 43.9 mm. The figure also shows that the load of specimen 1W-FRP increased linearly with deflection before the load reached 2.8kN. The first crack occurred in specimen 1W-FRP at an applied load of 2.7kN, and the beam was still able to carry load until final failure.

The load of 2W-FRP increased linearly with deflection before 18.2kN. Then the load dropped because the slipping of WPC cores was occurred. After the cracks occurred on the upper GFRP skins, the beams were still able to carry load but showed large deflection until final failure of the bottom. A similar load deflection behavior was observed in specimen 3W-FRP. The load deflection curves for specimen 3W-FRP are almost linear until the load of 35.2kN and 41kN. As the loading continues, the Specimen 3W-FRP continued to carry load even after compressive failure of the upper GFRP sheets. The specimen behaved non-linearly with a reduced stiffness up to final failure.

![Figure 4 Load and mid-span deflection relationship of specimens](image)

**CONCLUSIONS**

The flexural behavior of GFRP composite sandwich beams with WPC cores was determined through experimental investigation. The ultimate load of specimens W-FRP, 2W-FRP and 3W-FRP increased by 1.9 times, 14 times and 26.9 times compared with specimen WPC, respectively. The results show that GFRP composite sandwich beams with WPC core resulted in a stronger and more stable section than individual WPCs. The results also suggest that the presence of GFRP skins increases the load carrying capacity and result in a more ductile failure behavior. The final failure of the specimen is due to tensile failure of the GFRP sheets. Finally, the results of this study demonstrated the high possibility of developing a structural beam from GFRP composite sandwich structures. Currently, research is being conducted to make full use of the GFRP composite sandwich beams with the objective of exploring the practical application of this for composite structures.

ABSTRACT
This paper investigated cyclic loading responses of three full-scale shear walls, including two precast concrete sandwich shear walls (PCSSWs) with FRP connectors and one cast-in-place (CIP) control shear wall. Horizontal connections of the PCSSW specimens were achieved through one or two rows of connecting bars spliced by steel sleeves. Test results revealed that all specimens failed in bending and exhibited stable hysteresis loops and similar energy dissipation. The difference in load-carrying capacity between the three specimens was less than 2%. Besides, all specimens behaved in a ductile manner, the ductility of the two PCSSWs (2.4 and 2.65) was slightly higher than that of the CIP control specimen (2.35). No damage was observed in the FRP connectors during the whole test. Moreover, a restoring force model was developed based on the test results. Overall, the PCSSW specimens showed better seismic performance, especially the specimen with single-row connecting reinforcements.

KEYWORDS
Precast concrete, sandwich shear walls, FRP connectors, row number of connecting bars, cyclic test, load-carrying capacity, ductility, restoring force model.

INTRODUCTION
As one of the most appropriate structures for residential buildings, precast concrete can be divided into precast concrete solid shear walls and precast concrete sandwich shear walls (PCSSWs). Among these, PCSSWs have been in use for several decades, first appearing in North America more than 50 years ago (K. Seeber et al. 1997). A typical PCSSW consists of external and internal precast concrete panel, called wythes, separated by an insulation layer (PCI 2011). The concrete wythes are connected through the insulation layer by connectors. Based on good mechanical properties and thermal insulation, fibre-reinforced polymer (FRP) connector is a common choose in PCSSWs. At present, PCSSWs with FRP connectors are commonly used in commercial and institutional structures as well as residential construction (Holmes et al. 2005) since they have excellent durability and fire-resistance on the premise of adequate thickness of cover, and can achieve a same life span of thermal insulation and load-bearing.

Although PCSSWs have been applied in some seismically active regions, investigations on the behaviour of them are very scarce. Therefore, it is necessary to study the mechanical properties, including seismic behaviour. Existing researches of precast concrete shear walls mainly concentrated on solid shear walls. Soudki et al. (1995) tested six full-scale specimens to investigate the behaviour of mild steel connections for precast concrete shear wall panels. The horizontal connection was reinforced by two continuity reinforcing bars spliced by sleeve, welded to steel angle or bolted to tube section. Results from the test revealed that precast shear walls all behaved satisfactorily. Qian et al. (2010) conducted quasi-static tests of five concrete shear wall specimen with different methods of vertical reinforcement splicing. According to the analysis, splicing sleeve transferred stresses of vertical reinforcement effectively.

There are some general provisions about designing precast concrete shear walls but no detailed provisions for the PCSSWs investigated in this study in ACI 318, EC 8, NZS 3101, and the Chinese code for seismic design of buildings.

Since 2007, our research team developed a kind of FRP connector and finished a series of tests to investigate its mechanical properties, durability and fire-resistance. Reliable performance of the connector was confirmed through above-mentioned tests. On this basis, this paper conducted cyclic loading tests under high axial load ratio.
(0.4) to investigate the cyclic loading response of PCSSWs with the new FRP connectors. In addition, the influence of row number of connecting bars was also discussed.

**EXPERIMENTAL PROGRAM**

**Specimen Details and Materials**

A total of three specimens were tested under cyclic loading. These three specimens comprised two PCSSWs of size 2000m x 2900m x 310mm (Specimen ID: TW1, TW2) and one CIP shear wall of size 2000m x 2900m x 200mm (Specimen ID: SW1). The PCSSW was composed of a 50-mm-thick extruded polystyrene (XPS) foam insulation layer with FRP connectors encased in a 200-mm-thick internal wythe and a 60-mm-thick external wythe. A precast specimen consisted of upper wall and ground beam joined by a horizontal connection. The horizontal connection of specimen TW1 was reinforced by two rows of continuity reinforcing bars while specimen TW2 only had one single row of connecting reinforcements. The dimensions and reinforcement details are shown in Fig. 1. A 20-mm-thick gap was reserved between the external wythe and the top beam. The concrete mixture was designed for a cube compressive strength of 35 MPa for all specimens. As for reinforcing bars, the yield strength was around 400MPa and the ultimate strength was about 540MPa.

**Test setup and test procedure**

The specimens were fixed to the rigid floor by anchor bolts as shown in Fig 2 and were subjected to a combination of horizontal and vertical loading. A constant axial load was applied to the specimens by using a vertical 10000kN capacity hydraulic actuator. The level of load on the wall was 40% of its capacity, which was calculated by multiplying the gross section of concrete area (not the XPS core) by the average compressive strength of all tested specimens.
panels. The lateral cyclic loading was divided into two phases. Initially, loading was applied under load control with increments of 50 or 100 kN. Following the cracking of concrete, the behaviour of the specimen became inelastic and loading was switched to displacement control. The second phase consisted of successive cycles progressively increasing 0.25% story drift. Three fully reversed cycles were applied at each story drift level. The test was continued under displacement control until failure of the specimen occurred or lateral load was lower than 85% of the capacity.

![Figure 2 Reversed displacement control cyclic history](image)

**EXPERIMENTAL RESULTS**

**Failure Pattern**

All shear walls failed in bending. At the time of failure, yielding of longitudinal reinforcement was followed by concrete crushing and spalling at the bottom of wall. (Fig. 3a and b) No pull-out of the continuity reinforcement from the sleeve was found in the precast specimens TW1 and TW2. The damage of both precast specimens was concentrated on internal wythes. Little damage of external wythes or connectors were observed during the whole test, which indicated the low participation level of external wythes in resisting lateral load. (Fig. 3c)

![Fig 3 Typical failure patterns](image)

**Hysteresis characteristics**

The lateral load-displacement hysteresis curves of all specimens are given in Fig. 4. The hysteresis hoops of PCSSW specimens were quite similar to those of the control specimen, which was considered a satisfactory performance. For all specimens, the hysteresis hoops exhibited pinching to some extent. Area of hysteresis loops of specimen TW2 was slightly larger than that of specimen TW1.

![Figure 4 Hysteresis curves](image)
The yield load, peak load, and corresponding displacement of three specimens were very close, which can be seen in skeleton curves (Fig. 5). The bearing capacities were 1455kN, 1473kN, 1417kN for specimen TW1, TW2 and SW1, respectively. The small difference between precast specimens and monolithic specimen lied in the presence of splice sleeve. All specimens exhibited similar trend of stiff degradation.

![Skeleton curves](image)

**Figure 5 Skeleton curves**

### Displacement ductility and deformability

The displacement ductility is the ratio of the displacement at failure to the yield displacement. Table 1 listed the yield displacement $\Delta_y$, the displacement at failure $\Delta_u$ and corresponding displacement ductility $\mu = \Delta_u / \Delta_y$. The yield displacement was determined according to the criteria suggested by Park (1989). The failure of the specimen was defined as the point at which the applied lateral load was 85% of the peak load. According to the results in Table 2, the following conclusions could be drawn:

1. The displacement ductility factor of monolithic specimen was 2.35, which is lower than the displacement ductility factor of precast specimens. This difference revealed that splice sleeves confined the concrete near the bottom of wall and delayed the crushing, thus increased the displacement ductility of specimen.

2. The displacement ductility factor of specimen T1 was 2.40; for specimen T2, it was 2.65. PCSSW with single-row connecting reinforcements exhibited better displacement ductility than that with double-row connecting reinforcements.

3. The ultimate deformability of PCSSWs was slightly larger than the monolithic shear wall.

### Restoring force model

By analysis of hysteresis hoops, skeleton curves and characteristic loads of two PCSSW specimens, a four-linear restoring force model was proposed, as shown in Fig. 6. The normalized characteristic parameters for the P-$\Delta$ hysteretic model were listed in Table 2. In this table, $P_{cr}$, $P_y$, $P_{max}$ and $P_u$ symbolized cracking load, yielding load, peak load and failure load, respectively; $\Delta_{cr}$, $\Delta_y$, $\Delta_{max}$ and $\Delta_u$ were lateral displacement corresponding to these loads, respectively. In Fig. 6, “+” and “-” in front of letters denoted the characteristic values in positive and negative directions, respectively.

</tbody>
</table>
Main hysteretic rules were expressed as follows:

(1) The skeleton curves of specimens were simplified into four-fold line in both positive direction and negative direction. The characteristic points were cracking point, yielding point, peak point and failure point.

(2) Before cracking, the initial stiffness $K_1 (= P_{cr}/\Delta_{cr})$ was taken as the loading stiffness, and stiffness degradation and residual deformation were not taken into account during unloading. Reloading rules in the negative direction were that the curves directly pointed to a cracking point in the negative direction.

(3) During the stage between cracking point and yield point, $K_2 (= (P_y - P_{cr})/(\Delta_y - \Delta_{cr}))$ was taken as loading stiffness, and stiffness degradation and residual deformation were considered.

(4) Post-yielding stiffness $K_3 (= (P_{max} - P_y)/(\Delta_{max} - \Delta_y))$ was defined as loading stiffness after yield point. Loading stiffness $K_4 (= (P_u - P_{max})/(\Delta_u - \Delta_{max}))$ became negative stiffness after peak point.

(5) The initial stiffness $K_1$ was taken as unloading stiffness by reduction factor $\beta$. Here, $\beta = (\Delta_y/\Delta_m)v$, where $\Delta_m$ was the maximum displacement experienced, and $v$ was regressed from the test results.

(6) Reloading rules in the negative (positive) direction after post-cracking unloading were that the curves directly pointed to pivot pinching point, $M (N)$ (the ordinates of which are listed in Table 4) in the positive (negative) direction, then pointed to the maximum previous displacement point, and then took $K_2, K_3$ as the loading stiffness pointing to the skeleton curve.

![Figure 6 Restoring force model](image)

Energy dissipation capacity

The energy dissipation capacity of a shear wall is a function of the area under the load-displacement curve, and indicates the degree of effectiveness of the wall to withstand earthquake loading. The cumulative energy dissipated during the test was plotted in Fig. 7. By comparison of cumulative energy dissipated after same number of cycles, it can be found that the energy dissipation capacity of the PCSSW with single-row connecting reinforcements (70.2 kN-m) was higher than that of PCSSW with double-row connecting reinforcements (44.7 kN-m). This difference may lie on the connecting reinforcements at the connection area. To be more specific, the double rows of longitudinal reinforcements were replaced by one single row of connecting reinforcements in specimen T2. Consequently more reinforcements existed in the area of anchorage length.

![Figure 7 Energy dissipation](image)

CONCLUSIONS

Based on test results presented here and from the observations during the test, the following conclusions may be drawn.
(1) All specimens failed in bending. The connecting reinforcements didn’t rupture or pull-out from the sleeve. The external wythe participate in resisting lateral load to a very small degree and had little damage. In addition, no damage was observed in the FRP connectors during the whole test.

(2) The difference in load-carrying capacity between three specimens was less than 2%.

(3) Each specimens exhibited stable hysteresis behavior until the onset of failure, followed by pinched loops during post-failure cycles.

(4) The displacement ductility of three specimens was larger than 2, which indicated a ductile manner.

(5) Based on the above, precast concrete sandwich shear walls have similar seismic performance to the CIP shear wall. It is feasible to use splice sleeves as connections in precast walls, and simply the connection into single row.

BOND BEHAVIOUR OF COMPOSITE SANDWICH PANEL AND EPOXY POLYMER MATRIX

Wahid Ferdous 1, Allan Manalo 1 and Thiru Aravinthan 1
1 Centre for Future Materials (CFM), School of Civil Engineering and Surveying, Faculty of Health, Engineering and Sciences, University of Southern Queensland, Toowoomba, QLD 4350, Australia.

ABSTRACT
Fibre composite sandwich panel made up with glass fibre reinforced polymer skins and phenolic foam core can be glued or cast together to produce a large structural beam section. To ensure the structural integrity and composite action, the sandwich panels should be effectively bonded with polymer matrix. However, the bond behaviour between sandwich panel and polymer matrix is not well understood. This paper experimentally investigated the effect of epoxy polymer matrix properties, bond length, bond thickness, and bond width on the bond behaviour, and evaluated the optimal parameters for effective bonding. The experimental program was designed by Taguchi method to reduce the number of experiments. Results showed that the polymer matrix consist with 40% filler and 60% resin (by volume) is the optimal binder. A bond length of at least 70 mm and bond thickness of 5 mm were found effectively to utilise the strength of the composite sandwich panel. The bond width however has insignificant effect on the bond strength.

KEYWORDS
Bond behaviour, sandwich panel, epoxy, filler, effect of design parameters.

INTRODUCTION
In recent years, a composite sandwich structure has become an effective alternative structural element for industrial applications due to its excellent design flexibility and good balance between rigidity and lightness (Manalo 2013). Applying this type of composite sandwich system to develop cost-effective civil infrastructure including bridge beams, railway sleepers and floating waler is now being explored (Ferdous et al. 2015). As sandwich panels are generally produced with limited thicknesses for production efficiency, a number of panels are bonded together with an epoxy polymer matrix to achieve the desired cross-section. This combination can be used for manufacturing bridge girders, railway sleepers and similar structures. Despite the cost benefits of vinyl-ester and polyester compared with epoxy, they are not suitable if excellent mechanical and thermal properties, superior resistance to humidity, low shrinkage and high elongation are required to produce a durable and flexible polymer matrix (Loos 2014). This study used epoxy resin for the polymer matrix because of its superior mechanical, durability and thermal properties and examined whether such a matrix is suitable for binding composite sandwich panels. In this process, the structural integrity and composite action of both the panels and matrix used are important in terms of transferring the load from one panel to another through the bond as de-bonding between a sandwich panel and binder interface can lead to premature failure of the structures.

Studies conducted on using externally bonded FRP/steel plates to rehabilitate existing structures (Chen and Teng 2001; Yuan et al. 2004) have found that the properties of the adhesive materials, and the bond length, thickness and width are some of the parameters that influence bond behaviour. However, those studies were conducted for the specific purpose of retrofitting existing structures where the FRP was bonded with concrete by a very thin layer of resin (< 1 mm) (Arenas et al. 2010) which was applied on the surface of concrete before placing FRP sheets. In the present study of a sandwich panel bonded with an epoxy polymer matrix, the properties and thickness of the matrix and casting method were different, which could affect the bond performance, the findings from retrofitting studies may not be applicable. Therefore, the main motivation for this study was to determine how the matrix properties, bond length, thickness and width affect the bond between a composite sandwich panel and epoxy polymer matrix.
MATERIALS AND METHODS

Materials

Sandwich panel

The composite sandwich panel consists of GFRP composite layers (skins) bonded to a phenolic core. The top and bottom skins were 2 mm thick with a fibre volume ratio of 45%. The phenolic foam core material came from natural plant (non-food) products derived from vegetable oils and plant extracts and was chemically bonded with the polymer resin (Van Erp and Rogers 2008). The properties of the constituent materials of sandwich panel are determined by (Manalo et al. 2012) and the necessary properties are provided in Table 1.

Epoxy polymer matrix

Polymer matrix was prepared by mixing resin and filler. Fillers were added from 30% to 50% (by volume) with the resin in increments of 10% as, from a previous study by the authors (Ferdous et al. 2016), mixes in that range were found to be the most suitable. The two main components of these resin systems were a DGEBA type epoxy resin and amine-based curing agent, with three different filler materials a fire retardant filler, hollow microsphere and fly ash, mixed together in approximate percentages to obtain an effective filler mix. The properties of the three mixes are provided in Table 2.

Taguchi Design of Experiments

The experimental program is designed in accordance with Taguchi method which is an effective tool for the design of experiments. Among the different parameters influencing bond strength such as matrix properties, bond length, bond thickness, bond width, surface roughness, and curing temperature, method and time, this study primarily focuses on the matrix properties and influence of bond dimensions on bond behaviour. Therefore, the design parameters considered in this study are the matrix properties, and bond length, thickness and width, each with three levels are shown in Table 3. These three levels of each parameter are considered for understanding the influence of the variation of matrix properties and bond dimensions.

As four independent design parameters, each with three levels that have no interactions with each other require a minimum of 9 experiments instead of 81 (i.e. 3⁴) as used in the traditional factorial experimental design, an $L_9(3^4)$ orthogonal array should be the best choice. The 9 experiments selected based on this array are shown in Table 4 (Olivia and Nikraz 2012).

The influence of the design parameters on the final output depends on the signal-to-noise ratio (SNR) that can be calculated by Eq. (1).

\[ SNR = -10\log\left(\frac{1}{n} \sum_{j=1}^{n} \frac{1}{y_j^2}\right) \]  

where, ‘j’ the trial number, ‘n’ is the total number of trials and ‘y_j’ is the magnitude of jth trial.

Sample Preparation and Test Setup

In order to investigate the effects of different parameters on bond behaviour, a special specimen configuration was designed to perform bond tests (Figure 1a). MTS Insight 100 kN capacity twin-column testing machine was used that can reliably perform standard tests such as peel, tear, shear, tensile, compression, and flexure. Five specimens in each category (Figure 1b) were tested in order to obtain reliable results. The bond between a sandwich panel and polymer matrix was investigated by a direct compression test in accordance with the most relevant test standard ASTM D905 at a speed of 1.2 mm/min. Under compression loading (Figure 1c), the sandwich panels transferred stresses to the matrix from two opposite directions that generated a shear stress in the polymer matrix.

RESULTS

Failure Behaviour

Three types of failure observed for the specimens (Figure 2) under compression loading were: (a) adhesion failure, where the bond failed at the interface between the polymer matrix and sandwich panel; (b) cohesion failure, where the polymer matrix fractured; and (c) panel failure, where the sandwich panel failed. An adhesion failure was observed for the samples in Expt. - 1, 6 and 8 (Figures 2(a), (f) and (h)) whereas the specimens were failed due to the cohesion of polymer matrix in Expt. - 3, 5 and 7 (Figures, 2(c), (e) and (g)). The third mode of failure was the failure of sandwich panel which was observed in the samples for the Expt. - 2, 4 and 9 (Figures, 2(b), (d) and (i)). Adhesion failures occurred in Expt. - 1, 6 and 8 which indicated that a weak chemical bond formed at the interface, a kind of failure not desirable when a good bond is expected. On the other hand, the cohesion failures observed in Expt. - 3, 5 and 7 indicated strong chemical bond at the interface of a sandwich panel and polymer matrix. However, this type of failure does not ensure effective use of the full strength capacity of sandwich panel which is the main structural component. Therefore, the effective utilisation of sandwich panel in the structural application deserve a failure in it which was observed in the Expt. - 2, 4 and 9. The skin delamination followed by core tension failure of a sandwich panel not only ensures utilisation of the full capacity of the panel but also represents a very strong bond between panel and the matrix.
Analysis of the Results

Under compression loading the panels were subjected to high shear stress in the joint area and the bond strength between panel and matrix can be evaluated by Eq. (2).

$$ Bond \text{ strength} = \frac{Failure \text{ load}}{Bond \text{ length} \times Bond \text{ width}} $$  \hspace{1cm} (2)

The failure loads and strengths obtained from the nine sets of experiments, their standard deviations, SNRs and overall mean of SNRs are presented in Table 5.

Overall mean of signal-to-noise ratio (SNR) = 13.84

Note: T-1 to T-5 indicate Test-1 to Test-5 of replicate samples

Although Expt. - 2 showed superior performance to the others in terms of bond strength, this did not indicate the optimum set of parameters. Using the SNR values presented in Table 5, it was possible to determine the effect of individual parameters at different levels. The SNR of a particular design parameter at a specified level was calculated and termed the level mean SNR, are given in Table 6.

</table>

The difference between the maximum and minimum level mean SNR (ΔSNR) and ranks, which indicated the order of the influence of the four design parameters on bond strength, were calculated (Table 6). The highest ΔSNR value, which was assigned rank 1, indicated that the bond thickness had the greatest influence on bond strength, with the properties of the polymer matrix and bond length ranked second and third, respectively, followed by the bond width.

DISCUSSION

The variation of level mean SNR with respect to the each level of design parameter are plotted in Figure 3.

![Figure 3: Effect of design parameters on bond strength](image)

**Effect of Matrix Properties**

It can be observed in Figure 3(a) that increasing the filler content from 30% to 50% gradually decreased the SNR response which meant that an increase in the amount of filler gradually weakened the bond between a sandwich panel and polymer matrix. The adhesive properties of the polymer matrix depended primarily on the amount of resin which gradually decreased with increases in the filler content, similar to the tensile or flexural properties of the polymer matrices provided in Table 2. The flow-ability of the matrix had an effect on the quality of the bond; For example, Expt. - 8 produced the most inconsistent results (a large standard deviation in Table 5) due to the formation of voids in the joint during casting because the matrix was composed of 50% filler that had less workability and promoted to create voids while flowing. As the other two matrices (with 30% and 40% fillers) produced quite consistent results, they were strong matrices for use in the final application. However, as the economical design of a polymer matrix suggests an optimal use of resin, a matrix composed of 40% filler and 60% resin was the preferred choice.

**Effect of Bond Length**

Compression of the sandwich panel was transferred to the polymer matrix through shear stresses along the bond length. Results showing an increase in failure strength when the bond length increased from 40 mm to 70 mm while an insignificant variation was observed between 70 mm and 100 mm (Figure 3b). This led to an important aspect of effective bond length beyond which an extension of the bond length cannot increase the ultimate bond strength. From the present study, it can be concluded that the experimentally evaluated effective bond length for a sandwich panel and polymer matrix was approximately 70 mm.

**Effect of Bond Thickness**

Increasing the bond thickness from 3 mm to 5 mm increased the bond strength but, from 5 mm to 10 mm, decreased it, as is evident in Figure 3(c). The lower bond strength at 3 mm than 5 mm was due to the formation of voids during casting, caused by the polymer matrix not being able to flow smoothly through the thinner bond line. A close inspection of the failure modes of the specimens presented in Figure 2 and Table 5 indicates that the bond thickness had a very strong influence on failure behaviour. An observation of the failure modes of thicker bond
specimens (Expt. - 3, 5 and 7) indicates that the failure path of the polymer matrix was not vertical but rather angular. A decrease in failure strength due to a thicker bond could be attributed to the greater eccentricity of the load path. Similarly, thinner bond specimens (Expt. - 1, 6 and 8) exhibited less eccentricity of the load path, the primary cause of adhesion bond failure. The failure of a sandwich panel with a 5 mm bond thickness represented the desired failure mode and a strong bond between the two components.

**Effect of Bond Width**

The effect of the bond width on failure strength was investigated using three different widths of 20 mm, 40 mm and 80 mm. The responses from the analysis showed that an increase in the bond width slightly decreased the ultimate failure strength, i.e., the utilisation efficiency of the combined action of a sandwich panel and polymer matrix marginally reduced. However, variations among the responses of the three different widths were insignificant (Figure 3d) compared with those of the other variables in this study. Consequently, an increase in bond width could increase the load-carrying structure but its effect on the ultimate failure strength was minimal which indicated that a wider sandwich structure bonded with polymer matrix could be designed for a unit width.

**CONCLUSIONS**

From the bond behaviour of sandwich panel and epoxy polymer matrix, the following conclusions are drawn-

1. The bond strength between a sandwich panel and epoxy polymer matrix decreases with an increase in the amount of filler due to the reduced adhesive properties of the matrix. To minimise voids and make the matrix economical, a polymer matrix with 40% filler and 60% resin is preferable.

2. The bond strength is improved by increasing the bond length up to 70 mm, beyond which the extension of the bond length cannot increase the bond strength.

3. The thickness of the polymer matrix has the greatest influence on the bond performance and failure mode. The failure of a sandwich panel with a 5 mm bond thickness indicates a very strong bond between the panel and matrix, which is the desired mode of failure for the effective utilisation of panels.

4. The bond width has an insignificant influence on the bond behaviour.

ABSTRACT
This paper provides a summary on the research activities and research findings on FRP enhanced structures and structural components by the author’s research team in recent years. The research started with designing and establishment of several key experimental testing equipment, including large-size split Hopkinson pressure bars (SHPB), large-scale drop-weight machine, and a full-scale field testing facility for vehicle/structure collision. Fundamental tests on concrete cylinders and confined concrete cylinders under high-strain rate impacts were carried using the large size SHPB equipment. The research indicates that FRP confinement can enhance the impact resistance of the concrete and increase the energy dissipation capacity. The large-capacity drop-weight loading tests of FRP confined concrete or confined concrete filled steel tubes (CCFT) stub columns, reinforced concrete beams exhibited the enhancing effects of using external FRP wrappings. Dynamic loading tests on bond strength between CFRP and GFRP and concrete were also carried out, with findings exhibiting the dynamic effects. Finally, a large scale 3-story reinforced concrete frame model with 3 bay and 3 span was tested to examine the progressive collapse behavior due to sudden column failure by gas gun induced impacts.

INTRODUCTION
Research needs of structures against blast and impact loads are becoming increasingly important in recent years, particularly after the 9-11 event in New York in 2001. Sponsored by several national and international research grants, the author has led a team at the Hunan University undertaking the efforts of experimental and analytical research on bridges and buildings subjected to potential manmade threats, such as blasts, impacts and fires, etc.

This paper attempts to summarize the research activities related to concrete structures under impact loading, at the Center for Integrated Protection Research of Engineering Structures (CIPRES), at the Hunan University, and the Nanjing Tech University.

EXPERIMENTAL FACILITY DEVELOPMENT
Since 2001, the author’s team has designed and developed several important testing facilities at the Hunan University. With the success at the Hunan University, the author’s research team was also given several contracting opportunities to design and manufacture similar testing equipment in China and elsewhere.

Large-scale SHPB
As shown in Figure 1, a SHPB (Split Hopkinson Pressure Bar, or Kolsky bar (Hopkinson 1914; Kolsky 1949; Nemat-Nasser et al. 1991; Forquin et al. 2008) contains a projectile, an input bar, an output bar, and a specimen placed between the input bar and the output bar. The projectile, propelled by gas-gun, impacts the input bar and transmits an elastic compression wave travelling in the input bar towards the specimen. Because the impedance of the specimen is less than that of the bars, an elastic tensile wave is reflected into the input bar and an elastic stress is transmitted into the output bar. Strain gages mounted on the input bar record the incident strain ε_1 and the reflected strain ε_R pulses, whereas strain gages mounted on the output bar record the transmitted strain ε_T.

The SHPB test technique contains two basic assumptions. One is that stress and strain fields in the specimen are uniform at any given instant. The other is that the stress fields are one-dimensional, uniform over the cross-section.
and in the axial direction. Once all three waves are recorded, the strain rate, strain and stress histories of specimen in uniaxial compression can be computed respectively from the following well know equations,

\[
\dot{\varepsilon}(t) = \frac{C_0}{L_s} \left[ \varepsilon_t(t) - \varepsilon_R(t) - \varepsilon_T(t) \right]
\]

(1)

\[
\varepsilon(t) = \frac{C_0}{L_s} \int \left[ \varepsilon_t(t) - \varepsilon_R(t) - \varepsilon_T(t) \right] dt
\]

(2)

\[
\sigma(t) = \frac{AE}{2A_s} \left[ \varepsilon_t(t) + \varepsilon_R(t) + \varepsilon_T(t) \right]
\]

(3)

where, \( \varepsilon_t(t), \varepsilon_R(t) \) and \( \varepsilon_T(t) \) are the surface strain-time histories induced by the incident, reflected and transmitted waves, respectively; \( C_0, A \) and \( E \) are the elastic wave velocity, cross-sectional area and Young’s modulus of the pressure bars respectively; and \( L_s \) and \( A_s \) are the length and cross-sectional area of the specimen.

The HNU-CIPRES is equipped with two SHPB shown in Figure 2, one with 74mm diameter and a temperature chamber up to 600°C, and the other with 100mm diameter. Huo et al. (2009) tested concrete filled steel tubes (CFT) under combined impact and elevated temperature using the 74mm diameter SHPB. At present, the author’s research team is also developing a 150 mm diameter SHPB at the Nanjing Tech.

**Drop-weight Tester**

The high-capacity drop-weight equipment at the Center for Integrated Protection Research of Engineering Structures (CIPRES), Hunan University, has a maximum drop height of up to 16 m, as shown in Figure 2. The hammer head weighs 124 to 200 kg depending on the testing purposes, and can hold additional thick steel plates to increase the hammer mass up to 1,000 kg. During testing, the hammer head is lifted up to predetermined height based on desired impact energy input and then the electrically controlled safety hook is released. Shortly before impacting, the data acquisition system and high-speed camera are triggered by using a laser sensing system. The impact forces of the hammer head is measured by a strain gauge based load cell and a piezoelectric load cell, whereas the forces at the specimen base can be checked also by piezoelectric film load cells.

**Field testing Facility for Vehicle/structure Collision**

Structures, particularly bridges and transportation facilities can be subjected to collisions, accidentally or intentionally, by vehicles in their service life. Different than the investigation of vehicular collisions by automobile industry, the emphasis in structural engineering is to study the structural behavior of structures, components and
facilities which receive the collisions or impacts. Another important research purpose is to study and develop structures or facilities to prevent or reduce the impact effects on structures by vehicular collisions. The vehicle/structure collision testing facility developed by the author’s team is shown in Figure 4 (Chen and Xiao et al. 2015).

The testing field has two tracks, one for collision truck which is guided by a rail with a length of 120m, and the other for pulling truck with shorter distance. During testing, the collision and pulling trucks are connected by a steel wire through a 1:2 pulley assembly system, which enables the reduction of the speed and travel distance of the pulling truck for desired collision speed. The wire pulling the collision truck can be relieved by a trigger system positioned 3.5m in front of the testing specimen, shown in Figure 4(b). Figure 4(c) shows a Dongfeng EQ-140 truck for testing with collision prevention bollards.

**FRP CONFINED CONCRETE**

**SHPB Tests of FRP Confined Concrete Cylinders**
To study the dynamic mechanical properties of the FRP-wrapped concrete under dynamic loading, the 100 mm diameter SHPB (Split Hopkinson Pressure Bar) is adopted to conduct the impact compression test of C40 (mix cubic strength of 40 MPa) concrete cylinder wrapped with 1 to 3 layers of basalt, carbon and glass fiber reinforced polymer (BFRP, CFRP and GFRP) wrapping under different strain rates, ranging from static to more than 200/s. The dynamic stress-strain relationships and dynamic increase factors (DIF) of different FRP confined concrete were obtained. Increasing the wrapping layers of FRP can increase the dynamic strength and deformability. Figure
5 exhibits the stress strain relationships of CFRP confined concrete and GFRP confined concrete with different wrapping layers. As compared in Figure 5, the effects of increasing wrapping layers for CFRP confined concrete is not as dramatic as for GFRP confined concrete. This might be due to the more brittle nature of CFRP compared with GFRP and BFRP.

Figure 5 Stress and strain relationships of FRP confined concrete under dynamic compression with an average strain rate of about 180/s: (a) confined concrete with 1 to 3 layers of CFRP wrappings; (b) confined concrete with 1 to 3 layers of GFRP wrappings.

Axial Impact Behavior of Confined Concrete Filled Tubes (CCFT)

Confined concrete tube (CCFT) is a new type of structural columns originally proposed by the author (Xiao et al. 2003, 2005). The impact tests on the CFT and carbon fiber reinforced polymer (CFRP) confined CFT stub columns (CCFT) under different impacting energy levels, were conducted using the HNU-CIPRES large-capacity drop-weight machine. The time history curves of impacting force and deformation time history curves as well as failure patterns were investigated. The results indicate that the failure patterns are related to the impact energy. Increasing the thickness of steel tube and providing additional transverse confinement by CFRP can enhance the impact-resistant behavior. The failure pattern of one of the CFRP CCFT specimens is shown in Figure 6(a). Finally, the dynamic analysis software ANSYS/LS-DYNA are used to simulate the impact behaviors of the CFT and CCFT specimens, and the simulation results are reasonable comparing with the test results. Figure 6(b) shows the comparison of impact force time histories obtained from the tests and the analysis (Xiao and Shen 2015).

DYNAMIC BOND STRENGTH BETWEEN FRP AND STEEL OR CONCRETE

Huo et al. (2016a, b) experimentally investigated the effect of the loading rate on the bond strength between the FRP and concrete. Twenty-three CFRP and Twenty-eight GFRP reinforced specimens with details shown in Figure 7(a) were tested using the drop-weight equipment, with the bending beam configuration shown in Figure 7(b). The investigation was conducted by changing the impact velocity, the bond width of FRP sheet and the number of FRP sheet layers. Figure 8 presents an example of strain distribution in CFRP at different load levels during a dynamic loading test. The test results show that the strain distribution gradient of the FRP sheets bonded to concrete
surface under impact loading was larger than under static loading, indicating the increase of the bond strength with increase of loading rate. It is also found that the effective bond length is reduced under dynamic loading. Equations for assessing the dynamic effective bond length and bond-slip model are also proposed by Huo et al. (2016a, b).

Figure 7 Dynamic bond testing of FRP and concrete: (a) specimen details; (b) test setup.

Figure 8 Strain distributions in CFRP for specimen C50-2-D600-1

FRP SHEAR ENHANCEMENT FOR RC BEAMS

The impact behavior of strengthened reinforced concrete (RC) beams with or without stirrups was experimentally investigated using the drop-weight equipment developed by the author’s research team. The impact test configuration is shown in Figure 9. The beams were retrofitted with FRP strips for shear reinforcement via a complete wrapping scheme. The CFRP reinforcement ratio was ranged from low to excessively high. The crack patterns and dynamic response including impact force, inertia force, reaction force, mid-span deflection, and CFRP strain were investigated. The CFRP contribution to impact resistance of RC beams was evaluated.

Figure 9 Drop weight impact test of FRP enhanced RC beam: (a) test setup; (b) specimen.

Bases on the observation and experimental data, the CFRP strengthening could change crack patterns and failure modes of RC beams under impact loading from severe shear failure without retrofit, to shear-flexural mode with shear-deficient CFRP ratio, to predominant flexural cracks at the critical ratio for shear reinforcement, and even to ductile flexure mode with excessive shear retrofitting amount, as shown in Figure 10.
The CFRP strengthening could significantly reduce the deflection of RC beams without stirrups by 80%. The increase of impact energy could linearly increase the deflection while the increase of impact velocity under same impact energy could decrease the deflection, as shown in Figure 11. The deflection distribution along the span presented irregular shapes if suffering from shear failure.

During the impact process, all dynamic forces could satisfy the dynamic force equilibrium. The inertia and reaction forces were activated later than impact force. At the initial phase, the impact force was mainly resisted by the inertia force, while the reaction force was balanced by the combination of impact and inertia force at the final low-frequency phase. If the CFRP reinforcement ratio was larger than the critical ratio for shear reinforcement based on the static design code of ACI 440.2R (2008), the RC beams without stirrups but retrofitted with CFRP complete wraps could avoid shear failure and merely suffer from flexural failure under ultimate impact loading.

Figure 11 Maximum mid-span deflection

**CFRP CABLE RETROFIT OF RC FRAME FOR COLLAPSE RESISTANCE**

A half-scale, three-story, two-bay and three-span reinforced concrete model frame (Figure 12a) retrofitted with carbon fiber reinforced polymer (CFRP) strip cables (Figures 12b and c) was tested under sudden removal of two side middle columns in the long direction on ground floor to study dynamic responses, resisting mechanism and CFRP retrofit effects. The CFRP strip cables were anchored to concrete slabs by specially designed anchorage (Figure 12c). The experimental results are compared with previous tests of the same frame without CFRP retrofit (Xiao et al. 2015). Figure 13 shows the displacement time histories of beam column joints immediately above the removed columns for the unretrofitted frame tested previously (Xiao et al. 2015) and the retrofitted frame subsequently (Liu et al. 2016). The comparison shows that the CFRP strip cables were effective in preventing the total collapse of the frame after the loss of columns. With additional CFRP strip cables, the frame structure sustained the applied gravity load as moment resisting frames without the transition to catenary action. To further demonstrate the effects, the CFRP strip cables were released, causing the frame structure to deflect downward and eventually collapse.

CONCLUDING REMARKS

From the research reported in this paper, dynamic loading with high strain rates is shown to have significant effects on the behavior of FRP confined concrete columns and FRP enhanced reinforced concrete beams. Dynamic bond strength between FRP and concrete was shown to be increased with increased strain rates. A half-scale three story, three bay reinforced concrete frame structures strengthened using CFRP cables were demonstrated to be capable to avoid the progressive collapse due to the sudden removal of lower story columns.

Currently, the author’s team is continuing the research efforts on dynamic loading tests of reinforced and concrete filled steel tubular columns and the columns with FRP enhancement.

ABSTRACT

This study investigates the strengthening efficiency of modified reinforced concrete (RC) beams strengthened with longitudinal and U-wrap FRP. Two types of sections were studied, namely normal rectangular and modified sections. The RC beams were made of normal-strength concrete and then strengthened with different wrapping schemes, including longitudinal FRP layers and FRP U-wraps. The variables of this study are the thickness of FRP layers, the number of FRP U-wraps, and wrapping schemes. These specimens were tested under quasi-static loads until failure. The longitudinal strain and debonding mechanism of FRP are investigated. Experimental results have shown that the proposed modified section not only eliminates the stress concentration at the corners but also provides confinement to the longitudinal FRP layers. Thus, the modified beams showed higher load carrying capacity than that of normal-section beams even though the same amount of strengthening material had been used. Using FRP U-wraps together with modified section can maximize the effectiveness of longitudinal FRP layers. The strain of longitudinal FRP layers and U-wraps was also examined.

KEYWORDS

Fiber Reinforced Polymer, RC beams, U-wraps, strengthening, retrofitting.

INTRODUCTION

Fiber reinforced polymer (FRP) has been commonly used to strengthen reinforced concrete (RC) beams. The effectiveness of longitudinal FRP layers has been proven to significantly improve the flexural resistance of RC beams. However, it has been well documented that the premature debonding of FRP at the interface limits its efficiency (Quantrill et al. 1996; Garden et al. 1998; Ceroni 2010). There have been several methods to mitigate the premature debonding by using different anchors, for example, mechanical anchors, FRP fan anchors, and FRP U-wraps. Among these methods, using FRP U-wraps seems very attractive since it is a simple method and considerably delays the debonding of longitudinal FRP layers and thus enhances the flexural capacity (Buyukozturk et al. 2004; Ceroni 2010; Pham and Hao 2016). However, FRP U-wraps may fracture at the corners of the beam soffit because of the stress concentration even though the corners were rounded (Ceroni 2010). This study proposes a new method of modifying the beam soffit before wrapping with FRP. The proposed technique is expected to delay the premature debonding and eliminate the stress concentration and thus improve the strengthening effectiveness. This proposed strengthening technique is verified against the common strengthening technique through experimental tests carried out in the present study.

STRENGTHENING SCHEMES AND FRP DEBONDING

RC beams have been successfully strengthened with longitudinal FRP to increase their flexural resistance. In such cases, the soffits of beams were bonded with longitudinal FRP layers. However, the premature debonding of the longitudinal FRP strips limits the effectiveness of this strengthening technique. There are many causes leading to the debonding of longitudinal FRP strips as discussed in the study by Smith and Teng (2002). The most commonly reported debonding failure was at or near the FRP plate ends. This failure is likely due to high interfacial shear and normal stress (Smith and Teng 2002). In order to mitigate the debonding failure of FRP, transverse FRP wraps can be bonded to three sides of the beams, namely FRP U-wraps. The use of FRP U-wraps cannot generate force to against the peeling stress in the adhesive as shown in Figure 1, i.e., the tensile force in FRP does not contribute to resisting the peeling stress ($\sigma$) in the FRP U-wraps in the case of rectangular beams. The peeling stress is thus resisted by the tensile stress of the adhesive or concrete near the surface. On the contrary, if the beam soffit is modified to become an arc with a radius $r$, the FRP U-wraps can generate confining stresses which help to prevent the debonding of longitudinal FRP layers as shown in Figure 1. In such cases, the peeling stress is resisted by the
sum of the tensile stress in adhesive and the confining stress from the FRP U-wraps. The confining stress can be estimated as follows (Pham and Hadi 2014):

\[ \sigma = \frac{P}{r} \]  

where \( \sigma \) is the confining stress in the adhesive, \( P \) is the force in the FRP U-wrap, and \( r \) is the radius of the beam soffit.

![Debonding analysis of FRP strengthening](image)

**EXPERIMENTAL PROGRAM**

There are two beam groups with different sections, namely rectangular section and modified section. The beams with a modified section were cast in a special formwork including a rectangular steel formwork and curved polystyrene foam formwork. These beams were designed to fail in flexure so that their shear capacity is about four times of their flexural capacity (Table 1). For easier reference, the notation of the beams consists of three parts: The first part is N- and M- that states the shape of the section (Normal rectangular and Modified section). The second part indicates the wrapping arrangement in which L is for the number of the longitudinal layers while T stands for the number of transverse strips in half of a beam. For instance, L2T7 means this beam is wrapped with two layers of the longitudinal FRP layer and seven one-layer transverse FRP strips per the half beam.

- Not applicable

It is noted that these beams belong to the slender beam group as defined by MacGregor (2005) with the shear span ratio \((a/d)\) 4.52 in which \( a \) stands for the shear span and \( d \) is an effective depth of the beam. The dimensions of the rectangular beams were 150 mm in width, 250 mm in height, and 2200 mm in length. The modified section beams had the same length as the rectangular beams but the section was modified at the soffit which is an arc with a radius of 125 mm. The soffit of the beams was modified to postpone the premature debonding of the longitudinal FRP layers and reduce stress concentration at the soffit corners of FRP U-wraps. The details of the reinforcement are shown in Figure 2. The nominal tensile strength of deformed bars and plain bars are 500 MPa and 250 MPa, respectively. The ready-mixed concrete used to cast these beams had the compressive strength of 46 MPa at 28 day age.
The beams were bonded with a number of FRP layers at the beam soffit. In order to delay the debonding of FRP, FRP U-wraps were bonded vertically to three sides of the beams as shown in Figure 3. FRP was bonded to the substrate of concrete by the epoxy resin which has a tensile strength of 54 MPa, a tensile modulus of 2.8 GPa, and 3.4% tensile elongation (West System n.d. 2015). The adhesive used was a mixture of epoxy resin and hardener at 5:1 ratio. The FRP properties had been reported in previous studies (Pham et al. 2015a; Pham et al. 2015b). The CFRP used was 75 mm in width with a unidirectional fiber density of 340 g/m². The nominal thickness of FRP was 0.45 mm and the tensile strength was 1548 MPa. The average strain at the maximum tensile force and the average elastic modulus based on ASTM D3039 (2008) were 1.74% and 89 GPa, respectively.

Prior to bonding FRP to the beams, careful surface preparation was carried out to remove weak concrete. The concrete surface was roughened by using a pneumatic needle gun. An airgun was used to blow all dust and remove weak concrete particles. Acetone was used to clean the concrete surface. A primer was applied to the concrete surface before bonding with FRP. The epoxy curing time was maintained at least three days before testing.

A number of strain gauges were bonded to the soffit of the beams to monitor the longitudinal strains. The measurements are used to achieve: (1) the applied load versus FRP strain curves, (2) the distribution of FRP strain along the beams, and (3) the FRP strain at failure in which rupture or debonding of FRP could be expected. These strain gauges were placed at a spacing of 150 mm from one end of the beams to the midspan point as shown in Figure 3. Two strain gauges were also fixed on the side of each FRP U-wrap to monitor the FRP strain during the tests. The experiments involved testing six beams and measuring their responses to a monotonically increasing load. The beams were simply supported in a three point loading configuration using a roller and pin, creating an effective span of 1900 mm. The beams were tested using a hydraulic jack with a loading rate at 1 mm/min. The deflections of the beams were measured at different positions by linear variable differential transformers (LVDT).

EXPERIMENTAL RESULTS

Failure modes

As expected all beams failed under the flexure mode since they were designed to have relatively large shear resistance. The shear resistance of these beams is about 4 times higher than their flexural resistance. Vertical cracks appeared at the midspan of beams when the applied load reached about 19 kN. These cracks were observed for all beams including the reference beam and the strengthened beams as shown in Figure 4. As conventional RC beams failing in flexure, new vertical cracks were detected at positions closer to the supports. The widths of these cracks opened and their lengths developed from the soffit of the beams to the top. For the strengthened beams, when the applied load was substantial, the longitudinal FRP layers initially debonded at the midspan and the debonding extended to the beam ends. The longitudinal FRP layers were still able to carry tension stress as evidenced by the
increasing in longitudinal strain. Accordingly, the tension force in the longitudinal FRP layers horizontally pulled the vertical FRP U-wraps and caused the shear stress in the FRP U-wraps. When the FRP U-wraps ruptured, the beam failed due to the complete debonding of the longitudinal FRP layers as shown in Figs. 5b-c. Interestingly, the FRP U-wraps of Beams ML2T7 did not fail while rupture of the longitudinal FRP layers led the complete failure of this beam (Figure 5a).

**Figure 5 Fractures of FRP U-wraps**

**Load-displacement curves**

The load – displacement curves of the reference beam and rectangular beams are presented in Figure 6. At the early stage of loading, the slope of the curves of these beams is almost the same, which means that the FRP layers had not sufficiently contributed to the capacity yet. When the applied load is greater than 50 kN, the applied load of strengthened beams still increases while the load of the reference beam remains unchanged and decreases afterward. Some discontinuities in the load – displacement curves of the strengthened beams were caused by debonding of the longitudinal FRP layers at the midspan. After FRP debonding stresses in these beams were redistributed and the applied load continued increasing while the debonding of the longitudinal FRP layers propagated to the supports. The experimental results of these beams are presented in Table 2. After the FRP layers fractured, these beams still could resist a load of the same level as the corresponding load of the reference beam at the same displacement. The capacity of Beam NL1 was increased by 14% while NL2T2 was enhanced 20%, as compared to the reference beam. The FRP U-wraps helped to postpone the debonding of longitudinal FRP layers. Especially, the capacity of Beam NL2T7 was enhanced by 59%, in which the longitudinal FRP layers debonded at the load of 66 kN but the FRP U-wraps prevented the propagation of the debonding. As a result, the capacity of Beam NL2T7 increased significantly until all FRP U-wraps at the midspan fractured.

The load – displacement curves of the modified-section beams are presented in Figure 7. As expected, the modified beams exhibited higher capacity than their counterpart in normal rectangular section group. The increase of the capacity in Beam ML2T2 was 34% compared to the reference beam. Interestingly, the capacity of Beam ML2T7 increased 87% even though this beam used the same amount of materials and less cross-sectional area as compared
to Beam NL2T7. It is recommended that the modified beams can be made by separately casting rectangular beams and curved segments before bonding them together by epoxy. The similar section modification method has been used in previous studies (Priestley and Seible 1995; Hadi et al. 2013; Pham et al. 2013). At the maximum load, the FRP U-wraps of Beam NL2T7 did not fracture while the longitudinal FRP layers ruptured. The curved soffit of this beam provides two fold advantages. It generated the normal stresses on the longitudinal FRP layer and reduced the curvature of the bottom corner of the section, which eliminated stress concentration of the FRP U-wraps as shown in Figure 1. As can be seen that $r$ is a finite value in the case of the curved beam section so that the normal stress $\sigma$ in FRP U-wraps provides confinement to the longitudinal FRP layer and then mitigates the debonding failure of the longitudinal FRP layer (Eq. 1). On the other hand, $r$ is infinite in the cases of the rectangular beams, thus the normal stress $\sigma$ in the FRP U-wrap does not prevent debonding of the longitudinal FRP layers. Meanwhile, the FRP U-wrap restrains the longitudinal deformation of the longitudinal FRP sheets and thus increases the shear resistance at the interface but not the normal stress resistance.

### Debonding strain of FRP

Debonding in FRP strengthened concrete structures takes place in regions of high stress concentrations, which are commonly associated with discontinuities and the presence of cracks. Propagation path of debonding initiates from stress concentrations is affected by the material properties and their interface fracture properties (Buyukozturk et al. 2004). The FRP strain of Beam NL2T7 is used to analyze the debonding propagation and the debonding strain. It is noted that the locations of strain gauges are shown in Figure 3. Strain Gauges L3 and L4 located near the midspan of the beam increased steadily at the early stage of loading. After 950 seconds, these strain gauges suddenly dropped while Strain Gauges L1 and L2 were triggered at the same time. It means that debonding occurred and propagated to near the beam ends. Thus, the average value of Strain Gauges L3 and L4 is assumed as the debonding strain of this beam. In the meantime, the values of Strain Gauges TB1, TB2, TB3, and TB4 were very small (less than 0.16%) and thus are not presented. Interestingly, these FRP U-wraps fractured at the corners, implying the stress concentration at these positions was significantly high. The debonding strain of FRP of all the tested beams is summarized in Table 2.

In order to demonstrate the effectiveness of the proposed beam modification, the FRP strains of Beam ML2T7 is discussed. At about 1300 seconds, Strain Gauges L3 and L4 reached the average value of 1.09% while Strain Gauges L2 and L1 suddenly jumped to about 0.4%. This phenomenon was caused by the propagation of FRP
debonding from the midspan to the beam ends. In addition, some cracking sounds of the epoxy were heard at the same time. The beam then failed by rupture of the longitudinal FRP layers at the midspan (Figure 5a). The strain of the longitudinal FRP layers dropped while Strain Gauge TB4, which located on the FRP U-wrap at the midspan, suddenly jumped to a new value about 0.38%. It is obvious that the FRP strain of the proposed Beam ML2T7 was higher than the other beams and the stress concentration eliminated.

CONCLUSIONS

This study investigates the behaviour of RC concrete beams strengthened with FRP under quasi-static loads. The proposed beam modifications have been demonstrated successful in increasing the beam capacities. The proposed beam section modification delays the debonding of FRP and reduces the stress concentration at the corners. They significantly increased the beam capacities even though the same amount of materials is used as compared to its rectangular counterparts. Using FRP U-wraps is highly recommended to maximize the capability of longitudinal FRP layers. However, further studies are sought to quantify the effectiveness of FRP U-wraps on the premature debonding of longitudinal FRP and thus the flexural capacity of RC beams.

DYNAMIC TENSILE PROPERTIES OF CARBON AND BASALT FIBRE REINFORCED POLYMER MATERIALS

Hong Hao1, Wensu Chen1 and Xihong Zhang1
1Centre for Infrastructural Monitoring and Protection, School of Civil and Mechanical Engineering, Curtin University, Australia

ABSTRACT

Fibre Reinforced Polymer (FRP) has been widely used in structural retrofitting and strengthening. FRP can be made of carbon fibre, basalt fibre or glass fibre. The structures strengthened by FRP might be subjected to blast and impact loading. To predict the structural performance of strengthened structure under dynamic loading, dynamic material properties of FRP need to be well understood. However, the study on the dynamic properties of FRP materials is limited in the literature. In this study, the strain rate effects on the dynamic material properties of both Carbon FRP (CFRP) and Basalt FRP (BFRP) were investigated. Quasi-static and dynamic uniaxial tensile tests of both the CFRP and BFRP were conducted. The failure modes and the testing results such as dynamic strength and failure strain of FRP at different strain rates were recorded. CFRP and BFRP material were compared in terms of the strength and failure strain. Based on the testing results, the empirical formulae of Dynamic Increase Factors (DIF) for CFRP and BFRP are derived to predict the strength increment at different strain rates.

KEYWORDS

Fibre Reinforced Polymer, dynamic tensile testing, strain rate effect, dynamic increase factor.

INTRODUCTION

Fibre Reinforced Polymer (FRP) has been widely used in retrofitting and strengthening existing structures as FRP strengthening is proved effective to enhance structure load-carrying capacity. FRP is made from polymer matrix reinforced with high strength fibres, such as carbon fibre, basalt fibre and glass fibre. During the service life, structures strengthened by FRP might be subjected to blast and impact loading. To predict the structural performance of strengthened structures under dynamic loading, dynamic material properties of FRP need to be well understood. However, there is a lack of understanding of the dynamic material properties of FRP for reliable predictions of the performances of the FRP strengthened structures subjected to dynamic loads at different loading rates.

In recent years, some studies have been conducted to examine the static and dynamic mechanical properties of CFRP and GFRP materials (Ou and Zhu 2015; Gilat et al. 2002; Al-Zubiady et al. 2013; Barre et al. 1996; Shokrieh and Omidi 2009). Nevertheless, contradicted testing results were reported on the dynamic properties of FRP material. For instance, for CFRP material Welsh and Harding (1985) tested T300 carbon/epoxy laminates at strain rate from 1.5x10^{-4}s^{-1} to 700s^{-1}. An increase in both the tensile strength and elastic modulus was reported. Zhao et al. (2007) and Chen et al. (2013) also carried out dynamic tests using SHPB technique on T300 carbon/epoxy composite respectively. Both testing results indicated that the tensile strength and the initial modulus increase with the strain rate. Recently, Al-Zubiady et al. (2013) tested CF130 carbon/epoxy laminates in the strain rate range of 0.000242s^{-1} to 87.4s^{-1}. The increased strain rate was found to result in increase in material tensile strength and modulus. However, some opposite conclusions on the effect of strain rate were given based on dynamic testing results on CFRP material. For example, with dynamic tests on T300 carbon/epoxy laminates, Hou and Ruiz (2000) observed insignificant strain rate effect on material tensile strength and modulus, while the shear properties were found to be strain rate dependent. Similar conclusions were made by Taniguchi et al. (2007) through their dynamic testing on type T700 carbon/epoxy laminates. In general, there is no consensus on the significance or even existence of strain rate effect on CFRP material, and the degree of its sensitivity. For BFRP, available literatures on its dynamic material properties are very limited. Therefore, there is a need to properly understand dynamic material properties of CFRP and BFRP for better analysis and design of FRP strengthened structures against dynamic loads.
In this study, the strain rate effect on the tensile properties of carbon and basalt fibre reinforced polymers was investigated. A series of quasi-static and dynamic tensile tests were carried out. The strain rates of the dynamic testing in this study were up to $237 \text{s}^{-1}$ and $259 \text{s}^{-1}$ for CFRP and BFRP, respectively. The failure modes and the testing results were recorded and compared. Empirical formulae for the CFRP and BFRP tensile material properties are proposed.

**EXPERIMENTAL PROGRAM**

**Testing specimens**

The carbon fibre tested in this study is SikaWrap®-230C, which is a woven unidirectional carbon fibre fabric designed for structural strengthening applications. It is a mid-range strength CFRP material in its family. The fibre density is $1.8 \text{g/cm}^3$ and the fabric sheet has a nominal thickness of $0.131 \text{mm}$. The epoxy resin used is Sikadur®-330 whose tensile strength and elastic modulus are $30 \text{MPa}$ and $4.5 \text{GPa}$, respectively. Unidirectional basalt fibre (named BJ30) with a unit weight of $300 \text{g/m}^2$ and a nominal thickness of $0.12 \text{mm}$ was tested. CFRP and BFRP laminate specimens were prepared by using wet lay-up process as per the guidelines ASTM 3039-14 and ASTM 7565-10. The thicknesses of the CFRP and BFRP laminates are about $0.5 \text{mm}$ and $0.7 \text{mm}$, respectively. The laminate sheets were sliced into $25 \text{mm}$ wide strips. It is imperative that the fibres run parallel to the direction of loading. The tabs were glued onto the specimens to avoid any possible damage when gripping the specimen. The gauge length of the dynamic specimen is $50 \text{ mm}$. Figure 1 shows the dimensions of the specimens for quasi-static and dynamic testing.

![Figure 1](image)

**Testing setup**

The quasi-static and dynamic tensile tests were performed by using hydraulic testing system and INSTRON® VHS 160/100-20 testing system, respectively (Figure 2). The INSTRON® machine utilizes servo-hydraulic and control technology and is capable of providing a controlled testing velocity of up to $25 \text{ m/s}$ under open loop control and $1 \text{ mm/s}$ to $1 \text{ m/s}$ under closed loop control. A maximum impact load of $100 \text{ kN}$ can be achieved in the testing system. In the dynamic tests, actuator speeds were varied from $0.5 \text{ m/s}$ to $20 \text{ m/s}$.

The INSTRON® VHS system comprises a fast jaw grip, which accelerates in the direction of tension till the designed testing velocity is achieved. A pre-set wedge is kicked out to release the sprung grips which firmly grab the upper tap and pull the specimen at the designed testing velocity until its fracture. A piezo load cell is installed below the bottom grip head to monitor the force that the specimen experienced. An accelerometer was built on the fast jaw to measure its acceleration. In the tests, an extensometer in the fast jaw was utilized to track the stroke of the actuator. A strain gauge was glued to the centre of each specimen to measure its strain. All signals of the above transducers were connected to a data acquisition system with a sampling frequency of $65 \text{ kHz}$. A high-speed camera was installed to monitor the dynamic fracture process of the FRP laminates, which was triggered by a TTL pulse from the testing system. A 2000 w halogen light was used to provide the lighting for high-speed filming. The filming frequency was set to $30,000 \text{ fps}$.
TESTING RESULTS

Failure modes

The typical failure modes for CFRP and BFRP are shown in Figure 3. Under quasi-static state, coupon breakages occurred in the central part of the specimen while some breakages were found around the grip area due to stress concentration or unavoidable loading eccentricity. Under dynamic tension, the failure mode of CFRP specimen differed from that under quasi-static state. Two diagonal cracks were formed instead of a single crack at gauge centre. The CFRP specimen was eventually split into three segments by the two diagonal cracks. More energy was therefore consumed, which led to higher material strength. For the BFRP specimen, fibre fracture was observed around the grip area and the delamination of fibres was found across the whole gauge section.

Stress-strain curves

The typical stress-strain curves of CFRP and BFRP at different strain rates are shown in Figure 4. Under quasi-static state, the BFRP specimens behaved as linear elastic material until fibre fracture. An averaged fibre strength, failure strain and elastic modulus are calculated as 1642.2MPa, 0.021 and 77.9GPa, respectively. As can be observed, the CFRP specimens also behaved as a linear elastic material until the point of failure. At a strain rate of 8x10^-5 s^-1, the fibre strength of 2953MPa was measured. As loading rate increases, the tensile strength increased marginally. At a strain rate of 8x10^-4 s^-1, the fibre strength increased to 3062MPa. The corresponding failure strain reduces marginally from 1.09% to about 1.06%. Nevertheless, the increase in specimen strength is not continuous and stable with the increase of strain rate. When strain rates go up to 4x10^-3 s^-1 and then further to 7.7x10^-3 s^-1, there is no significant increase in coupon strength and fibre strength. As shown in Figure 4a, under dynamic tension the basalt fibre shows nearly linear elastic behaviour until failure. The stress-strain curves of the specimens indicate an increase in tensile strength and failure strain with the strain rate. When the strain rate increases to 259s^-1 (Figure 4a), the fibre strength of BFRP goes up to 3383.3 MPa, with an increment of 106.0%. The corresponding failure strain is observed to be around 0.03, indicating an enhancement on the dynamic failure strain as compared to the quasi-static failure strain of around 0.021. Under dynamic loading, the CFRP also showed elastic behaviour. Stress increases almost linearly with strain at the beginning. When the strain approaches failure strain, the stiffness increases slightly indicating minor non-linear behaviour. The plot also reflects that the response of CFRP laminates is strain rate dependent. At a strain rate of 11s^-1, the fibre strength of 2985 MPa is reached, which is similar to that under quasi-static loading. As strain rate increases, CFRP fibre strength increases. At a strain rate of 185s^-1, the
fibre strength rises to about 5009 MPa, which reflects an increment of 63%. When strain rate further increases to 233 s\(^{-1}\), the fibre strength goes up to 5506 MPa, indicating an 80% increment.

Figure 4 Stress-strain curves of BFRP and CFRP at various strain rates

**ANALYSIS AND DISCUSSIONS**

**Strain rate effect on tensile strength**

Figure 5 plots the tensile strengths of basalt fibre and carbon fibre versus strain rate. The tensile strengths of fibres are calculated by only considering the thickness of basalt fibre (i.e. 0.12 mm) and carbon fibre (i.e. 0.131 mm). As shown in Figure 5, the fibre strengths of both basalt fibre and carbon fibre in the current tests show consistent behaviour with strain rate. For CFRP, the fibre strength does not show much variation with strain rate at low-strain rates. Significant increase in fibre strength can be found when strain rate is over approximately 50 s\(^{-1}\), which rises quickly with strain rate. The strength of basalt fibre is in general lower than that of carbon fibre because of different fibre properties. Strong strain rate dependency can be observed in Figure 5 that the BFRP fibre strength increased from about 1800 MPa at quasi-static state to about 2000 MPa at a strain rate of around 10 s\(^{-1}\). When the strain rate goes above 120 s\(^{-1}\), the increase in BFRP fibre strength rises much quicker with strain rate.

Figure 5 Fibre tensile strength vs. strain rate

Figure 6 Fibre failure strain vs. strain rate

**Strain rate effect on failure strain**

Figure 6 shows the failure strains of the CFRP and BFRP versus strain rate. The quasi-static failure strain of the BFRP is around 0.021. The failure strain does not show prominent strain rate sensitivity when the strain rate is below 120 s\(^{-1}\). When the strain rate is over 120 s\(^{-1}\), the failure strain goes up quickly with strain rate. When the strain rate is 259 s\(^{-1}\), the failure strain is 0.03, with an increase of 42.9% as compared to the quasi-static failure strain. The failure strain of CFRP is much lower than that of BFRP fibre. In the quasi-static and low-strain rate range the CFRP fibre fractures at strain around 0.01. Similarly to the relationship between the strength and strain rate presented above, the failure strain in the low-strain rate range does not show much correlation with strain rate. But
when the strain rate increases beyond 50s$^{-1}$, apparent higher failure strain can be observed, which also increases with strain rate. When the strain rate is around 50s$^{-1}$ the failure strain increases to about 0.011 with an increase of 10% comparing with the failure strain at quasi-static state. When the strain rate reaches to around 200s$^{-1}$, the failure strain rises to about 0.014, indicating a 40% increase.

**Strain rate effect on fibre modulus**

Figure 7 shows the relationship of fibre elastic modulus versus strain rate. Similar to failure strain, the fibre elastic modulus of BFRP shows limited sensitivity to strain rate in the low strain rate range. When the strain rate goes above 120s$^{-1}$, the fibre elastic modulus increases remarkably with the strain rate. When the strain rate is up to 259s$^{-1}$, the elastic modulus increases from 77.9GPa to 111.7GPa, with an increment of 43.4%. The modulus of CFRP is much larger than that of BFRP. For instance, at quasi-static state the modulus of CFRP is over 200GPa, while that of BFRP was less than 80GPa. The fibre modulus of CFRP also shows strain rate dependency. In the low-strain rate region carbon fibre modulus appears to be steady around 200GPa with the increase of strain rate. Clear dynamic increase effect can be found in the high-strain rate range. For instance, at strain rate of 20s$^{-1}$, an averaged fibre modulus of 255GPa was measured. As strain rate increases to about 100s$^{-1}$, the fibre modulus increases to around 305GPa with an increment of 50% as compared with quasi-static state. When the strain rate increased to about 200s$^{-1}$, the averaged fibre modulus increases to about 375GPa indicating a further 23% increase.

**Empirical formula of DIF for fibre tensile strength**

Dynamic increase factor (DIF), as a ratio of dynamic strength over static strength, can be employed to describe the increase in material strength at different strain rates. The measured fibre strengths of CFRP and BFRP in the current study are normalized against their averaged fibre strength as quasi-static state to derive the DIF for fibre strength. Figure 8 shows the DIF for both CFRP and BFRP fibre strengths versus the testing strain rates. The DIF for BFRP is up to 2.09 at strain rate of 256 s$^{-1}$ and the DIF for CFRP is up to 1.83 at strain rate of 220 s$^{-1}$. A bi-linear trend line can be introduced to depict the trend of the DIF and strain rate relationships for both CFRP and BFRP.

The empirical equations to predict DIF of CFRP fibre strength can be given as follows:

\[
\text{DIF}_{\text{CFRP}} = 0.0001 \times \log_{10}(\dot{\varepsilon}) + 1.003 \quad \dot{\varepsilon} < 50 \text{s}^{-1}
\]

\[
\text{DIF}_{\text{CFRP}} = 1.095 \times \log_{10}(\dot{\varepsilon}) - 0.857 \quad \dot{\varepsilon} \geq 50 \text{s}^{-1}
\]

The empirical equations to predict DIF of BFRP fibre strength can be given as follows:

\[
\text{DIF}_{\text{BFRP}} = 0.0456 \log_{10}(\dot{\varepsilon}) + 1.180 \quad \dot{\varepsilon} < 120 \text{s}^{-1}
\]

\[
\text{DIF}_{\text{BFRP}} = 1.7 \log_{10}(\dot{\varepsilon}) - 2.25 \quad \dot{\varepsilon} \geq 120 \text{s}^{-1}
\]

where DIF$_{\text{CFRP}}$ and DIF$_{\text{BFRP}}$ stand for the DIF of CFRP and BFRP, respectively. $\dot{\varepsilon}$ is strain rate.

![Figure 7 Fibre elastic modulus vs. strain rate](image1)

![Figure 8 DIF of fibre strength vs. strain rate](image2)
CONCLUSIONS

In this study, experimental tests were conducted to investigate the quasi-static and dynamic properties of carbon and basalt fibres. The strain rates of the dynamic testing in this study are up to 237 s^{-1} for CFRP and 259 s^{-1} for BFRP. Stress-strain relationships of CFRP and BFRP at various strain rates were measured. It was found that the dynamic material properties of both carbon fibre and basalt fibre are sensitive to the strain rate. The fibre properties such as tensile strength, failure strain and fibre modulus increase significantly with the strain rate when the strain rate is over 50 s^{-1} for CFRP and 120 s^{-1} for BFRP. The failure modes at different strain rates were captured by high-speed camera to analysis the strain rate effect. Multiple fracture, diagonal cracks and delamination of the specimens were observed in the dynamic testing. Empirical formulae of DIF for the CFRP and BFRP fibre strength with respect to the strain rate were derived from the testing data.

ABSTRACT

The present study is intended to investigate impact behavior of Ultra High Performance Fibre Reinforced Concrete (UHPFRC) plates by conducting moderate velocity impact tests. In a series of tests, a steel hemispherical projectile with a mass of 8.3kg collided to 6cm-12cm-thick UHPFRC panels, in which steel fibres were mixed with pre-mix high strength mortar. A range of impact velocity was around 40m/s. Test results revealed that the UHPFRC panels have significantly suppressed the scabbing and perforation failure compared to plain concrete plates. Based upon test data such as impact load-time history, reaction load-time history, strain response on the back surface and failure behaviour captured by a high speed video camera, a failure mechanism of the UHPFRC panel was discussed.

KEYWORDS

UHPFRC, moderate velocity impact, protective design

INTRODUCTION

In recent years, tornado and volcanic activity, which have been affected by climate change and crustal movement, has increased and made awareness on the protection of key structures or shelters. The velocity of a tornado missile is set to be 51 m/s (about 184 km/h) in the assessment guide for tornado effect on nuclear power plants (Nuclear Regulation Authority of Japan 2013). In the volcanic eruption, volcanic missiles were flown to approximately 2 km from the crater. The velocity of the volcanic missile with 10cm diameter is assumed approximately 100 m/s (360 km/h) (Cabinet Office of Japan 2015). While several studies have investigated the impact resistant design of concrete structures against the low to moderate velocity impacts described above in recent years, Ultra High Performance Fibre Reinforced Concrete (UHPFRC) has been developed and utilized as a structural member (e.g. Tanaka et al. 2002). The UHPFRC has excellent strength and durability characteristics compared to plain concrete. Hence, the UHPFRC can be used in protective structures against the impact loads. In regard to the impact resistance of the UHPFRC, past studies have focused on their impact resistant capabilities in low-velocity impact whose velocity is less than 10 m/s (e.g. Fujikake et al. 2006) and high velocity impact whose velocity is 100 m/s-500 m/s (e.g. Soe et al. 2013; Sovjak et al. 2013). On the other hand, few studies on the low to moderate-velocity impact of the tornado and volcanic missiles were done.

This study aims to investigate impact behavior of UHPFRC panels experimentally, subjected to low to moderate-velocity impact. Using low or moderate-velocity, impact tests on 18cm thick plain concrete plates and 6cm-12cm thick UHPFRC panels were conducted. Based upon test data such as impact load-time history, reaction load-time history, strain response on the back surface and failure behaviour captured by a high speed video camera, a failure mechanism of UHPFRC panels was discussed.

EXPERIMENTAL SETUP

Moderate-velocity impact test machine

A schematic diagram of a projectile launching system is depicted in Figure 1. This system consisted of an air compressor of an air booster, an air chamber and accelerating tube. This system was able to launch a projectile with a mass of between 4kg and 10kg, and with an impact velocity of between 10m/s and 80m/s, by adjusting
compressed air pressure. Impact velocity of the projectile was measured by two laser type speed sensors with resolution of 1cm/s.

**Projectile and Specimen**

In a series of tests, an 8.3kg spherical steel projectile with a diameter of 90mm was used as shown in Photo 1, and this mass is identical to the steel missile mass prescribed in the assessment guide for tornado effect on nuclear power plants (Nuclear Regulation Authority, Japan. 2013). An outlook of a plain concrete plate is shown in Photo 2. Dimension of the plain concrete plate was 1.2m in length and height and 18cm in thickness. The compressive strength of the plain concrete was 33.9N/mm$^2$ on average. Dimension in length and height of UHPFRC panels used in this study have the same dimension as the plain concrete plate and thicknesses were 6cm, 9cm and 12cm. The mix proportion of the UHPFRC followed the guidelines of UHPFRC construction design (draft) (Japan Society of Civil Engineers 2004) and mixing ratio of high-strength steel fibre, whose tensile strength $P_u=2,800$N/mm$^2$, diameter $\phi=0.2$mm, length $L=15$ mm, is 2 Vol%. The average compressive and tensile strengths of the UHPFRC were 216N/mm$^2$ and 24.6 N/mm$^2$ respectively, by standard heat curing of 48 hours in 90°C steam. Table 1 shows the mix proportion of the plain concrete and UHPFRC. The static punching shear strength of the UHPFRC of 6cm, 9cm, and 12cm thick panels were 249kN, 448kN and 697kN respectively.

**Measurement items and testing case**

Measurement items were displacement, velocity of the projectile, impact and reaction loads as well as penetration depth, diameter of spalling and strain response of back surface. Impact velocity varied from 37.9 m/s to 43.5 m/s. In general, load cell is used for measurement of an impact load, but a wire of the load cell seemed to be taken broken in this test condition. Hence, the impact load was estimated by multiplying the acceleration by the projectile mass of 8.3kg which was calculated by differentiating the velocity-time history of the projectile captured by a high-speed video camera with a frame rate of 50,000fps. In order to get rid of high-frequency components in the acceleration-time history, a moving average filter has processed at cut-off frequency of 3 kHz. Figure 2 shows the location of measurement items. Penetration depth was the deepest position of the dent from the impact surface. The spalling diameter was measured in four directions. Figure 3 shows the location of strain gauges on the back surface of the specimens. To measure the collision time on the impact surface, a 60 mm strain gauge was set in the center of impact surface. To investigate the failure response on the back surface, five 60mm strain gauges were attached in a 100 mm interval from the center of the back surface. The location of load cells (response frequency: 30 kHz) for measurement of the reaction force is shown in Figure 4. The plain concrete plates were installed with

![Figure 1 Outline of a moderate velocity impact test machine](image)

![Photo 1 Steel projectile](image)

![Photo 2 Plain concrete specimen](image)
a 4 sides support frame assuming that they were used as slab members in practice. On the other hand, the UHPFRC panels were installed with a 2 sides support frame because they were used generally as precast members (e.g. Musha et al. 2013).

RESULTS AND DISCUSSIONS

Failure state

Table 2 and Photo 3 summarize test results and damages of the specimens respectively. Case name is listed using material type "PLAIN" or "UHPFRC" with thickness (mm) and case number. The failure mode of PLAIN-180-1 at an impact velocity of 37.8 m/s was spalling with the penetration depth of 12.3mm, where thin diagonal and radial cracks were observed in the cross section and the back surface, respectively. The failure mode of PLAIN-180-2 was spalling with the penetration depth of 33.1mm at an impact velocity of 41.4 m/s, as diagonal and radial cracks developed as the impact velocity increased. Note that since some fragments in the back surface were detached during cutting of the specimen, the diagonal crack looked greater than the actual state. The failure mode of PLAIN-180-3 at an impact velocity of 43.5m/s was judged the limit of perforation because a clear hole was generated, but the projectile didn’t pass through the specimen. From the failure states of the specimens, the velocity which yields the scabbing for the 18cm-thick plain concrete plates was assumed between 41m/s and 43m/s. In all cases, diagonal cracks in the cross section of the specimen looked like punching shear failure. Referring to several definitions of local damage or overall response proposed by the literatures, a further investigation is needed to examine the failure mechanism precisely.

The failure mode of UHPFRC-60-1 was perforation limit with spalling diameter of 85 mm which was slightly smaller than the diameter of the projectile. The UHPFRC-90 specimens at an identical impact velocity of 41.4m/s showed scabbing (UHPFRC-90-1) and was spalling (UHPFRC-90-2), respectively. This fact indicates that the thickness of 9cm of the UHPFRC panel is the scabbing limit at an impact velocity of 42m/s, when using an 8.3kg projectile. Although the boundary condition of the UHPFRC panels was different from that of the plain concrete plates, both failure states resemble each other and the scabbing limit thickness of the UHPFRC panels was reduced approximately by 50% compared to the plain concrete plates. This finding indicates the same trend of the test result conducted by Musha et al (e.g. Musha et al. 2013). Also, diameters of spalling, scabbing and perforation, were smaller than those of the plain concrete plates. In the cross section of UHPFRC-90-1, many diagonal cracks
were dispersed from the center of the impact area due to the cross-linking effect of the fibre reinforced concrete (e.g. Fujikake et al. 2006). The failure mode of UHPFRC-120 was spalling with the spall diameter of 112 mm. whereas the spalling diameter was longer than the other cases, occurrence of the diagonal cracks in the cross section has been greatly restrained. The experimental results indicate that UHPFRC panels subjected to low to moderate-velocity impact of a hard projectile have restrained the local failure significantly compared to plain concrete plates.

**Figure 5** shows the displacement-time, impact velocity-time and impact load-time histories of the projectile of PLAIN-180-3, which are recorded by the high-speed video camera, and reaction load-time history is also shown in the figure. It can be seen from Figure 5(a) that the displacement increases gradually with time and comes to 38mm at t=1.8ms, which in accordance with the penetration depth of 35mm estimated from Photo 3. Figure 5(b) indicates that the initial impact velocity is 48m/s, which is 5m/s higher than that obtained with the velocity sensor. This discrepancy may be caused by an acceleration of the projectile after passing the velocity sensor. Figure 5(c) indicates that peak impact load shows 490kN at t=0.7ms. Subsequently, the impact load decreased and oscillation with high frequency components was induced during t=1.4ms-1.8ms, which was caused due to a cloud of dust by
the collision of projectile. Reaction load arose at t=0.8ms and came to 200kN at t=2.2ms. Figures 6 and 7 show the displacement-time, impact velocity-time and impact load-time histories of the projectile recorded by the high-speed video camera and the reaction load-time history of the UHPFRC-60-2 and UHPFRC-90-1, respectively. Figure 6(b) indicates that after maximum displacement at t=3ms, the impact velocity of the projectile showed almost zero, namely, most of the kinetic energy of the projectile was consumed in the penetration process. Figure 6(c) indicates that the impact load gradually increased to approximately 400kN at t=0.3ms. Subsequently, after the impact load dropped sharply, the impact load came to 200kN at t=0.7ms with duration time of 3.0ms. The duration of impact load was 1.5 times longer than that of PLAIN-180-3, because the failure developed gradually by the cross-linking effect. With regard to the UHPFRC-90-1, Figure 7 indicates that the maximum displacement was 22mm at t=1.0ms which was 2 times of measured penetration depth of 10 mm and the impact velocity showed zero at t=1.2ms. The discrepancy of the penetration depth between data analysis and observation might be caused by the overall deformation of the specimen in addition to the local failure. The maximum impact load as shown in Figure 7(c) was 700kN which is twice that of UHPFRC-60-2 and the duration time of the impact load was 1.4ms. The shorter duration time compared to plain concrete plates was caused by the high stiffness of the UHPFRC-90-1 panels. The impulse of UHPFRC-90-1 calculated by integrating the impact load time-history was 371kN * ms which is agreed well with the initial momentum of the projectile. The reaction load was generated at t=1ms and the impact load decrease to zero at the same time. This fact indicates that the overall deformation of UHPFRC panels arose at the end of the contact between the projectile and the UHPFRC panels.

Strain in the back surface and failure behavior of specimen

Figures 8 and Photo 4 show the strain-time history on the back surface and pictures of the failure behavior by the high-speed video camera in the case of UHPFRC-60-2, respectively. Figure 8 indicate that strain gauge B1 showed extremely large tensile strain at t=0.2ms because the strain gauge was disconnected by the penetration of the
From the photos of high-speed camera as shown in Photo 4, where the origin time was determined by recognizing a crack in the picture, the circumferential crack was developed around the center of specimen (gauge B1-B2) at t'=0.12ms. By comparing strain-time history with the pictures, the tensile strain of gauge B2 as shown in Figure 8 indicates the strain generated by the local deformation, and it finally arose sharply with the progress of the scabbing. At t'=0.66ms, the fragment of the scabbing was broken into pieces and debris inside and outside the specimen. By comparing the impact load-time and reaction load time-histories as shown in Figure 7(c), the crack and fragment in the back surface occurred at the initial phase of the reaction load and the local damage prior to the overall response.

CONCLUSIONS

This study investigated impact behavior of UHPFRC panels experimentally, subjected to low to moderate-velocity impact. The results of this study are summarized as follows.

(1) Moderate-velocity impact tests of plain concrete plates and UHPFRC panels were conducted. As a result, failure states of the UHPFRC panels, which had almost half thickness of the plain concrete plates, were similar to the plain concrete plates at an impact velocity of 42m/s. This fact indicates that the UHPFRC panels had a superior impact resistance capability.

(2) By comparing an impact load-time, reaction load-time, strain-time histories and failure behavior, the 6-9cm thick UHPFRC panels were failed by the local damage rather than the overall response arose.

IMPACT RESISTANCE OF ULTRA-HIGH STRENGTH CONCRETE BEAMS WITH FRP REINFORCEMENT

Alex Remennikov\(^1\), Matthew W. Goldston\(^1\) and M. Neaz Sheikh\(^1\)
\(^1\)Centre for Infrastructure Protection and Mining Safety (CIPMS), School of Civil, Mining and Environmental Engineering, University of Wollongong, Australia

ABSTRACT
Composite materials, including Fibre Reinforced Polymer (FRP) bars, have been used for decades in the structural and civil engineering sectors over traditional steel reinforcement. The main reasons for this are that FRP composites possess a number of advantages. They are non-corrosive, non-conductive, and lightweight and possess high longitudinal tensile strength. This paper presents the results of an experimental investigation into the effects of the use of glass FRP (GFRP) bars as internal reinforcement on the behaviour of concrete beams with high strength concrete (HSC) and ultra-high strength concrete (UHSC). Both static and dynamic (impact) behaviours of the beam have been investigated. Twelve GFRP reinforced concrete (RC) beams were designed, cast and tested. Six GFRP RC beams were tested under static loading (three point bending) to examine the failure modes, load carrying capacity, deflection and energy absorption capacities. The other six GFRP RC beams were tested under impact loading using a drop hammer apparatus at various levels of impact energy. It was found that the use of UHSC in conjunction with larger amounts of tensile reinforcement showed higher levels of post-cracking bending stiffness. GFRP RC beams under static loading displayed a flexural response at failure. The GFRP RC beams under impact loading displayed a dynamic punching shear failure response at various levels of impact energy.

INTRODUCTION
Experimental studies carried out have investigated the impact behaviour of RC beams reinforced with conventional steel reinforcement (Chen and May 2009, Fujukake et al. 2009, Saatci and Vecchio 2009). There are three types of responses that a RC beam can be subjected to – local response, global response or a combination of both. Localised failure modes of RC beams under impact have been described as being scabbing, which results in spalling and detachment of the tensile concrete cover, penetration, diagonal shear cracking around contact zone. This type of response is typically referred to as a shear “plug” type, even for flexural-critical RC beams (Saatci and Vecchio 2009) or localised dynamic punching shear failure (Kishi et al. 2002, Zhang et al. 2005) which has shown to occur at higher velocities of impact (Ohnuma et al. 1985). This type of response results in the majority of energy from the impact being dissipated around the impact area. A global response represents the bending and deformation response of the RC beams under impact. The behaviour of RC beams under impact loading has been described as a combination of both local and global response (bending and deformation). However, the global response has been documented as the main concern for RC beams subjected to impact loading (Hughes and Beeby 1982). The influence of different parameters including shear mechanisms, impact velocity, cracking response, impact energy and comparisons between static and impact failure modes were investigated in the literature. Also, most of the previous studies were limited to normal strength concrete (NSC). Only a limited number of studies have examined the impact response of high strength concrete beams reinforced with conventional steel reinforcement (Ágárdh et al. 1999). Although the behaviour of steel RC beams under impact loading were extensively studied, limited attention has been focused on experimentally investigating the impact response of concrete beams reinforced with GFRP reinforcement bars (Goldston et al. 2016). Goldston et al. (2016) reported that flexural-critical GFRP RC beams under impact loading displayed a shear “plug” type of failure, indicating the importance of shear mechanisms. Also, higher strength concrete and larger amounts of reinforcement, fewer inclined shear cracks were present along the surface of the GFRP RC beams (Goldston et al. 2016). However, there have not been any studies so far addressing the impact behaviour of ultra-high strength concrete (UHSC) beams reinforced with GFRP bars.
EXPERIMENTAL PROGRAM
Details of GFRP RC Beams

A total of twelve simply supported GFRP RC beams (2400 mm long, 100 mm wide and 150 mm deep) were constructed and experimentally tested under static loading and impact loading. The experimental program was divided into two series. The first series consisted of six GFRP RC beams tested under static loading (S) (three-point bending) to further investigate the influence of GFRP reinforcement bars on the flexural behaviour of beams. The test variables were the longitudinal reinforcement ratio and concrete strength. Three beams were cast with concrete of 80 MPa nominal concrete compressive strength with three beams cast with concrete of 120 MPa nominal compressive strength. At time of testing, concrete strength was measured as 97 MPa and 116 MPa. The parameters investigated were load-deflection behaviour, failure mode, energy absorption and strain in the concrete and GFRP reinforcement bars. The second series consisted of six beams tested under impact loading to investigate the dynamic response of UHSC GFRP RC beams. The six GFRP RC beams under impact loading (I) were cast with 120 MPa nominal compressive strength. Three beams had a reinforcement ratio of 1.0% and three with a reinforcement ratio of 2.0%. The GFRP RC beams were subjected to three different heights for specimens with reinforcement ratios of 1.0% and 2.0%. The height of the drop hammer was calculated based on the energy absorption capacity (50%, 75% and 100% energy absorption capacity) from static testing results. For the three beams with a reinforcement ratio of 1.0%, beams were subjected to heights of 355 mm, 533 mm and 710 mm. The three beams with a reinforcement ratio of 2.0% were subjected to heights of 550 mm, 825 mm and 1100 mm. Test parameters investigated included dynamic mid-span deflection, dynamic bending resistance, dynamic strain in GFRP reinforcement bars, failure mode and crack patterns. The GFRP RC beams were labelled according to the series, nominal concrete strength, longitudinal reinforcement type, reinforcement ratio and type of loading. The arrangement is in the form of A–B–C–D where A is the nominal concrete strength (80 or 120 MPa), B is the GFRP reinforcement bar type (#2S, #3HM or #4HM), C is the GFRP reinforcement ratio and D is for the type of loading, static (S) or impact loading (I). For GFRP RC beams under impact loading, the subscript I represents the height of the drop hammer in metres. For example, GFRP RC beam 80–#3HM–1.0–S was designed with concrete compressive strength of 80 MPa with #3HM GFRP reinforcement bars, a longitudinal GFRP reinforcement ratio of 1.0% and tested under static loading. For GFRP RC beam 120–#4HM–2.0–I1,1, nominal concrete compressive strength was 120 MPa, with #4HM GFRP reinforcement bars, a reinforcement ratio of 2.0% and subjected to a 1.1 m height under impact loading.

EXPERIMENTAL SETUP
Static Testing

The beams were simply supported, with a pin support at one end and a roller support at the other end as shown in Figure 1. The simply supported conditions allowed for the GFRP RC beams to deflect under static loading. A 600 kN hydraulic actuator anchored to an independent steel frame was used to apply a monotonic increasing load on a steel circular plate positioned at the mid-span. The hydraulic actuator was also used to measure mid-span deflection. GFRP RC beams were tested under displacement controlled loading at a rate of 1 mm/min until failure. Two electrical resistance strain gauges were attached at the top on each side of the GFRP RC beams, directly underneath the position of the load cell for measurement of concrete strain. One strain gauge was attached to each of tensile GFRP reinforcement bars, at the centre for measurement of tensile strain. All data including load, mid-span deflection and strain were recorded using the high speed data acquisition system.

Figure 1 Experimental Set-up for GFRP RC Beams under Static Loading
Impact Testing

Six GFRP RC beams were subjected to a 580 kg high capacity free falling drop weight apparatus used to apply impact load as shown in Figure 2. The setup procedure involved fixing two steel blocks to the floor to allow for the GFRP RC beams to have a clear span of 2000 mm with 200 mm overhang on each side. All impact GFRP RC beams were simply supported and positioned on a steel pin and steel roller. For the prevention of rebound during impact, steel frame rollers were connected to the steel blocks, which allowed the GFRP RC beams to roll during impact. The drop hammer was mechanically lifted to the required drop height using an automotive control system and released using an electronic quick release system. Dynamic mid-span deflections were determined by image processing technique using high-speed video camera recordings. Dynamic concrete strain was not measured due to the extensive damage in the impact area caused by the drop hammer. However, dynamic tensile strain was measured from the strain gauges located in the middle of each GFRP tensile reinforcement bar. This allowed for an average reading of dynamic tensile strain at the mid-span to be obtained. The recording rate of the high speed camera was 1000 frames per second.

Figure 2 (a) Experimental Set-up for GFRP RC Beams under Impact Loading; (b) Data acquisition system and high speed camera used in impact tests.

EXPERIMENTAL RESULTS AND DISCUSSION

Static Testing

GFRP RC beams under static loading were designed to have two distinct failure modes: GFRP reinforcement rupture and concrete crushing. During testing, the beams designed as under-reinforced displayed vertical flexural cracking, initially forming around the mid-span. Flexural cracks began forming at around 3 kN. At higher loading levels, new vertical cracks began propagating closer towards the supports. Already formed cracks around the mid-span continued to propagate further, vertically. The under-reinforced GFRP RC beams failed due to rupture of the GFRP reinforcement bars as shown in Figure 3, whereas the GFRP RC beams defined as over-reinforced failed by concrete crushing as shown in Figure 4. However, the over-reinforced GFRP RC beams showed signs of continually sustaining load, indicating signs of reserve capacity or an amount of pseudo “ductility”. At higher loading stages, concrete cover continued to crush prior to total failure. At total failure, the over-reinforced GFRP RC beams failed by rupture of the GFRP reinforcement bars. Figure 5 shows the experimental load-deflection graphs for the GFRP RC beams under static loading. All GFRP RC beams displayed a bi-linear relationship. Initially, prior to cracking, beams had high bending stiffness. Once cracking occurred, bending stiffness reduced, especially for the GFRP RC beams with the lowest amount of reinforcement. Concrete strength was shown to be more influential for GFRP RC beams with tensile longitudinal reinforcement ratios of 1.0% and 2.0% in increasing the load carrying capacity, due to the failure being governed by the strength of the concrete (crushing of concrete cover). For reinforcement ratios of 1.0% and 2.0% load increased by 27% (from 33 kN to 41.8 kN) and 13% (from 46.1 kN to 52.2 kN), respectively by increasing concrete from 95 MPa to 116 MPa. At higher reinforcement ratios, higher concrete strength (UHSC) did not show to improve post-cracking bending stiffness. Table 1 reports the experimental load carrying capacity and mid-span deflection of the GFRP RC beams under static loading.

Impact Testing

Three GFRP RC beams with reinforcement ratios of 1.0% and 2.0% were subjected to various levels of impact energy. For GFRP RC beam 120II-#3HM-1.0-S, static energy absorption capacities were calculated as 2029 J, 3043 J and 4057 J, at 50%, 75% and 100%, respectively. Hence, three impact heights were calculated as 355 mm, 533 mm and 710 mm, respectively. For GFRP RC beam 120II-#4HM-2.0-S, static energy absorption capacities were calculated as 3189 J, 4783 J and 6377 J, at 50%, 75% and 100%, respectively. Hence, the impact heights were calculated as 550 mm, 825 mm and 1100 mm, respectively. Overall, the experimental failure mode and general behaviour including crack patterns was relatively similar for all six GFRP RC beams subjected to various impact heights. The experimental failure mode, defined as a “dynamic punching failure” was given, which can be defined as the GFRP RC beams being subjected to a moving punch (from the drop hammer) in the mid-span. This resulted in localised concrete crushing on the top surface with the majority of damage (crack propagation) occurring in the impact area.

For the GFRP RC beams with a reinforcement ratio of 1.0%, GFRP RC beam 120-#3HM-1.0-I-0.355 experienced a dynamic punching failure response, with minor crushing of the concrete cover on the top surface, at impact point. During impact, cracks, predominately observed as a combination flexure, flexure-shear and minor shear cracks propagated from the tensile region throughout the height of the GFRP RC beam. Majority of these cracks were observed to be localised around the impact zone, with a few flexure-shear cracks closer towards the supports. No permanent deformation was observed when subjected to an impact energy of 2029 J. GFRP RC beam 120-#3HM-1.0-I-0.533 showed signs of further additional concrete cover crushing, with the exposure of the compressive GFRP reinforcement bars. Crushing of cover was not symmetric under impact, with localisation to one side of the impact point. Under an impact height of 533 mm, a small amount of rupture of the bottom concrete cover occurred, also exposing the GFRP tensile reinforcement bars around the impact zone. This caused a few cracks around the midspan to significantly widen. Cracks were predominately flexure cracks throughout the span of the GFRP RC beam, with the inclusion of a few flexure-shear and minor inclined shear cracks present. GFRP RC beam 120-#3HM-1.0-I-0.710 showed extreme localised concrete cover crushing and rupture of the tensile concrete cover occurred, causing the concrete to spall off as shown in Figure 6. The spalling off of the concrete was shown to be more symmetrical under the impact point, causing exposure of the compressive and tensile GFRP reinforcement bars. Again, a predominant flexural crack pattern was observed around the impact zone, with a very few signs of flexure-shear cracks and minor inclined shear cracking. This GFRP RC beam showed the least number of cracks during impact. By close inspection, some signs of splitting of fibres from GFRP tensile reinforcement bars were observed.

Figure 6 Dynamic Punching Failure and Crack Propagation of GFRP RC Beam 120II-#3HM-1.0-I-0.710
CONCLUSIONS

An experimental study of twelve simply supported GFRP RC beams subjected to static loading and impact loading has been conducted, highlighting the effectiveness of HSC and UHSC. Observations from the experimental testing have led to the following conclusions being made:

1) Failure mode of GFRP RC beams under static loading can be determined using sectional analysis used for beams reinforced with steel reinforcement. It was found that the ratio of the reinforcement ratio to the balanced reinforcement ratio held true for the governing failure. For the GFRP RC beams with more than balanced reinforcement, failure was shown to be caused by crushing of concrete cover. For the GFRP RC beams with less than balanced reinforcement ratio, failure was shown to be caused by GFRP reinforcement rupture.

2) Load-deflection behaviour of GFRP RC beams under static loading showed a bi-linear response. The first section represented an uncracked section, followed by a crack section, resulting in a reduction in bending stiffness. The GFRP RC beams with more reinforcement than balanced reinforcement displayed signs of pseudo “ductility”, where the beams were able to resist load before total collapse. As opposed to the under-reinforced GFRP RC beams which failed suddenly by rupture of GFRP reinforcement, resulting in no reserve capacity.

3) Effect of HSC and UHSC on the GFRP RC beams under static loading were shown to be more influence load carrying capacity, deflection and post-cracking bending stiffness. For the GFRP RC beams with a reinforcement ratio of 0.5%, increasing the concrete strength from 95 MPa to 116 MPa, load increased by 8% (from 15 kN to 16.2 kN). The reason for this is because these GFRP RC beams are designed as under-reinforced and thus their failure is governed by the tensile strength of the GFRP reinforcement bars. For GFRP RC beams with a reinforcement ratio of 1.0% and 2.0%, load increased by 27% (from 33 kN to 41.8 kN) and 13% (from 46.1 kN to 52.2 kN), respectively by increasing concrete from 95 MPa to 116 MPa. However, increasing concrete strength showed to increase mid-span deflection for a reinforcement ratio of 1.0% and 2.0%/m by 17% and 10%, respectively. In terms of post-cracking bending stiffness, for a reinforcement ratio of 1.0%, stiffness increased 10% for a change in concrete strength. However, for a reinforcement ratio of 2.0%, a reduction in 0.07% in post-cracking bending stiffness was observed. At higher reinforcement ratios, higher concrete strength doesn’t seem to improve post-cracking bending stiffness.

4) Under impact loading, regardless of the shear capacity of the GFRP RC beams, the GFRP RC beams displayed a dynamic punching shear failure response. Minor shear cracking around the impact area with crushing of concrete cover was observed. However, the GFRP RC beams under static loading were shown to failure in a flexural response. Thus, the shear behaviour of flexure-critical GFRP RC beams must be considered when designing structures subjected to impact loads.

ABSTRACT

The bond between the FRP and concrete plays a critical role in a strengthening system of concrete structures with externally bonded FRP. Modelling of concrete damage and fracture is of crucial importance for any reasonable prediction of the bond behaviour. The dynamic increase factor (DIF) in the strength of concrete-like materials is a subject of extensive investigation and debate for many years. It now tends to be generally accepted that the compressive DIF as observed from standard sample tests is mainly attributable to the dynamic structural effect, whereas for concrete under tension the DIF is deemed to be governed by different mechanisms, probably more from the material at the micro-fracture level, which needs to be modelled as a material property. This paper presents a review of the existing empirical research on the tensile DIF based on the Split Hopkinson pressure bar (SHPB) tests. A numerical investigation is also proposed, with a particular focus on how the DIF, irrespective of its cause, should be included in an appropriate manner in the FE modelling with a local concrete model. The inevitable mesh-dependency issue due to numerical localization and its implications on rate effects in meso-scale modelling of FRP-concrete bond behaviour are also discussed in detail.

INTRODUCTION

Fibre reinforced polymer (FRP) composites have been used to retrofit concrete structures against dynamic loading such as impact (Boyd et al. 2008, Bhatti et al. 2011), blast (Hefferman et al. 2011; Wu et al. 2009; Buchan & Chen 2007; Crawford et al. 1997) and earthquake (Niroomandi et al. 2010; Pan-telides & Gergely 2007; Teng et al. 2007). These studies have confirmed that FRP retrofitting is effective in increasing the structural resistance against these dynamic loading and it has also been observed that debonding on the FRP-concrete interface is one of the predominant failure modes under dynamic loadings. Most of early studies were either experimental (Tarapada and Debrata 2006) or macroscale numerical simulations focused on the global structural behaviour (e.g. Crawford et al. 2001), with limited analytical investigation (De Lorenzis and La Tegola 2005). Little attention has been paid to the FRP-concrete interfacial bond behaviour under dynamic loading.

As many debonding failures occur in the concrete adjacent to the FRP, the modelling of concrete damage and cracking is of crucial importance for any reasonable prediction of the bond behaviour. For concrete structures subjected to rapid loading such as impact and blast, high strain rates in the range of $1 \times 10^3$ are typical. At such high strain rates, the apparent strength of concrete can increase significantly compared with the quasi-static strength. Experimental observations (e.g. Malvar and Crawford 1998) have shown that the dynamic increase factor (DIF), i.e. the ratio of the dynamic to static strength, is a function of the strain rate.

This paper discusses the appropriate incorporation of the DIF in a general finite element framework and its application in modelling FRP-concrete bond behaviour with a local concrete material description. The pertinent issues with regard to strain localisation and the consequent mesh dependence, especially the associated “strain rate localisation” and subsequent need of using a mesh-objective local DIF input versus strain rate relationship, are investigated.
DIF AND ITS NUMERICAL APPLICATION
DIF of concrete materials

The key issue in the debate of DIF is whether the DIF should be treated as an inherent material property, despite that in common practice, e.g. in the widely-used CEB-FIP (1993) model code, the DIF has been introduced as a material property. It tends to be generally accepted that under “uniaxial” compression, the DIF is rather a dynamic structural effect than a material property. Recent studies have demonstrated that the inertia-induced radial confinement makes a large contribution to the dynamic compressive strength enhancement (e.g. Li and Meng 2003; Zhang et al. 2009; Lu et al. 2010). When a high compression stress pulse is imposed to the specimen, the specimen tends to expand in the hoop direction, resulting in a radial inertia force which is equivalent to a confining stress, and subsequently increasing the axial strength of the concrete. As such, it is argued that the concrete DIF in compression should not be imposed at the material constitutive model level, i.e., it should be disabled or simply set as unity for material models that incorporate DIF for compression in a refined finite element analysis. On the other hand, when concrete is under tension, the radial inertia force would change direction (to become radial expanding stresses), so the effect of the lateral (inertia) stress on the axial tensile strength is very different from that of confining stress on the axial compression. Concrete tensile failure is also usually much more localized than that under compression. Furthermore, experimental observations have indicated that the DIF for tension can be considerably larger than that for compression at a comparable strain rate. For example, for a concrete with a static compressive cylinder strength $f'_c = 30$ MPa, when the strain rate is 100$s^{-1}$, the apparent DIF is 8.0 and 2.3 for tension and compression respectively. Such a difference is hardly explicable by the effect of inertia force theory. Numerical studies using the discrete element modelling (e.g. Hentz et al. 2004) or the finite element (FE) modelling (e.g. Lu and Li 2011) of dynamic tensile tests (direct tension, splitting or SHPB spalling), suggested that the DIF of the tensile strength observed in dynamic tensile tests could be a genuine material effect. Consequently, it is deemed to be rational to include the DIF for the dynamic tensile strength in the material description in an analysis where tension plays a dominant role.

The CEB-FIP (1993) recommended DIF curve for compression and Malvar and Crawford’s (1998) tension DIF formula have been commonly adopted for modelling under high-rate loading conditions. Note that in the experimental determination of the apparent dynamic strength using Split Hopkinson pressure bar (SHPB) tests, the strain rate and the global DIF are calculated according to the stress wave time histories measured from the strain gauges attached on the incident and the transmitter bars (e.g. Li and Meng 2003; Tedesco et al. 1991; Tedesco et al. 1989; Ross et al. 1990; Ross 1989). This means that the results are representative of the bulk or macroscopic behaviour of the specimen. When such an “apparent” global DIF is considered in a FE model involving a local concrete model as a material parameter, issues pertinent to the localisation naturally arise, especially when the element size is much smaller than the general crack band width of concrete, which is approximately equal to three times the maximum aggregate sizes (Bazant and Oh 1983).

**DIF mesh correction**

To illustrate the issue related to the localisation of the strain rate in a FE model, a simplified direct tension test was simulated. The DIF curve in Malvar and Crawford (1998) was used directly in the model, whereas different mesh sizes were employed and the results were compared. The specimen used in this analysis is a cylinder with a length of 50.8mm and a diameter of 50.8mm, as typically used in standard dynamic tests (e.g. Tedesco et al. 1991). For illustrative purpose, a simplified 2D plane stress model was employed. To control the occurrence of fracture, a 2x2mm notch was created in the middle of the specimen on both sides. Three different meshes were chosen for the investigation, with element size equal to 2mm, 1mm, and 0.5mm, respectively.

To rectify the mesh-dependent strain rate localisation effect on the DIF, it would be rational to firstly establish a reference characteristic width within which crack softening is deemed to take place in the numerical model. Such a characteristic width may be regarded as a baseline for which empirical tensile DIF formulas in cracking would apply. Similar to Malvar et al.’s (2000) suggestion, herein a characteristic width of 25.4mm (one inch) is adopted, which is roughly three times the size of the 9.5mm (3/8-inch) aggregates that are commonly used in concrete samples. For mesh size differing from (especially smaller than) 25.4mm, the computed strain rate due to localisation should be corrected by the mesh size normalised with respect to the characteristic width before the empirical DIF formula is applied. This is equivalent to introducing a correction to the local DIF formula as an input to the model:

$$DIF = f_l / f_{tt} = (\frac{\dot{\varepsilon}}{\dot{\varepsilon}_c})^\gamma \quad \text{for} \quad \dot{\varepsilon} \leq \frac{\dot{\varepsilon}_{c0}}{x} s^{-1}$$

(1a)
where $X$ is the current element size in mm; $L_{x0}$ represents the characteristic width of the current concrete model in mm, herein 25.4 mm. Three loading rates were then simulated, namely 5, 50 and 200 mm/s ($\dot{\varepsilon} = 0.1, 1.0$ and 4.0 s$^{-1}$), respectively. The results are compared with Ross’s (1989) test data together with the global DIF curve proposed by Malvar et al. (2000) and they. The FE predictions for the direct tension test with the proposed mesh-corrected local DIF in Equations (1a) and (1b) are in good agreement with the empirical global DIF data, especially for strain rates up to the order of 1 s$^{-1}$. Further simulation for higher strain rates, however, did not produce as such “good” results. The DIF from FE simulations with local DIF curve expressed in Equations (1a) and (1b) for 4 s$^{-1}$ strain rate is lower than the value based on the modified CEB curve and experimental results. This is explicable by the fact that the simple correction in Equations (1a) and (1b) assumes the localisation of strain (and strain rate) within a single element, so the validity is limited to cases where failure does localise in a single element width. This is usually valid under quasi-static and relatively low strain rate dynamic tension. When the loading rate is higher, however, damage tends to distribute in a wider area due to strong transient dynamic effects. Such a phenomenon renders the localisation correction more complicated and warrants further investigation, as follows.

Mesh and rate dependency of DIF

As the simplified direct tension model cannot properly represent the real concrete behaviour under higher strain rates, the split-Hopkinson pressure bar (SHPB) test for direct tension of concrete was modelled with the inclusion of the pressure bars and the concrete specimen. The SHPB setup for direct tension as developed by Ross (1989) was adopted in this study. Two strain gauges are located at the middle of the incident and transmitted bars, so that the stress wave time histories can be measured. During the test, a striker impacts a tup which is attached at the end of what becomes the tensile incident bar. The overall dimension of the tested specimen was 50.8 mm (2 inches) in diameter and 50.8 mm in length. A 3.175 mm square notch was located at the mid-length of the specimen. The pressure bars were made of PH 13-8 MO stainless steel. The concrete being tested had the following properties: Young’s modulus $E_s = 37.93$ GPa; compressive stress $f'_c = 57.7$ MPa; tensile strength $f_t = 4.53$ MPa; density $\rho = 2405$ kg/m$^3$ (Tedesco et al. 1991). For simplicity, this SHPB test is treated as a plane stress problem in the numerical modelling, as was done in some previous studies (e.g. Zhou and Hao 2008; Tedesco et al. 1991), and only half (along the longitudinal symmetry plane) of the SHPB is modelled considering symmetry. A tensile stress pulse is imposed at the end of the incident (right side) bar instead of modelling the striker.

Different tensile impulses can be imposed on the incident face of the pressure bar to achieve different strain rates (e.g. Tedesco et al. 1991). To examine the adequacy of considering the local DIF at the material level, two options were examined with the current concrete model, one without any DIF, and the other with a local DIF which incorporates the simple mesh correction (Eq. 1). The results showed that a further correction is necessary to take into account the tendency of an increasing spread of tension failure in the higher strain regime. Combining with the mesh correction, this provides a more robust model for dealing with the issues in the FE modelling for dynamic tension arising from strain / rate-localisation and its increased complexity due to transient dynamic effect. Equations (2a) to (2d) present a “double-corrected” DIF curve for local concrete model. The strain rate correction of the localisation is achieved by introducing a dynamic characteristic length, such that $L_{x0} = L_{x0}(1+\xi \log \dot{\varepsilon})$ for $\dot{\varepsilon} > \dot{\varepsilon}_c$, where $\xi$ is an empirical coefficient, $\dot{\varepsilon}_c$ is a numerical critical strain rate below which only the mesh correction on the DIF is required.

$$DIF = f_i / f_n = \frac{\dot{\varepsilon}}{\frac{L_{x0}}{\dot{\varepsilon}_t}}^y \text{ for } \dot{\varepsilon} \leq \dot{\varepsilon}_t$$

(2a)

$$DIF = f_i / f_n = \left( \frac{\dot{\varepsilon}}{\frac{L_{x0}(1+\xi \log \dot{\varepsilon})}{\dot{\varepsilon}_t}} \right)^{1/3} \text{ for } \dot{\varepsilon} \leq \dot{\varepsilon}_c$$

(2b)

$$DIF = f_i / f_n = \beta \left( \frac{\dot{\varepsilon}}{\frac{L_{x0}}{\dot{\varepsilon}_t}} \right)^{1/3} \text{ for } \dot{\varepsilon} \leq \dot{\varepsilon}_c$$

(2c)

$$DIF = f_i / f_n = \beta \left( \frac{\dot{\varepsilon}}{\frac{L_{x0}(1+\xi \log \dot{\varepsilon})}{\dot{\varepsilon}_t}} \right)^{1/3} \text{ for } \dot{\varepsilon} \leq \dot{\varepsilon}_c$$

(2d)
\[ \xi = 6.8 \left( \frac{1}{L_{\text{so}}^2} \right) - 1 \quad (2c) \]

\[ \frac{e_0}{L_0} \delta \left( \frac{e_0}{L_0} \right)^{\beta} = \beta \left( \frac{e_0}{L_0} \left( 1 + \frac{\xi}{\varepsilon} \frac{\delta}{\varepsilon} \right) \right)^{1/3} \quad (2d) \]

MODELLING FRP-CONCRETE BOND WITH DIF

The numerical modelling of the impact test

The K&C concrete damage model (Malvar et.al 2000) with the above “double corrected” concrete local DIF was next introduced to perform meso-scale modelling of a series of FRP-to-concrete bond impact test conducted by Chen et al. (2012) where details of the test specimens can be found.

The beam specimen was idealized as a 2D plane stress problem so only a single layer of concrete element in the through thickness direction was modelled using the 3D solid element in LS-DYNA. Only half of the specimen was modelled considering symmetry. A pin-end boundary condition was applied. Both FRP and steel reinforcement bar was assumed to be perfectly bonded to the concrete. The impact load (Figure 1) was treated as a uniformly distributed pressure load applied at an \(100 \times 100 \text{mm}^2\) impact zone. Three element sizes, 10mm, 5mm, 2.5mm, were used for mesh convergence analysis (Figure 2), and the finally adopted mesh consists of 2.5mm square elements. The concrete compressive cylinder strength \(f_c\) was 25 MPa.

![Figure 1 Impact pressure load time history](image1)

![Figure 2 SG1 readings for test IT2](image2)

It can be seen from Figure 2 that the FE prediction at SG1 is in very good agreement with the test result. However, the other strains outputs do not match with the test results well: The closer the strain gauge location to the mid span where debonding starts, the better the FE strain prediction is in agreement with the test as shown in Table 1. Note that the strain gauge at SG3 was faulty in the test.

</tr>
</tbody>
</table>

The poor match for strain measurements except that at SG1 is mostly due to the difference in the failure mode. Total debonding occurred at the test, but only at less than 50mm from the middle gap in the FE simulation. Among various possible causes, the most plausible could be: 1) the FRP-to-concrete bond was in a poorer state in the test so that the FE model over estimates the strength, and 2) the impact load is under estimated. These two factors are investigated below.

Discussion of test results

A numerical attempt was done with an impact load 20% higher than the measured from test IT2. The predicted damage pattern is shown in Figure 3. Clearly the debonded length in this case is longer than the original one. The strain outputs are compared in Figure 4.
From Figure 4, the FE predicted peak strain at SG1 increases slightly due to the increase of the impact load. However, the predicted SG2 strain increases significantly and give a good agreement with the test value, because the debonding length for the case with 120% impact load is over 50mm starting from the middle span where SG2 is located at 50mm away from the mid span. For the case when 100% measured impact load is applied, the SG2 output is much lower than the test results as the debonding has not been developed so far. The strain outputs of SG4 and SG5 also indicate that more damage occurs at the bond, the closer the strain outputs agree with the test results. The unmatched SG4 and SG5 FE strain outputs to the test results are still due to the debonding failure does not happen there. Accordingly, it is clear that there are two main possible causes: 1) The inaccuracy of the load measurement. As presented in Figure 4, with an additional 20% impact load, the predicted SG 1 value is only slightly increased whereas the debonded length is increased and SG2 output is significantly increased. There was just one striker available with the load cell fixed to it at the time of test. The measurement range of the load cell in the test was up to 2000 kN (Chen et al. 2012). Due to the low impact heights used in the test; the peak load measured was only around 100 kN for test IT4 and 35 kN for test IT2. 2) The method of surface treatment. The surface treatment might not offer sufficient bond strength in the test. In the test, total debonding occurred with less than 1mm mortar attached to the FRP. However, in the FE total debonding failure does not occur. In the numerical model the debonding depth of the concrete adjacent to FRP was thicker due to the ideal bond assumption.

CONCLUSIONS

This paper has presented a study which shows that the commonly adopted empirical global DIF model cannot be applied directly in the FE analysis with a local concrete material model due to strain and strain rate localisation. A new “doubly corrected” local DIF model has been proposed considering both element size and strain rate effects. A preliminary study on the effect of dynamic loading rate on the behaviour of FRP-to-concrete bonded joint has been presented. By deploying the K&C concrete damage model and the proposed local DIF model, the FE predictions have been shown to be in close agreement with the test results.

ABSTRACT
In this work, CFRP plates were made using vacuum assisted resin transfer molding (VARTM) technique. CFRP/Steel single-lap shear joints were manufactured by bonding steel and CFRP together with epoxy resin. Specimens were tested under dynamic tensile loading (0.625 m/s) on a servo-hydraulic high rate testing system under four temperatures (-25, 0, 50, 100 °C). The experimental results showed that the mechanical properties of joints were sensitive to temperature. In a certain range, both the bond strength and interfacial fracture energy of specimens increased from -25 to 50 °C. When the temperature exceeded the glass transition temperature of the adhesive, bond strength and interfacial fracture energy decreased significantly. The failure modes of specimens were different at varying temperatures. At the low temperature (-25 °C and 0 °C), the failure mode of joints were adhesive/steel interface debonding failure. At the temperature of 50 °C, the failure mode turned to the mixed failure. When the temperature reached 100 °C, the failure mode changed to adhesive/CFRP interface debonding failure. Moreover, the strain field distribution of FRP in overlapping area at different temperatures was analyzed using a digital image correlation (DIC) method. The results showed that the strains of FRP at the edge of overlapping area were larger than those in the center, and final failure was initiated at the edge of the specimen.

INTRODUCTION
FRP materials are especially useful in a wide-range of applications such as strengthening and rehabilitation of structures (Gholami et al. 2013; Zhao and Zhang 2007). Their high strength to weight ratio, attractive energy dissipating, corrosion resistance, and lower manufacturing costs enable them to be very efficient when compared with conventional metals for use in building reinforcement. The most commonly used FRP for the strengthening of steel structures is carbon fibre-reinforced polymer (CFRP), owing to its high strength and high modulus. One of the relevant issues is the bond mechanical performance between CFRP and steel (Schnerch et al. 2006; Korayem et al. 2015), as it significantly influences the mechanical properties of the long service performance. Extensive researches (Wu et al. 2012; Liu et al. 2010) had already been conducted on CFRP/steel double strap joints for the understanding of the mechanics and failure mechanisms. Liu et al. (2010) studied the effect of fatigue loading on bond strength and failure modes, and reported that fatigue loads have little effect on the bond strength and failure modes of high modulus CFRP-sheet bonded steel plates. Wu et al. (2012) performed the bond tests of ultra-high modulus CFRP laminates and steel plates, and described bond strength, effective bond length, failure pattern, CFRP strain distribution and adhesive shear stress distribution along the overlapping areas. Haghani (2010) dealt with analyses of adhesive joints used to bond CFRP laminates to steel substrates using a numerical and experimental approach. Different aspects of joint behaviour, such as strain distributions along bond line and through the thickness of the adhesive layer and failure mechanisms are discussed. The aforementioned researches were conducted at ambient temperature. However, information on CFRP/steel adhesively joints subjected to varying temperatures remains limited (Nguyen et al. 2011), although such high or low temperature is realistic in different regions.

In this paper, a series of CFRP/steel single-lap shear joints were examined in tension in the range of -25 to 100 °C at the same loading rate of 0.625 m/s. The primary objective of the experimental research is to investigate the effect of temperature on the mechanical properties of joints under dynamic tensile loadings. In the next section the
EXPERIMENTAL PROGRAM

High speed tensile test methodology

The high speed tensile tests were conducted using a servo-hydraulic testing machine with a load capacity of 25 kN operating under open-loop mode. The speed of the actuator was controlled by the servo-valve of hydraulic supply. By manually turning the servo-valve, the rate of flow of hydraulic fluid can be controlled, resulting in different stroke speeds. The setup of the dynamic tensile testing is presented in Figure 1. An environmental chamber, temperature controller and liquid nitrogen were employed for testing under varying temperatures. A Phantom v7.3 high speed digital camera with sampling rate of 10,000 fps captured the deformation, cracking, and failure behaviour of the full size of the specimen in between the grips. More details of the testing system can be found elsewhere (Zhu et al. 2010).

Figure 1 Experimental facility (MTS servo-hydraulic high-rate testing machine)

Specimen preparation

The carbon unidirectional fiber fabric made by Nanjing Hitech Composites Co., Ltd (Nanjing, China) was adopted in this study. Hot rolled steel plates (Q235, a nominal yield stress of 235 MPa, China standard, GB/T 700) were chosen to prepare CFRP/steel single-lap shear joints. Modified epoxy resin provided by Hunan Good Bond Construction Technic Development Co., Ltd (Changsha, China) was utilized as matrix to manufacture CFRP laminates by using vacuum-assisted resin transfer molding (VARTM) technology. Details about physical and mechanical properties of these materials are listed in Table 1.

The joints were formed using a wet lay-up method. The steel plates and CFRP laminates were cut to the required dimension of 25 mm × 80 mm × 4 mm (width × length × thickness) and 25 mm × 80 mm × 0.95 mm (width ×
length \times thickness), prior to the fabrication of single-lap CFRP/steel shear joints. The surface of steel plates were sandblasted and cleaned with acetone to remove grease, oil and rust. Steel plates and CFRP sheets were bonded together with an overlapping length of 25 mm by epoxy resin Sikadur 330, which is widely used in the FRP/concrete system. Two end spacers (CFRP and steel) of 25 mm long, 25 mm wide were glued on each side of specimens for loading applied and easy alignment, as shown in Figure 2. Great attention was paid to the thickness of the adhesive layer, which influences the mechanical properties of the bonding (Arenas et al. 2010). The final steel/CFRP single lap shear joints were fabricated as shown in Figure 6.

**RESULTS AND DISCUSSIONS**

**Temperature effect**

The results of the experimental work are presented and discussed in this section. Dynamic tensile tests were undertaken with four temperatures of -25, 0, 50, 100 °C. The bond stress is given by:

![Figure 3 Bond Stress vs. Displacement curves at different temperatures: (a) -25 °C, (b) 0 °C, (c) 50 °C, (d) 100 °C](image)
\[ \tau = \frac{F}{b \times l} \]  

(1)

Where \( \tau \) is the bond stress, in MPa, \( F \) is the tensile load, in N, \( b \) is the joint width and \( l \) is the joint overlap length, in mm. Interfacial fracture energy is evaluated using the area under the bond stress-displacement curve, as defined in Eq. (2).

\[ G_f = \int_{0}^{s_f} \tau ds \]  

(2)

Where \( G_f \) is the interfacial fracture energy, in MPa-mm, \( s \) is the displacement and \( s_f \) is the maximum displacement, in mm. Shear stiffness is defined as the slope of the curve in the elastic region.

Figure 3 illustrates the experimental bond stress-displacement responses of specimens at the same loading rate of 0.625 m/s. The responses of individual specimens are quite different. It is obvious that these curves show different degrees of discreteness, especially at the temperature of 50 °C, the ascending branch and descending branch of each curve show large difference. In fact, dynamic tests always show relatively larger scatter compared to quasi-static tests. The reason for the difference at 50 °C is that when the temperature is close to the glass transition temperature of epoxy resin, the adhesive becomes unstable, therefore the dynamic tensile shear mechanical properties of the specimens are seriously affected. While the temperature reaches 100 °C (already higher than \( T_g \)), the adhesive has turned into a soft elastic plastic body, thus the bond tension between CFRP and steel plates is reduced, causing the decrease of bond strength.

Figure 4 shows the experimental observations of the influence of temperatures on the dynamic mechanical properties of specimens. It indicates the temperature-sensitivity of the CFRP/steel adhesively bonded joints. Overall, both bond strength and interfacial fracture energy of joints increase from -25 to 50 °C and decrease from 50 to 100 °C. The bond strength increases from 4.50 ± 1.23 MPa at a subzero temperature of -25 °C to 6.59 ± 1.77 and 7.54 ± 1.91 MPa at the temperature of 0 °C and 50 °C. Interfacial fracture energy increases in the range of -25 °C to 50 °C. However, when the temperature increases from 50 °C to 100 °C, bond strength decreases about 31% from 7.54 ± 1.91 MPa to 5.22 ± 3.02 MPa, interfacial fracture energy decreases from 5.34 MPa-mm to 4.88 MPa-mm, which can be attribute to the softening of the adhesive when the \( T_g \) is reached. Besides, the trend of shear stiffness as a function of temperature decreases almost linearly. Specifically, shear stiffness decreases as much as 68% from 7.78 MPa/mm to 2.52 MPa/mm with temperature increasing from -25 to 100 °C.

Figure 4 Temperature effect on the mechanical properties of single-lap shear joints: (a) bond strength, (b) interfacial fracture energy, (c) shear stiffness
Failure mode

Figure 5 compares the failure modes of the specimens at different temperatures under high speed tensile loads, which clearly shows a remarkable difference in the overlapping area. It is obvious that the actual failure is different from the expected in-adhesive failure, i.e., the fracture is partially in-adhesive and partially interfacial in nature. Three failure modes are observed in the test specimens, including adhesive/CFRP interface debonding, adhesive/steel interface debonding and mixed failure mode. The mixed failure mode is defined as some adhesive remaining on CFRP and steel. At low temperature (-25 and 0 °C), the failure modes are mainly adhesive/steel interface debonding, as shown in Figure 5a and Figure 5b. However, when the temperature increases to 50 °C, the inside adhesive between CFRP and steel begins to disintegrate, part of adhesives remains on the steel and CFRP, as shown in Figure 5c. When the temperature exceeds the $T_g$ of the adhesive, bond strength decreases rapidly and failure mode changes to adhesive/CFRP interface debonding.

Image analysis (DIC method)

As a full-field approach, image analysis techniques are widely used in different aspects of fields such as civil engineering (Corr et al. 2007), mechanical engineering (Helfrick et al. 2011), material science (Catalanotti et al. 2010) and biomedical engineering (Thompson et al. 2007). The use of DIC to obtain overlapping area (FRP) strains in joints is relatively new. By performing digital image processing on the images of the test specimen before and after applying loads, the entire displacement field can be constructed.

Figure 5 Fracture morphologies under different temperatures: (a) -25, (b) 0, (c) 50, (d) 100 °C

Figure 6 Painted specimen with speckle pattern
Figure 6 shows the random speckle pattern and area of interest (AOI) selected in the current study. A commercial software Vic-2D 2009 developed by Correlated Solutions, Inc. was used to perform image analysis. As shown in Figure 7, a relative uniform distribution of strains is obtained at the beginning of the test. As the load increases, normal strain starts to localize at the edge of the AOI. The localization of normal strain indicates the concentration of stress along the edge of the adhesive while the far fields are still well bonded. Then the localization zone continues to grow and propagate towards the inner areas. The development of non-uniform strain fields implies the fact that the damage of the adhesive joint may initiate at the edges and spread out to the far fields. It is worthy to mention that the pattern of strain fields seems to be independent on the effect of temperature.

Figure 7 CFRP strain-field in the overlap area under different temperatures: (a) -25, (b) 0, (c) 50, (d) 100 °C

CONCLUSIONS

This paper presents the dynamic tensile properties and failure morphology of CFRP/steel single lap joints at four temperatures by using a servo-hydraulic high-rate testing machine with an environmental chamber. The results and discussions presented in the paper allow the following conclusions to be made:

(1) Bond strength increases 68% from -25 °C to 50 °C, and interfacial fracture energy increases from -25 °C to 50 °C. While the temperature increases from 50 to 100 °C, bond strength decreases about 31% from 7.54 ± 1.91 MPa to 5.22 ± 3.02 MPa, interfacial fracture energy decreases from 5.34 MPa•mm to 4.88 MPa•mm.

(2) Three failure modes are observed in the current work. Most specimens show adhesive/steel interface debonding failure mode. When the temperature increases to 50 °C, the failure mode changes to mixed failure mode. At the temperature of 100 °C, the failure mode turns to adhesive/CFRP interface debonding.

(3) DIC method can better analyze the failure process and displacement/strain field of the specimens. The failure initiates from the upper and low edges along the bond area. Higher strains were observed at the edge of the bond line and lower strains at the center.

TRANSVERSE RESISTANCE OF CFRP CABLES UNDER DROP-WEIGHT IMPACT

Y. Xiang, Z. Fang * and Y.W. Fang
College of Civil Engineering, Hunan University, China. Email: fangzhi@hnu.edu.cn

ABSTRACT

Bridge cables may be subjected to lateral impacts caused by vehicle collisions when in service. When Carbon-Fiber-Reinforced Polymer/plastic (CFRP) cables are used to replace traditional steel cables, their impact behavior warrants further investigation. However, to date, few investigations have focused on the impact behavior of CFRP cables. In this paper, drop-weight tests were conducted on three scaled CFRP cables. Each specimen was composed of a seven-wire CFRP strand and two reactive powder concrete (RPC)-grouted bond-type anchors at both ends of the specimen. Results showed that the damage patterns include indentation and complete fracture of the CFRP cable. The anchor with a bond-length of 250 mm provided the CFRP strand with a sufficient anchorage under impact. The transverse impact resistance and energy dissipation capacity were 16 kN and 727 J, respectively, for a CFRP cable under a pretension of 40 kN.

KEYWORDS

CFRP cable, impact, drop-weight test, strand, resistance.

INTRODUCTION

Bridge cables may be subjected to lateral impacts caused by vehicle collisions when in service, therefore, when employ carbon-fiber-reinforced polymer/plastic (CFRP) cables to replace traditional steel cables, the impact behavior of CFRP cables warrants further investigation. To date, extensive research has been conducted on the impact behavior of CFRP laminates, but few if any such investigations have focused on CFRP cables. Experiments were carried out to study the macro damage phenomena and few influential factors that affect the impact behavior of CFRP laminates under impact (Cantwell and Morton 1989; Ghelli and Minak 2011; Mitrevski et al. 2006). Regarding the composite components that are used in the field, they are usually under initial stresses before being subjected to impact. Thus, the effect of preload on the impact resistance, stiffness and energy dissipation capacity of CFRP laminates have been investigated using experiments (Sun and Chen 1985; Whittingham et al. 2004; Heimbs et al. 2009; Saghaifi et al. 2014;) and analytical predictions (Khalili et al. 2007). This paper presents drop-weight tests on three scaled CFRP cables to investigate their impact behavior which includes the damage pattern, transverse impact resistance, and energy dissipation capacity.

EXPERIMENTAL PROGRAM

Specimen Preparation

The specimens were designed to have the same slenderness ratio and initial stress level as a suspender in a prototype bridge with a main span of 856 m. Each scaled specimen was composed of a Φ12.5 mm seven-wire CFRP strand and two bond-type anchors grouted by RPC at each end. The specimen had a full length of 2000 mm and a free length of 1500 mm, as shown in Figure 1(a). The anchor at each end of the specimen had a fixed bond-length of 250 mm with external M50×3 thread for imposing the pretension. The CFRP strand was untwisted inside the anchor tube, to achieve well anchoring performance of the anchor, as shown in Figure 1(b).

Figure 1 The specimen: (a) overall geometry; and (b) details of the untwisted CFRP strand
The CFRP strand used in present study was manufactured by Tokyo Rope Company. It had feature and configuration similar to the traditional steel strand, and was composed of seven twisted CFRP wires, as shown in Figure 2. The nominal diameter and effective cross-sectional area of the CFRP strand were measured to be 12.54 mm and 76 mm², respectively. The average tensile breaking load, tensile strength, and the modulus of elasticity of the CFRP strand were measured to be 193 kN, 2539 MPa and 157 GPa, respectively.

Figure 2 1×7Ø12.5 mm CFRP strand used in present study

Test setup and method

Figure 3 illustrates the drop-weight impact test setup. A special fixture was designed to provide each specimen with enough support. Two test pedestals at both ends of the specimen were connected by four Φ48 mm high-strength screws. Moreover, the whole fixture was bolted to the concrete foundation of the laboratory to reduce vibration during the impact.

Prior to an impact test, a pretension of 40 kN was applied to a specimen. Then a drop hammer with a mass of 187 kg was dropped freely onto the mid-span of the specimen from three different heights: 200 mm, 600 mm and 1000 mm. The drop hammer has a semi-cylindrical impact head with a radius of 20 mm. The impact force was measured through a piezoelectric load washer built into the hammer. The transverse deflection and axial deformation of the specimen were measured by three potentiometers. The data acquisition system recorded the impact force and deflection at a sampling rate of 500 kHz.

Figure 3 Drop-weight impact test setup

RESULTS AND DISCUSSIONS

An overview of the impact conditions and main results are summarized in Table 1. The nomenclature indicates the specimen number and the drop heights. For example, specimen code C3-H1000 means the third specimen of the present study was subjected to a drop weight impact from a 1000 mm height.

Note: \( E_{imp} \) = the incident impact energy, calculated by \( E_{imp} = mgH \); \( H \) = the drop height; \( F_{max} \) = the maximum impact force; \( t_δ \) = the contact duration for impacting; \( d_{max} \) = the transverse deflection at the \( F_{max} \); \( d_u \) = the transverse deflection when the specimen fractured; \( E_{dis} \) = the dissipated energy.
Damage pattern

Two typical damage patterns observed after the drop-weight tests are shown in Figure 4. The first pattern of indentation occurred under a relatively low incident impact energy, corresponding to specimen C1-H200, the hammer hit the CFRP strand and rebounded, and an indentation was observed afterward on the top surface of the CFRP strand, see Figure 4(a). The second pattern of complete fracture occurred under high incident impact energies, corresponding specimens C2-H600 and C3-H1000, the seven wires of the CFRP strand were successively cut off during the impact process, see Figure 4(b). In addition, the anchor with a bond-length of 250 mm provided the untwisted CFRP strand with sufficient anchorage under the impact, because no obvious anchor slip was observed among all specimens, as shown in Figure 5.

Impact force and energy deflection curves

Figure 6 shows the impact force versus deflection curves for specimens under different incident impact energies. It can be observed that the features of the curves are closely related to the damage patterns. For the indentation-type pattern, specimen C1-H200 exhibited almost overlapping ascending and descending phase of the curve. The impact force and deflection simultaneously increased to their maximum values of 12.7 kN and 57.3 mm, respectively, and eventually returned to zero after the rebound of the hammer. Little reduction is evident in the slope of the ascending and descending phases. Moreover, concerning the pattern of fracture, both specimens C2-H600 and C3-H1000 presented open-type curves. The impact forces for specimens C2 and C3 linearly increased to their maximum values of 15.8 kN and 15.9 kN, at deflections of 61.6 mm and 69.3 mm, respectively. Then a subsequent stepwise decrease in the impact force accompanied by a continuous increase in deflection can be observed from each curve of specimen C2 and C3, reflecting the sequential fracturing of seven individual wires. The maximum values of impact forces initially increased with the increasing incident impact energy and then reached a plateau value as the transverse impact resistance of the CFRP cables was approached, as shown in Figure 7. Consequently, the transverse impact resistance of the CFRP cable under a pretension of 40 kN was determined to be approximately 16 kN.
The energy transferred from the hammer to the specimen in an impact event can be calculated by integrating the impact force-deflection curve, as given in Figure 8. The specimen C1-H200 showed that the energy increased with the deflection at the ascending phase and gradually recovered at the descending phase. It can be observed that approximately 327 J energy was transferred to the specimen C1, then most of the energy was transferred back to the hammer for the rebound, and only 45 J energy was permanently dissipated ($E_{dis}$) as the damage pattern of indentation. Concerning fractured specimens C2-H600 and C3-H1000, despite incident impact energies for these two specimens were 1100 J and 1833 J, just 725 J and 728 J energies transferred to specimens C2 and C3 and fully dissipated by the fracture of the specimens, respectively. The excess energies remained in the hammer after the complete fracture of the specimens. From the relationship between the dissipated energy and incident impact energy, as shown in Figure 9, it can be concluded that the average energy dissipation capacity of a CFRP cable under a pretension of 40 kN is approximately 727 J.

### CONCLUSIONS

This study investigated the impact behavior of the CFRP cables under pretention by drop-weight tests. The conclusions can be drawn as follows:

1. Typical damage patterns of the CFRP cables, including indentation and complete fracture, were observed to be closely related to the incident impact energies.
2. No obvious anchor slip was observed among all specimens, which indicated that the anchor with a bond-length of 250 mm provided the untwisted CFRP strand with proficient anchorage under impact.
3. The transverse impact resistance and energy dissipation capacity were 16 kN and 727 J, respectively, for a CFRP cable under a pretension of 40 kN.

THE CHARPY IMPACT BEHAVIOR OF CFRP RODS AND STRANDS

Yawei Fang, Zhi Fang*, Yu Xiang and Yu Zhang
College of Civil Engineering, Hunan University, Changsha, China

ABSTRACT
An increasing application of Carbon-fiber-reinforced-polymer (CFRP) in civil structures has been witnessed in recent years, however, the impact behavior of CFRP rod and CFRP strand failed to meet the expectation whilst was seldom reported. In present paper, the impact behavior of CFRP rod and strand was investigated by conducting Charpy impact tests on four groups of specimens, which composed of CFRP rod, entire CFRP strand, central and outer individual wire of CFRP strand. All specimens were cut into 100 mm long and impacted by a Charpy impact energy of 300 J. Test results showed that the damage modes include debonding between fibres and matrix of CFRP rod and wire decentralization and fracture of CFRP strand. The average absorbed energies for CFRP rod and CFRP strand are 45.3 J and 32.9 J, respectively; the average absorbed energies for central and outer individual wires of a CFRP strand are both 2.5 J.

KEYWORDS
CFRP rod, strand, Charpy impact, absorbed energy.

INTRODUCTION
Carbon-fiber-reinforced-polymer (CFRP) has recently been widely used in many fields, due to its advantages of light weight, high strength and excellent durability, as well as the convenience of forming into components with complex shapes. However, this kind of material is well accepted to be vulnerable to transverse load, especially under impact event (Reid and Zhou. 2002).

To date, much effort has been spent on the impact behavior of CFRP laminates. Sohn and Hu (1996) researched the delamination mechanisms and energy dissipation of CFRP under impact; Hufenbach et al. (2008) investigated the influence of key parameters, including fiber reinforced type, hybrid materials, fiber type and core fiber orientation, on the impact behavior of CFRP with the Charpy impact test; Ghasemnejad et al. (2010) experimentally investigated the Charpy impact response of hybrid delaminated composite beams and simulated the impact process of composite beams with LS-DYNA. The research on impact behavior of CFRP rod and CFRP strand were seldom reported. Therefore, in the present study, Charpy impact tests were conducted to examine the transverse impact behavior of CFRP rod, entire CFRP strand, central and outer individual wires of the CFRP strand. The energy absorption capacities of these specimens were obtained, and damage modes after failure were observed.

MATERIALS AND SPECIMENS
Two types of CFRP tendon adopted in present research, including the CFRP rod and the CFRP strand, are shown in Fig 1. The CFRP rod has a nominal diameter of 9.8 mm and a deformed surface wrapped in helical rib. The post-processed rib was designed with a width of 6 mm, thickness of 0.15 mm and interval of 10 mm. The cross-sectional area of the core part of the rod is measured to be 71 mm². In addition, the average tensile breaking load and the ultimate tensile strength of the CFRP rod are 187 kN and 2655 MPa, respectively.

CFRP strand, with the same appearance of common used steel strand, was made by twining six spiral outer CFRP wires around one straight central CFRP wire with a fixed spiral pitch. All wires were numbered from 1# to 7#, as shown in Fig 1(b). The nominal diameter and effective sectional area for individual wires of the CFRP strand are 4.16 mm and 10.1 mm², respectively. As for the entire CFRP strand, its nominal diameter and effective sectional area are 12.48 mm and 78 mm², respectively. The average breaking load of the CFRP strand is 195 kN and the ultimate tensile strength is about 2539 MPa. Moreover, epoxy resin is filled in the gapping place among wires in CFRP strand to bond wires together and to improve the integrity of CFRP strand.
In accordance with the test standard (ISO179-1, 2001), four groups of specimens with the same length of 100 mm were prepared for the Charpy impact tests. These specimens composed of CFRP rod, entire CFRP strand, central wire of CFRP strand and outer wire of CFRP strand, and were marked as CR, CS, CS-C and CS-O, respectively. The photographs of typical specimens are shown in Fig 2.

**EXPERIMENTAL PROCEDURE**

The impact tests were conducted with a pendulum Charpy impact system, as seen in Fig 3. The Charpy device is a dynamic three-point bending experiment of an un-notched beam. The experimental setup consists of the specimen, the anvils where the specimen is freely supported, a pendulum with a defined mass attached to a rotating arm pinned at the machine body. The pendulum falls along a circular trajectory and hits the middle span length of the test specimen transferring kinetic energy to it when pendulum swings to the lowest position. After hitting specimen, residual kinetic energy leads pendulum to continue moving up and the pendulum pushes a hand rolling on a dial to display the dissipated energy which can also be regard as the energy absorbed by the specimen regardless of friction and air resistance due to their small contribution to the energy balance.

In present study, the swing arm length is 750 mm leading to an impact velocity of 5.2 m/s and a stored energy of 300 J and the span of specimen support is 40 mm. The impact direction must be perpendicular to specimens’ surface. To get reliable results, at least 5 test specimens were tested for each group, and the average values of the experimental results were acquired.
RESULTS AND DISCUSSIONS

Absorbed Energy

The absorbed energies for all specimens were recorded and summarized in Table 1. It can be found that specimens in group CR absorbed the highest energy of 45.3 J among four groups of specimens due to their excellent structural integrity; and the specimens in group CS presented a lower energy absorption capacity of 32.9 J as a result of their poor integrity and stiffness in spite of their larger effective sectional area compared with group CR. Such result reveals that the energy absorption capacity of a CFRP tendon is quite sensitive to the integrity. The average absorbed energy of group CS-C and group CS-O were both 2.5 J, thus indicating that energy absorption capacity of CFRP wires were not significantly influenced by the spiral shape. Comparing the absorbed energy of group CS, group CS-C and group CS-O, it can be found that the absorbed energy of an entire CFRP strand was much larger than the sum of that of all seven wires, which is due to the composite effect of wires along the impact direction.

Damage Patterns

Typical damage patterns, including debonding between fibres and matrix of CFRP rod, wire decentralization and fracture of CFRP strand and complete fiber fracture of individual CFRP wire, can be observed, as shown in Fig 4. It can be seen that debonding/delamination between fibres and matrix, together with partial fibres fracture, was the main damage mode of specimens in group CR. During the failure process, damage firstly occurred in the middle of specimen where was directly impacted by the pendulum, and then extended from the middle to the end region. When specimens suffered the impact load, their internal energy accumulated and afterwards matrix micro-crack initiated and expanded, which performed as debonding and delamination in the macroscopic, as illustrated in Fig 4(a). In addition, serious fibre crush appeared on the impact area due to the compression stress generated by the strong impact force on small contact area; on the rear face, the fibers fractured as a result of the large transverse deformation under impact; partial inner fibers survived owning to energy dissipation by the form of delamination and fiber fracture.

The failure mode of specimen in group CS is shown in Fig 4(b). It can be observed that the wires in specimens decentralized which was possibly due to the adhesion force weakened with the destruction of epoxy resin under impact. Moreover, the damage pattern of each wire in specimens was determined by its location in the cross section of the CFRP strand. The 3# wire was the first to be applied impact load. For the wire 1# to 3#, the support to 2#, the direct impact on 3# and the location on the centre line of impact direction, made them cannot move on that direction when they were subjected to stronger impact, so that complete fibre fracture occurred. Whilst, the epoxy resin among wires were destroyed since the deformation of wires 1# to 3#, and consequently the adhesion force and the constraints weakened, which may induce wires’(4# to 7#) movement when bear follow-up load. Therefore, partial fibre fracture was observed in 4# and 5# wire, and 6# and 7# wire survived because of the avoidance of direct contact with pendulum. Furthermore, the fracture surfaces of the wires were observed to be not parallel to
the impact direction, which was resulted from that the wires suffered from multi-directional forces transferred from surrounding wires.

Damage patterns of groups CS-C and CS-O are shown in Fig 4(c) and (d), respectively. It can be found that group CS-C and group CS-O had a similar impact damage pattern, namely complete fibre fracture. Specimens were broken into two parts and just connected by winding yarn on surface. In addition, under no multi-directional force transferred from ambient wires, the fracture surfaces of CS-C and CS-O were all parallel to the impact direction, which was different with that of wires in group CS.

Figure 4 Damage patterns of specimens

CONCLUSIONS

In the present study, the transverse impact behavior of CFRP rod and CFRP strand were investigated by Charpy impact tests. The main conclusions are given below.

(1) The energy absorption capacity for CFRP rod was 45.3 J and its main damage pattern was debonding/delamination and partial fracture of the fibers.

(2) The average absorbed energy for CFRP strand is 32.9 J; the damage pattern for an entire CFRP strand was wire decentralization and partial fracture. For each wire in a CFRP strand, the damage pattern was determined by its location in the cross section of the CFRP strand.

(3) A central wire and an outer wire of a CFRP strand have the similar damage pattern and the same absorbed energy of 2.5 J. The results indicate that energy absorption capacity of wires is not significantly influenced by the spiral shape.

ABSTRACT

Six reinforced concrete (RC) beams without stirrups were tested under static and impact loading. Two out of the six beams were not strengthened as control specimens while the rest were wrapped with carbon fiber reinforced polymer (CFRP) strips for shear enhancement. This paper discusses the impact behaviour of the CFRP strengthened RC beams, including failure modes, CFRP contribution to shear strength, and dynamic responses, such as impact force, inertia force, reaction force, and midspan deflection. A nonlinear explicit finite element (FE) analysis was conducted using software program LS-DYNA. The numerical results agree well with the experimental results in terms of midspan deflection, impact force, and reaction force. The study demonstrates that the CFRP strengthening can apparently improve the impact resistance of concrete beams without stirrup. As the CFRP reinforcement ratio increased, the failure mode under impact loading was changed from brittle shear failure mode to flexural-shear mode, even to flexural ductile mode.

KEYWORDS

CFRP, RC beams, impact loading, dynamic response, finite element analysis.

INTRODUCTION

FRP composites have been extensively applied in past three decades for externally strengthening old and deficient RC structures due to the significant performance improvement contributed from FRP. A considerable amount of research has demonstrated the excellent load capacity and ductility of FRP strengthened RC structural members under various static loads. Recently, the existing RC structure members may be vulnerable to extreme loads, such as blast and impact. The prominent properties of FRP would make the application for improving the dynamic behavior against extreme loads promising. Some studies (Erki and Meier 1999; Hamed and Rabinovitch 2005; Tang and Saadatmanesh 2003, 2005; White et al. 2001) investigated the impact behavior of FRP strengthened RC beams and mostly focused on the flexural-strength improvement. Saatci and Vecchio (2009) demonstrated that the shear mechanism affected the overall behavior of RC beams under impact loading and should be considered to accurately evaluate the dynamic performance. However, few efforts were spent on such area. Shafei and Kabir (2015); Pham and Hao (2016) experimentally assessed the shear-strength improvement from FRP under impact loading. The useful data was still far deficient in making reasonable impact-resistant design guideline.

In this study, an experimental program was conducted to study the impact behavior of CFRP strengthened RC beams without stirrups and a three-dimensional finite element analysis was performed to establish reasonable numerical method for providing much more useful data. Six specimens were designed and tested under static and impact loading. The impact test was conducted using a well-instrumented drop-weight impact machine under simply supported condition. Two of the six specimens were not strengthened as control specimens for both loading conditions, while the rest were wrapped with CFRP strips for shear enhancement.

EXPERIMENTAL PROGRAM

All the testing beam specimens had a 200 × 400 mm rectangular cross section with 362 mm effective depth and a 2400 mm clear span associated with a shear span ratio of 3.32. The longitudinal reinforcements consisted of four 16 mm diameter deformed steel bars at the bottom and two 14 mm steel bars at the top. The average concrete
Cube compressive and cylinder compressive strengths were 46.5 MPa and 36.5 MPa, respectively. The average yield and ultimate tensile strengths of steel bars were 490 MPa and 630 MPa, respectively.

The test setup under the three-point static bend loading is shown in Figure 1. During the static test, a force-control loading mode was used at a rate of 5 kN per 3 minutes. Two specimens, BS1 without CFRP strengthening and BS2 with a CFRP reinforcement ratio of 0.04%, were designed to fail in a shear mode under three-point static bend loading, as listed in Table 1. The theoretical load capacity $P_u$ associated with flexural failure and $P_n$ associated with shear failure are calculated based on the ACI 318-14 (2014) and ACI 440.2R2 (2008) as tabulated in Table 1. The value of $P_n / P_u$ less than one indicates shear failure.

![Figure 2 Impact test details: (a) test setup and FRP strengthening scheme; (b) overview; and (c) instruments](image)

The schematic diagram of drop-weight impact test setup and CFRP complete wrapping scheme is presented in Figure 2 which also displays some types of instruments for acquiring dynamic response, such as impact force, reaction force, deflection, acceleration, and CFRP strain. Impact parameters including drop weight $M$ and drop...
height $H$, and some parameters of CFRP strips, such as width ($w_f$), thickness ($t_f$), center to center spacing ($s_f$), and reinforcement ratio ($\rho_f$), are listed in Table 1. One non-strengthened specimen BD1 and three CFRP-strengthened specimens BD2~BD4 were subjected to identical impact loading condition, except for BD3 with a higher impact height of 3.0 m. The ultimate tensile strength and elastic modulus of unidirectional CFRP sheets were 3561 MPa and 240 GPa, respectively. The four specimens were designed to fail in a shear mode under three-point static bend loading.

**EXPERIMENTAL RESULTS AND DISCUSSIONS**

**Static Test**

To investigate the contribution of CFRP under impact loading, the static test as control condition was necessarily conducted. As shown in Figure 3, the two specimens actually suffered from similar shear failure with a critical diagonal crack. At the initial stage of loading, several fine flexural cracks appeared in the midspan region. As the load continued to increase, the amount of flexural cracks increased and some propagated upward. When the load reached about 80% of the peak, some flexural cracks were inclined to the loading position and meanwhile some diagonal cracks developed adjacent to supports. Up to the peak load, a critical diagonal crack suddenly appeared without any warning, signifying the shear failure. For specimen BS2, the CFRP strips intersecting with the critical shear crack mostly fractured with the side segment torn away.

As illustrated in Figure 4, the load versus midspan deflection curves for specimens BS1 and BS2 show similar initial slopes and the decrement of slopes induced by cracking. Compared to non-strengthened BS1, the curve of BS2 displayed somewhat larger post-cracking slope and could rise up to a higher peak. The experimental peak loads, $P_t$, of BS1 and BS2 are tabulated in Table 1. It is calculated that the CFRP reinforcement ratio of 0.04% could contribute to an increase of the load capacity by about 81.1 kN corresponding to an increase ratio of 45.9%. The theoretical contribution from such amount of CFRP strips based on the ACI 440.2R (2008) is about 63.4 kN equal to 0.78 times of the experimental value, indicating the conservative design in such code.

**Impact Test**

The final crack patterns developed on one side-surface are marked and displayed in Figure 5. It can be clearly seen that non-strengthened specimen BD1 was subjected to severe shear damage and split into four parts under the 383 kg-weight impact with a falling height of 1.5 m. However, specimen BD2 with a CFRP reinforcement ratio of 0.04% merely developed some shear-plug cracks and support diagonal cracks without appearance of shear failure. As the ratio increased to 0.08% for BD4, even few wide flexural cracks developed in the midspan region and some fine diagonal cracks distributed along both sides. Under a high falling height of 3.0 m, specimen B3 suffered from brittle but less severe shear failure with an almost 45-degree major diagonal crack and several CFRP strip fracture. It was demonstrated that the CFRP strengthening could change the failure modes under impact loading from a shear failure mode to a flexural-shear mode and even to a flexural mode, and meanwhile improve the impact resistance against the blow with higher impact velocity.

The initial 30 ms-time histories of impact force, inertia force, and reaction force were illustrated together in Figure 6(a) for four specimens under impact loading, where the positive ordinate axis represents the downward direction of impact force but the upward direction of inertia and reaction forces. The origin of time axis is considered as the moment when the drop weight contacted the midspan surface of specimens. The inertia force was calculated from the following Eq. 1:

![Figure 3 Failure modes: (a) BS1 and (b) BS2](image1)

![Figure 4 Load-midspan deflection curves of specimens BS1 and BS2](image2)
Figure 5 Failure modes: (a) BD1; (b) BD2; (c) BD3; and (d) BD4

\[ F = \int_0^L m \dddot{u}(x, t) \, dx \]

where \( L \) is the entire span length of a specimen; \( m \) is the mass of reinforced concrete per unit length, equal to 1.80 kN/m; \( \dddot{u}(x, t) \) is the distributed acceleration, which was simplified to individual \( A_i(t) \) recorded by corresponding accelerometers shown in Fig. 3(c), assuming the same responses on symmetric locations and neglecting the effect of overhang parts at each end.

At the initial stage, the time histories of impact and inertia forces of four specimens started with similar high-frequency triangular shapes with high amplitude and short duration irrespective of different CFRP reinforcement ratio. The inertia forces show similar peaks and time lags to impact forces. Small negative reaction forces were excited together with time lags to impact forces, mainly because the pretightening compressive force generated by tightening the bolts threading cross beams was released due to the uplift tendency of both beam ends after the applied impact loading. Hence, it was acknowledged that the impact force was primarily resisted by the inertia force at the initial stage. Specimen B3 was tested with a higher impact height associated with larger impact energy twice than that of B2 leading to greater peaks of impact and inertia forces, stating that the CFRP reinforcement ratio of 0.04% could apparently enhance the impact resistance, even almost twice. As the ratio increased to 0.08%, the same impact condition produced the similar response to lower ratio with large residual impact resistance. After the initial stage, the impact force decrease to nearly zero but the inertia force rapidly increased to the opposite maximum values while the reaction force ascended to the positive peak. The similar absolute values of inertia and reaction forces demonstrated that the inertia force was mainly balanced by the reaction force at this stage. Thereafter, the low-frequency vibrations with lower amplitude and longer duration were excited again for impact forces except that specimen B1 showed another triangular shape without several oscillation possibly due to the severe failure. The impact force was approximately identical to the resultant of reaction force plus inertia force at such stage. If considering the actual direction of forces, the reaction force was basically balanced by the combination of the impact and inertia forces. At the final of impact, all forces approached to diminish but the deflection still continued to increase.

The 100 ms-time histories of midspan deflection of four specimens are shown in Figure 6(b), where the origin at time axis represents the contact moment and the positive at ordinate axis represents the downward deflection. Compared with the previous time histories of forces, the midspan deflections were not sufficiently activated at the high-frequency stage and subsequently increased rapidly to the peaks at the low-frequency damping-vibration stage. It was obvious that the control specimen B1 without CFRP strengthening yielded the greatest deformation while CFRP strengthened specimens B2 and B4 produced much smaller deflections. Specimen B3 was subjected to high impact height corresponding to high impact energy, resulting in almost half deflection of B1, though larger than that of B2 and B4. Hence, the CFRP strengthening could significantly limit the deformation of RC beams without stirrups.

**FINITE ELEMENT ANALYSIS**

The numerical analysis was performed using commercial nonlinear explicit software program LS-DYNA (2015) to establish an analytical method that can reasonably simulate the behavior of RC beams fully wrapped with CFRP strips under static and impact loading and to provide more useful data for impact-resist design.
Figure 6 Time histories: (a) impact force, inertia force, and reaction force; and (b) midspan deflection

Finite Element Model

Due to bidirectional symmetries, only a quarter three-dimensional finite element (FE) model was established and an example for impact test was shown in Figure 7. The drop weight was simplified to a cylinder with a specific mass density equal to the testing drop weight divided by its volume. The actual support systems were simulated by two support bars with only compressive stiffness. One end of two bars were connected to steel plates while the other end shown in Figure 8 was limited with all translational motions and permitted with all rotations. The FE model for static test was similar only excluding the drop weight and upper support and the load was applied at the middle nodes on top surface. A 3D eight-node solid hexahedron element, Solid 164 used to model the concrete, drop-weight cylinder, and the steel plates. Steel reinforcing bars and support bars were modeled using a two-node beam element, Beam 161. CFRP strips were modeled by a 2D four-node shell element, Shell 163. Perfect bond were assumed between concrete and steel bars or CFRP strips by sharing the common nodes. The continuous surface cap material model, MAT 159, was used to characterize the rate-sensitive nonlinear behavior of concrete. The steel rebars were modeled using a strain rate-sensitive uniaxial elasto-plastic material model, MAT 024. The plastic hardening modulus was assumed as 1% of elastic modulus. An orthotropic composite damage material model, MAT 022, was used for unidirectional CFRP strips with tensile rupture failure criteria. The discrete beam elements for support bars utilized the elastic spring-mass material model, MAT 196 input only compressive force-displacement curves. The drop cylinder and steel plates implemented the elastic material model, MAT 01, using the Young’s modulus and Poisson’s ratio of real steel material.

Figure 7 A quarter FE model of RC beam

Numerical Results

The numerical load-midspan deflection curves of specimens BS1 and BS2 are plotted with dash lines in Figure 4. It was seen that the FE model could accurately capture the initial stiffness and post-cracking stiffness, though the peak loads and corresponding maximum deflections showed some deviations.

The FE model was verified under impact loading in terms of time histories of impact force, reaction force, and midspan deflection. The numerical results are plotted with dash lines in Figures 6(b) and 8. It was seen that the FE model could well predict the tendency and duration of all curves and accurately capture the maximum
deflections with differences less than 10%, but large differences for impact force about 40% or more, and for reaction force about 30% or less. Despite the drawbacks, the FE model was mostly reasonable to be used for predicting the impact behavior of CFRP strengthened beams and for offering a feasible and effective approach to obtain considerably useful data for the design of FRP against impact load.

CONCLUSIONS

Based on the experimental and numerical results of reinforced concrete beams with or without retrofit, it is found that the CFRP strengthening can apparently improve the impact resistance if concrete beams without stirrups, and change the failure modes under impact loading from brittle shear failure mode to flexural-shear mode, even to flexural ductile mode. During the impact process, all the forces can satisfy the dynamic force equilibrium. The finite element method was reasonably well verified by the experimental results and shown to be able to obtain substantially useful data for the impact-resist design of CFRP strengthened RC beams.

ABSTRACT

To investigate the impact behavior of reinforced concrete beams strengthened with externally bonded carbon fibre reinforced polymer (CFRP) strips, five beams including two control specimens were tested against static and impact loads. The failure modes and time-histories of impact force, reaction force, inertia force and mid-span displacement were analyzed and discussed, the shear mechanism of CFRP strengthened RC beams without stirrups under impact loading was obtained. The experimental results show that the CFRP strengthening significantly improved the impact resistance and stiffness of FRP strengthened RC beams, and can change the dynamic failure mode from shear failure to flexural failure. A discussion on inertia force verified the previous research that all the forces can satisfy the dynamic force equilibrium during the impact process.

KEYWORDS

CFRP, RC beams without stirrups, impact behavior, shear mechanism

INTRODUCTION

The adoption of fiber reinforced polymer (FRP) for the strengthening of RC structure has become a popular technique world-wide. The enhancement of load capacity and ductility under static loads has been demonstrated by extensive researchers. The terrorist attacks and accidents indicate that RC structures are possibly subjected to dynamic loading, such as blast, impact, during their service life. Some research have been conducted to experimentally study the ductility and blast resistance of FRP-reinforced concrete structures under blast loading (Banthia et al 1989; Cotsovos et al 2008; Xu and Zeng 2015). However, most of the existing research focus on the bending behavior and are only qualitative in character, and the failure mechanism of FRP-strengthened structures under impact loading has not been well understood (Erik and Meier 1999; White et al 2001; Tang and Saadatmanesh 2003; Wu et al 2009). Kishi (2002) carried out falling-weight impact tests on 27 shear-failure-type RC beams without shear rebar, and proposed a simple equation to evaluate the required static shear capacity for RC beams against impact load. Saatci and Vecchio (2009) demonstrated that the shear characteristics, mass and geometric properties of structure are important factors in resisting the impact loads. Huo (2016) observed that the impact loading has remarkable influence on the strain distribution in CFRP sheets, which may further affect the performance of FRP-strengthened structure under impact loading. Zhao (2015) observed two different failure modes of RC beams without stirrups strengthened with FRP U-wraps. The beams failed in shear failure mode when subjected to higher impact velocity and in flexural failure mode when subjected to lower impact velocity. Pham and Hao (2016) discussed the FRP contribution to shear strength under impact and verified against the ACI440.2R-08. There is still limited data to establish a reasonable evaluation method for impact resistance.

The impact behavior of CFRP strengthened RC beams without stirrups was investigated in this paper. Five RC beams without stirrups were designed and tested to failure, including two static tests and three impact tests. Three of the five beams were strengthened with externally bonded FRP sheet, which were of the same width and spacing, and the other two beams were control RC beams. The beams were subjected to only one impact except for U60-D-1, which was tested under three impacts. The different impact times was intended to observe the effect of previous damage on the shear behavior of the beams.
EXPERIMENTAL PROGRAM

All beams had the identical geometric dimensions and reinforcement layout. The beams were 150 mm in width, 300 mm in height, and 2700 mm in length. Three 16mm diameter longitudinal reinforcement bars were placed in the soffit and spanning the entire length of the beam. A 25 mm clear cover was provided between the top and the bottom beam surfaces and the bars. No transverse reinforcement for shear was provided.

All CFRP-strengthened beams were strengthened by the identical three-side FRP U-wraps, which were 60mm in width and at the spacing of 60 mm, as shown in Figure 1. For both static and impact tests, CFRP strain, concrete strain, steel strain were measured by strain gauges mounted onto specimens and the deflections of the beams were measured at the mid-span by a Dial gauge or LVDT. Five accelerometers were mounted onto the specimens to measure the accelerations during the impact-induced vibrations. The specimens were tested under simply supported conditions with a shear span of 1860 mm, leaving a 420 mm overhang at each end as shown in Figure 1. Table 1 shows the summary of the specimens and the main results of the static and impact tests.

A single layer of CFRP sheet with the thickness of 0.167 mm was used and the ultimate strength, Young’s modulus and ultimate strain of concrete at 28 days were 38 MPa. The average yield strength and ultimate strength of the reinforcement bars were 515 MPa and 636 MPa, respectively.

For both static and impact tests, the beams were tested in a three-point loading scheme. The static tests were conducted with a hydraulic jack which was used to apply a monotonic load at the rate of 5 kN per 3 minutes, as shown in Figure 2(a). Impact tests was carried out using the drop hammer which was dropped at a certain height onto the midspan of the beams, as shown in Figure 2(b). Two load cells were fixed to the support on each end of the beam in order to measure the reaction force during the impact. A steel cross beam was fixed at the top surface of the beams above the supports to prevent uplift of the beam without creating restraint moments at the supports.
during the vibrations induced by impact loads. An oscilloscopic fast data acquisition system captured the electric signals of the impact force and strain gauges at a rate of 5 millions sample/s per channel.

**EXPERIMENTAL ERESULTS AND DISCUSSIONS**

**Failure mode**

Figure 3 shows the comparison of failure modes of static test specimens and impact test specimens. As can be seen in Figure 3, two static test beams had similar crack patterns and both failed with a main diagonal shear crack formed from the loading point to the support. At the initiation of loading, it was observed that a first vertical crack appeared at the midspan of beam, then the width of the cracks increased and some new flexural cracks and diagonal cracks appeared with the increase of the applied load. Upon reaching the peak load, one of the diagonal crack propagated quickly and run through the whole beam. The strengthened beam U60-S had less number of cracks than the control beam and failed suddenly with the debonding of CFRP sheet.

For the impact tests, it can be seen that the beams failed in shear mode except U60-D-1, which failed in flexural mode and suffered more flexural cracks and less diagonal cracks. Control beam R-D failed in shear behavior and developed severe diagonal cracks, originating at the impact point and propagating downward with an angle of approximately 45 degrees, and then forming shear-plugs. Strengthened beams U60-D-1 and U60-D-2 had identical strengthening scheme but different failure modes when they were subjected to impacts form different drop height. It can be seen that U60-D-1 had more flexural cracks and less diagonal cracks compared to the U60-D-2, and the latter failed in flexural mode while the former failed in shear mode, resulting in different vibration characteristics. Besides, the diagonal cracks of U60-D-2 initiated from the supports upward to the beam top away from the impact point. The phenomenon can be attributed to the sufficient FRP strips, which were strong enough to prevent the diagonal cracks from running through the half span to the mid-span section.
Midspan deflection

The load versus mid-span deflection curves for the static test are shown in Figure 4. It is evident that beams strengthened with FRP strips were loaded to failure with increased stiffness and strength, and larger deflection. With the cracking of concrete, it was evident that stiffness of the strengthened beams was largely increased with the increase of the deflection. As compared to the reference beam, the stiffness of Beam U60-S increased by 98% and the shear capacities increased by 112%.

Figure 5 shows the time histories of the mid-span displacement. As can be seen, Beams R-D and U60-D-2 deflected from the original positions to the maximum displacement positions and back to the residual deflection positions. However, Beam U60-D-1, which behaved in a different way, deflected downward from the original positions to the maximum positive displacement positions and deflected upward to the negative maximum displacement with smaller residual deflection. This phenomenon may be due to the effectiveness of FRP-strengthening arrangement and the different impact energy, resulting in different failure mode: shear mode and flexural mode.

Impact load & reaction force

The time histories of the impact and reaction forces during the 30 milliseconds (ms) are shown in Figure 6 and details of the measured impact forces and reaction forces are presented in Table 1. It can be observed that the peak of impact and reaction responses depended on the beam stiffness and crack patterns. It can be found that the impact and reaction forces of the FRP-strengthened beams were larger than those of the RC beam when subjected to identical impact energy (U60-D-1a v.s. R-D). Besides, the increased drop height led to the increased impact force, reaction force and a change of failure mode from flexural failure to shear failure (U60-D-1 v.s. U60-D-2). It is also noted that the first impact deteriorated the stiffness of beams (U60-D-1a), and the impact force and reaction force decreased obviously when subjected to the second or third impacts.
Impact force vs. displacement relations

Figure 7 depicts the hysteretic loops of impact force versus mid-span displacement relations of beams R-D and U60-D-2. These loops are approximately triangular. The value of the absorbed energy are estimated by integrating the loop-area and it can be found that the absorbed energy increases with the increases of impact velocity. The energy ratio $E_a/E$ for Beams R-D, U60-D-2 are 0.75, 0.6, respectively, where $E_a$ is the absorbed energy and $E$ is impact energy. The energy ratio for both beams in the paper are similar to that described in Kishi et al. 2002.

![Figure 7](image)

Equilibrium of the beams

When a beam is impacted and accelerated, the acceleration of the beam caused inertial forces, which participated in the equilibrium of specimens, as demonstrated by (Banthia et al. 1989; Saatci and Vecchio 2009; Pham and Hao 2016). The time histories of inertial forces, impact force and reaction force of U60-D-1a, as shown in Figure 8, can be used to verify the equilibrium of the beams. In order to simplify the calculation of inertial forces, the assumption of linear distribution of acceleration was introduced and the inertial forces can be expressed as follows

$$I = \int_0^L \bar{m} \ddot{u}(x,t) \, dx = \bar{m} \left[ 0.23 \left( \frac{A_1(t) + A_2(t)}{2} \right) + 0.23 \left( \frac{A_2(t) + A_3(t)}{2} \right) + 0.23 \left( \frac{A_3(t) + A_4(t)}{2} \right) + \frac{0.24}{2} A_4(t) + 0.42A(5) \right] \times 2$$

Where $A_i(t)$ is the acceleration measured by the accelerometers, $i=1-5$, $m$ is the mass per unit length, giving $m=0.1125t/m$.

It can be found that the inertial force exactly balanced the impact force before the activation of the reaction force. However, thereafter the inertial force generally was larger than the summation of the impact force and reaction force. The unbalanced forces can be attributed to the complicated vibration characteristics of the impact-damaged beams, the effect of the environmental noise and concrete cracking, and the assumption of linear distribution of acceleration.

![Figure 8](image)

CONCLUSIONS

This paper investigates the shear behavior of RC beams with and without retrofit under static loading and impact loading. The tested results showed that CFRP strengthening can change the dynamic failure mode from shear failure to flexural failure. The impact resistance and stiffness of CFRP strengthened beams was improved and the strengthened beams developed less diagonal cracks but suffered more severe vibration when subjected to relatively low impact energy. It is also verified that impact force, reaction forces and inertial forces satisfy the dynamic force equilibrium when subjected to impacts.

ABSTRACT

This paper demonstrates a numerical study on ultra-high performance concrete (UHPC) slab retrofitted with fibre reinforced polymer (FRP) plate subjected to steel ogive-nosed projectile penetration with striking velocity of 710 m/s. A calibrated and improved Karagozian & Case (K&C) concrete model, namely, MAT_Concrete_Damage_Rel3 (Mat_72R3), is used for UHPC, and an orthotropic linear elastic shell element with shear deformation model, namely, *MAT_ORTOTROPIC_ELASTIC, is applied to FRP plate. The depth of penetration (DOP) and crater diameter of UHPC slab retrofitted with FRP plate, as well as plain UHPC slab, are investigated.

Numerical study, UHPC, projectile, FRP, DOP, Crater diameter

INTRODUCTION

In recent years, terrorist attacks are becoming more and more frequent throughout the world. Not only does the terrorism lead to structural damage, but it seriously threatens resident’s regular life. Therefore, investigations on the resistance of construction materials against impact loading caused by projectiles have attracted much attention by researchers and engineers. Ultra-high performance concrete (UHPC) is a promising construction material with excellent material qualities, such as ultra-high strength, good ductility, excellent durability, outstanding abrasion resistance, self-consolidating workability and low shrinkage (e.g. Rossi et al. 2007; Prem et al. 2012 ). Experimental investigations on UHPC against high-velocities projectile impact have been conducted throughout the world (e.g. Sovják et al. 2013; Máca et al. 2014; Wu et al. 2015), indicating UHPC has a better impact resistance against impact loading than conventional concrete, but very limited numerical research has been carried out to investigate impact response of UHPC. Attempts have been made to build and optimize the material model for accurately numerical simulations of fibre reinforced polymer (FRP) composite (e.g. Deka et al. 2008; Nam et al. 2009; Chandekar et al. 2010). This paper presents a numerical study on impact response of UHPC slab and UHPC slabs retrofitted with glass FRP and carbon FRP plates subjected to high velocity projectile penetration.

FINITE ELEMENT MODEL VALIDATION

Material sample tests, such as uniaxial compression test, split tensile test and flexural strength test, were carried out so as to obtain the mechanical properties of UHPC slab retrofitted with FRP plate (UHPC-FRP), and to evaluate the parameters input in the finite element model for numerical simulation. In this study, uniaxial compression and four-point bending tests were conducted to validate the accuracy of the material model for UHPC used in the numerical simulation (Máca et al. 2014). In the numerical simulations of uniaxial compression and four-point bending tests, shown in Figure 1, LS-DYNA Implicit Solver was used for the quasi-static analysis. The numerical results in terms of compressive strength, modulus of elasticity, flexural strength and mid-span deflection have been obtained within 15% deviation compared with experimental results, shown in Table 1.
NUMERICAL SIMULATION OF UHPC-FRP TARGET AGAINST PROJECTILE PENETRATION

Three-dimensional numerical models of both UHPC-FRP and steel ogive-nosed projectile were built and meshed by using finite element software ANSYS. The process of projectile penetration into UHPC-FRP target was simulated and analysed by using explicit finite element package LS-DYNA. The FRP plate was employed in four-point shell elements, and the UHPC slab and steel projectile were developed as different parts using eight-node solid elements with one-point integration and hourglass control. *CONTACT_ERODING_SURFACE_TO_SURFACE was defined for the contact between the projectile and the FRP plate, as well as between the projectile and the UHPC slab. *CONTACT_AUTOMATIC_SURFACE_TO_SURFACE was defined for the contact between the FRP plate and the UHPC slab. In the numerical simulation of UHPC-FRP target against projectile penetration, LS-DYNA Explicit Solver and Lagrangian solution technique were used for the dynamic analysis.

Material models

Figure 2 (a) shows the geometry of UHPC slab with dimensions of 400 mm × 400 mm and thickness of 50 mm. *MAT_CONCRETE_DAMAGE_REL3 was used to build UHPC slab with 156 MPa compressive strength. As the K&C concrete model is only available for conventional concrete, including NSC, HSC and HPC, a K&C concrete model with manually calibrated parameters, which has been validated in the simulated static compressive test and four-point bending test, was employed in UHPC. The key inputs for UHPC employed in the simulation of projectile penetration are listed in Table 2. \( \lambda \) and \( \eta \) govern the damage function and scale factor, respectively. The relationship between \( \lambda \) and \( \eta \) is demonstrated in Figure 3, where the red solid line represents the fit for the conventional concrete, and the blue dash line represents the fit for UHPC.

Previous research shows the mechanical properties of concrete are very sensitive to strain rate, and the mechanical properties of concrete under high loading rate conditions significantly differ from those under quasi-static conditions (e.g. Rong et al. 2010; Rong and Sun 2012). Typically, the strain rate effects on both tensile and compressive strength of concrete are defined as a dynamic increase factor (DIF), which is the ratio of dynamic to quasi-static strength versus a range of strain rates. DIF for UHPC used in the present study was taken into account by conducting Split Hopkinson Pressure Bar (SHPB) tests (Su et al. 2016), and DIF values both in compression and tension are shown in Figure 4.

An automatic generated equation of state *EOS_TABULATED_COMPACTION with calibrated bulking unloading modulus was applied to reflect the volumetric stress and strain with respect to impact response caused by high velocity projectile penetration. An erosion algorithm *MAT_ADD_EROSION was also employed in the material model to simulate the localized damage of UHPC targets. Two erosion criteria with tensile stress and shear strain corresponding to material fracture and failure are defined and applied independently in the present study. Once any one of the criteria reaches the critical value, the failed nodes and elements will be immediately deleted from calculations. In this simulation, the maximum values for the shear strain and tensile stress are set as 0.4 and as double uniaxial tensile strength of the UHPC slab, respectively, according to existing studies proposed by Teng et al. (2008), Wang et al. (2010) and Liu et al. (2016).

According to previous research by Nam et al. (2009) and Pan et al. (2011), the orthotropic linear elastic shell element with shear deformation model, namely, *MAT ORTOTROPIC ELASTIC, was used to build FRP plate with thickness of 2 mm. For the dynamic behaviour of FRP, the bond effect is an insignificant parameter in the overall structure as a results of extremely frequency incident and wave governing response of the structure (Nam et al. 2009). Therefore, bond effect between FRP plate and UHPC slab can be ignored and assumed as a perfect bonding condition (Choi and Krauthammer, 2003). The material parameters of glass FRP (GFRP) and carbon FRP (CFRP) were obtained from Pan et al. (2011) and Siromani et al. (2014), shown in Table 3.

The geometry of steel ogive-nosed projectile, where the caliber-radius-head (CRH) ratio value is 3.0, is shown in Figure 2(b). The material model *MAT_JOHNSON_COOK coupled with equation of statement *EOS_GRUNEISEN was used to build the three-dimensional steel ogive-nosed projectile. The material properties of projectile were estimated by experimental data, and inputs of the material model are shown in Table 4. During the numerical simulation, the ogive-nosed projectile was launched with striking velocity of 710 m/s, to penetrate the centroid of the UHPC-FRP target.

### Simulation data

In the present simulation, 3 shots of projectiles on the plain UHPC slab (UHPC-P) and the UHPC slabs retrofitted with glass and carbon FRP plates (UHPC-GFRP and UHPC-CFRP) with thickness of 2 mm were carried out to investigate the depth of penetration (DOP) and impact crater subjected to projectile penetration with the striking velocity of 710 m/s. Sovják et al. (2013) investigated the impact response of UHPC with 2% fibre addition subjected to the projectile penetration with the striking velocity of 710 m/s, labelled as UHPC-2-1. Máca et al. (2014) conducted the similar test on UHPC with 2% fibre addition subjected to the projectile penetration with the striking velocities of 692 m/s and 706 m/s, labelled as UHPC-2-2 and UHPC-2-3, respectively. All the data have been recorded in Table 5.

### Results and discussion

Figure 5 demonstrates the velocity histories of UHPC-P, UHPC-GFRP and UHPC-CFRP during projectile penetration. When penetration into the UHPC slab retrofitted with glass FRP plate, the velocity of projectile reduces more rapidly, compared with plain UHPC slab. If the UHPC slab is retrofitted with carbon FRP plate, the velocity of projectile presents a greater decreasing trend. The termination time for UHPC-P, UHPC-GFRP and UHPC-CFRP targets when stopping to penetrate and starting to bounce back is 99 µs, 90 µs and 70 µs, respectively.

![Figure 5 Velocity histories of UHPC-P, UHPC-GFRP and UHPC-CFRP during projectile penetration](image)

Figure 6 presents the impact response of UHPC-2-1 (Sovják et al. 2013), UHPC-P, UHPC-GFRP and UHPC-CFRP subjected to projectile penetration. From Figures 6(b) to 6(d), the colour varying from red to blue means the UHPC target suffers more serve localized damages. Therefore, it can be seen that the plain UHPC slab...
suffers the most severe localized damages, and the UHPC slab retrofitted with carbon FRP plate suffers the least severe localized damage.

![Figure 6 Impact response of UHPC targets against projectile penetration](image)

In Table 5, the DOP and the crater diameter of UHPC-P are 20 mm and 68 mm, respectively, which show a good agreement with the average experimental results for UHPC-2-1, UHPC-2-2 and UHPC-2-3, indicating the validation of the material model proposed for UHPC. In addition, the DOP and the crater diameter of UHPC-GFRP are 13 mm and 64 mm, respectively. The DOP and the crater diameter of UHPC-CFRP are 9 mm and 56 mm. Above results illustrate that UHPC slab retrofitted with glass FRP has a better impact resistance than plain UHPC slab, and carbon FRP plate is more effective in enhancing the impact resistance against projectile penetration compared to glass FRP plate. The impact resistance will be improved by the increasing thickness of FRP plate according to previous research by Pan et al. (2011).

CONCLUSION

The present study numerically investigate impact response of plain UHPC slab (156 MPa), as well as UHPC slabs respectively retrofitted with glass FRP and carbon FRP plates subjected to steel ogive-nosed projectile penetration (710 m/s). From this study, the following conclusions could be drawn herein:

1. *MAT_CONCRETE_DAMAGE_REL3* with manually calibrated parameters can well characterize UHPC’s quasi-static behaviour under uniaxial compression and flexural tension, as well as the dynamic behaviour subjected to high velocity projectile penetration;

2. UHPC slab retrofitted with FRP plate has a better impact resistance compared with plain UHPC plate, and carbon FRP plate is more effective in enhancing the impact resistance than glass fibre FRP plate.

MODULAR CORELESS FILAMENT WINDING FOR LIGHTWEIGHT SYSTEMS IN ARCHITECTURE

J. Knippers 1, V. Koslowski1, J. Solly1, T. Fildhuth2
1Institute for Building Structures and Structural Design (ITKE), University of Stuttgart, Germany. Email: j.knippers@itke.uni-stuttgart.de

ABSTRACT

The paper describes novel strategies towards coreless filament winding of geometrically complex fibre reinforced building components. The research focuses on winding processes that reduce the need for formwork, allowing for the fabrication of individual one-off components made of glass and carbon fibre rovings. The component geometry and layout of the rovings is adapted to the structural loading of the system. Through the development of a modular system, the dimension of the resulting structure is not limited by the robotic fabrication set-up, which demonstrates how the coreless winding method is applicable in large scale building implementations. The paper presents two prototypes produced by modular coreless winding: First, the ICD/ITKE Research Pavilion 2013-14 investigated and demonstrated the geometric variability of the system. Second, the Elytra Filament Pavilion at the Victoria and Albert Museum in London in 2016 extended this approach towards a fully functioning roof system of significant scale. The Elytra Filament Pavilion is additionally equipped with a fibre optic monitoring system, allowing for on-line sensing of strain and temperature and illustrating the potential of multi-functional fibre systems.

KEYWORDS

filament winding, roof structure, glass and carbon rovings, robotic fabrication.

INTRODUCTION

Filament winding represents a cost effective and often-used fabrication method for synclastic composite components such as pipes, vessels or aircraft fuselages. Typical filament winding techniques require the production of a positive mould onto which the fibres are later laid. The fabrication of this mould is an elaborate process and causes waste material. In addition, the size of the core is usually limited by fabrication constraints. Thus, filament winding is often used for repetitive synclastic components of limited size and diameter. To overcome these drawbacks, a Coreless Winding process was conceived to avoid the production of a large positive core.

CORELESS WINDING FOR MODULAR STRUCTURES – ICD/ITKE RESEARCH PAVILION 13-14

Initially, the coreless winding process was used for large scale monocoque structures (La Magna et al. 2014, Reichert et al. 2014). In a second step the process is adapted to smaller individual components (Parascho et al. 2015). The aim was the development of a winding technique for modular, double layered fibre composite structures, which reduces the required formwork to a minimum while maintaining a large degree of geometric freedom and leading to a strong and robust structural system. Through the development of computational design and simulation tools, both the robotic fabrication characteristics and the structural requirements could be simultaneously integrated in the design process. A fabrication method was developed, which uses two collaborating 6-axis industrial robots to wind fibres between two custom-made steel frame effectors held by the robots. While the effectors define the edges of each component, the final geometry emerges through the interaction of the subsequently laid fibres. The fibres are at first linearly tensioned between the two effector frames. The subsequently wound fibres both lie upon and tension each other resulting in a reciprocal deformation. This fibre–fibre interaction generates synclastic surfaces from the initially straight deposited fibre connections. The order in which the resin impregnated fibre rovings are wound onto the effectors is decisive for this process and is described through the winding syntax. The specific sequence of fibre winding allows control
over the layout of every individual fibre, leading to a material driven design process. These reciprocities between material, form, structure and fabrication are defined through the winding syntax, which therefore becomes an integral part of the computational design tool.

Figure 1 ICD/ITKE Research Pavilion 2013–14 (photo: ICD/ITKE University of Stuttgart)

The effectors are adjustable to various component geometries, thus only one reconfigurable tool setup is required. Coreless filament winding not only saves substantial resources through the lack of individual moulds, but in itself is a very material efficient fabrication process since there is no waste or cut-off of fibre mats.

Figure 2 Fabrication Set-up for ICD/ITKE Research Pavilion 2013-14

The specific robotic fabrication process includes the winding of 6 individual layers of glass and carbon fibres plus an optional layer for enclosure (Fig 4). A first glass fibre layer defines the element geometry and serves as formwork for the subsequent carbon fibre layers. These carbon fibre layers act as structural reinforcement and are individually varied through the fibres anisotropic arrangement. A simplified FE Analysis, in which the
global structure is approximated as a continuous shell, gives the orientation of the stress tensors. They are transferred into fibre orientations which are finally corrected according to the constraints of fabrication (Fig 3). The generated winding syntax allows the automatic winding of the 6 fibre layers (Fig 4) including the structurally differentiated fibre layer 3.

The woven components are joined using aluminium sleeves that are integrated into the edge of the fibrous structure. These sleeves are mounted onto the winding frame before the process begins. As the fibres are placed by the robot they are wrapped around the aluminium sleeves, becoming permanently bonded to them as the epoxy resin cures. The accurate location of the aluminium sleeves allows adjacent components to be linked by steel bolts passed through pairs of the sleeves and tightened simply by hand. Due to the depth of the components the bending in the structure is converted into a push/pull tensile and compressive load. The bolts therefore carry tension and some limited shear.

In total 36 individual elements were fabricated. Each of them has an individual fibre layout which results in a material efficient load-bearing system. The biggest element has a 2.6 m diameter with a weight of only 24.1 kg. The research pavilion covers a total area of 50 m² and a volume of 122 m³ with a weight of 593 kg.
While the aim of the ICD/ITKE Research Pavilion 2013-14 was to demonstrate the geometric and structural potential of the developed fabrication method, the aim of the Elytra Filament Pavilion is to showcase how this approach could be used in a typical architectural application. The pavilion was installed in the John Madejski garden of the Victoria and Albert Museum, London, during summer 2016. It is based on the same modular concepts as described above but the fabrication process was further simplified for the use of a single robot.

The roof was configured as a planar, slightly inclined canopy supported by seven columns. The canopy was a modular structure made up of initially 37 and finally 40 hexagonal roof components. 3 components were produced on site at specific public events. The components were covered by a polycarbonate sheet to provide rain coverage and drainage. The outer dimensions of each component are identical: the depth is 40 cm and the diameter 2.40 m. After winding each component is tempered in an oven for about six hours at 80 C°. In this project the diameter of the central aperture as well as the reinforcement with carbon fibres along the edges and on the hyperbolic surface was differentiated according to the specific loading of the respective
component. For analysis a simplified model was used as in ICD/ITKE Research Pavilion 2013-14: the woven mesh is represented as a surface and the woven edge connectors are idealised to lines (Fig 6). From material testing, the characteristic capacities of the wound fibre composites were determined (Tensile Capacity $f_{tk} = 4000\text{MPa}$, Bending Capacity $f_{bk} = 1330\text{MPa}$). From these tests a design strength of $f_{td} = 445\text{MPa}$ was chosen.

Wind loading has been considered in accordance with EN1991-1-4 General Actions – Wind Actions and the UK National Annex. The site in the central courtyard is generally sheltered as a central well within a larger bluff building structure. The wind loads applied were: Maximum uplift 0.72 kN/m$^2$ along the edge, uplift on the remainder 0.46 kN/m$^2$, max downforce 0.142 kN/m$^2$.

Figure 7 Finite Element Model of the Canopy with all Columns

Two differently sized fibre composite columns were used to support the canopy. The three larger column heads around the fabrication core took majority of the horizontal wind loads (see Fig 6), while the smaller ones were connected to 10cm diameter steel tube and carried vertical forces mainly. The maximum tensile loading applied to any column is found to be 7kN. This requires an anchor to prevent uplift. A Spirafix helical anchor, common for temporary and semi-permanent structures in the UK, is used.

The maximum expected deflection of the structure under SLS loading combinations is found to be in the uplift case with maximum of 16mm uplift and 30mm downwards movement. Given the scale of the structure and the fact that these deformations will occur only in the worst case 1 in 50 year storm, this is considered to be acceptable. The structure is generally under a very low state of stress even in the most onerous loading condition due to the comparably small loads and large surface of structure across which these are distributed. At the junctions between elements and the support points for the polycarbonate covering some stress concentrations are developed. The peak value is seen as 152MPa therefore this is still acceptable compared to the 445MPa limit.

In addition to structural analysis a variety of components and columns were tested (Fig 8). The horizontal loading was increased until a bending moment as in FE Analysis of the global structure (Fig 7) was reached. In testing, as well as in analysis, buckling of the compression loaded edges proved to be the decisive failure mode. Deformation and stiffness properties were also measured. The results were used to adjust the stiffness properties of the global FE model shown in Fig 7.

Figure 8 Testing of components

The structural monitoring was achieved through optical fibre sensors that are integrated into the composite material (Gabler and Knippers 2014). This technology requires a light emitter and a reading station to be located close to the installation and permanently supplied with energy. The structural sensor fibres are equipped with
BRAGG gratings that serve as elongation sensors. If the sensors are mounted to a structurally active surface strain is measured and the stress state in the material will be computed. If the sensor is detached from the load bearing structure, e.g. placed in a tube, it measures temperature. Six components were equipped with strain and temperature sensors in Stuttgart prior to installation. The sensing chains of the components will be connected via very small so-called FP/APC plugs. Each instrumented component has four fibre chains, each with 3 strain and 1 temperature sensor. The latter is needed for the temperature monitoring and to separate the measured elongations from thermal and mechanical loading.

FOLDED FABRICATION OF COMPOSITE CURVED-CREASE COMPONENTS

T.U. Lee \(^1\) and J.M. Gattas \(^1\)

\(^1\) School of the Civil Engineering, University of Queensland, Australia

ABSTRACT

Curved-crease origami is a subset of origami patterns which induce a curvature into a sheet during folding. This property has led to a number of interesting applications in civil engineering and architecture, however concise geometric parametrisation and precise folded fabrication of such components remains an ongoing challenge. In this paper, the accuracy of an existing simplified geometric parameterisation for curved-crease origami is assessed by manufacture and measurement of curved-crease components. These are constructed with a new method for folding of fibre-reinforced timber (FRPT) sheet materials. A set of eleven prototypes are constructed using a simplified geometric parameterisation based on reflection of cylindrical surfaces about straight-crease origami patterns. This method was previously developed by the second author and provides a concise geometric description of curved-crease origami, but does not account for elastic or plastic bending energy. The 3D scanned prototype geometry is compared with the simplified design geometry, and it is found that the folded fabrication method is able to produce a consistent part and that variation between manufacture and design geometry is acceptable for applications where global form is critical, such as decorative components, but not for those where centreline geometry is critical, such as structural components.

KEYWORDS

FRP, curved crease origami, folded fabrication.

INTRODUCTION

Thin materials can be folded to create geometries with excellent structural performance characteristics, for example buckling resistance or bending capacity. The historical art of origami is rich with knowledge of material folding and thus origami-inspired engineering is concerned with application of novel folded geometries for new types of engineering structures and devices. Curved-crease origami is a subset of origami concerned with curved-line folding, which imparts a curvature in the sheet during folding (Demaine et al., 2011). This curvature is a striking feature which had led to successful application of curved-crease origami in many different field of design. In mechanical engineering, curved folds have been used to fold a car shell (Kilian et al., 2008), a deployable compliant rolling-contact element joint (Nelson et al., 2015), self-assembling propellers (Miyashita and Igarashi, 2015), and high energy-absorbing crash box and sandwich panels components (Garrett et al., 2016, Gattas and You, 2015).

In architecture and civil engineering, applications of curved-line folding are seen across a range of scales and materials. Modular or tessellated components have been used for kinetic façades with adaptive shading capability (Vergauwen et al., 2013) and robotically-fabricated sheet metal assemblies (Epps and Verma, 2013). Novel spatial structures have also been developed including polyhedra skeletons (Chandra et al., 2015a) and vault structures (Tachi, 2013). In terms of those with a demonstrated structural performance benefit, curved folded plate beams built with timber (Buri et al., 2011) and fibre-reinforced timber (Hansen et al., 2016) have been seen to have a substantial increase in strength and stiffness compared to convention thin-walled sections.

The above applications have all been enabled by extensive preceding work in mathematics, modelling, and simulation of curved-line folding. Pioneering work by Huffman (1976) has led to the modern design methods for curved crease origami geometry (Demaine et al., 2011; Koschitz et al., 2008). These include physical methods and computational methods. Physical methods include the mirror reflection method based on inversions of developable surfaces about truncation (Mitani and Igarashi, 2011), or manual tracing of physical prototypes (Tachi, 2011). Computational methods typically involve generation of a smooth curved developable surface from planar quadrilateral (PQ) strips, optimised for minimum discrete bending energy in curvature while enforcing developability (Kilian et al., 2008). Such methods have been extended to enforce exact developability at every
folding step (Solomon et al., 2012), to enable freeform geometries (Chandra et al., 2015b), and to convert known straight-crease origami into curved-crease variants (Gattas and You, 2014).

The mathematics and application of curved-crease origami thus has high potential for the creation of new and beneficial structural forms. However, concise geometric parametrisation and precise folded fabrication of such components remains an ongoing challenge, with diverse methods available for both but no benchmarking of their relative efficacy. This paper aims to assess the accuracy of an existing simplified curved-crease origami geometric parameterisation with manufacture and measurement of composite curved-crease components.

**GEOMETRY, MANUFACTURE, AND MEASUREMENT**

**Geometry**

A modular curved-crease origami component was designed using the simplified design method proposed in Gattas and You (2014). In this method, bending energy is neglected so that a curved-crease parameterisation can be developed as an extension of a straight-crease origami parameterisation. It can be understood as follows. First, consider a simple corrugated fold shown in Figure 1(a). It is folded from a square of paper with the crease pattern shown in Figure 1(d) and defined with three parameters; side length $s$, dihedral angle $\theta$, and corrugation proportion $l'=l_1/l$, where $l=\sqrt{2s}=2(l_1+l_2)$. This can be extended by introducing a reverse fold as shown in Figure 1(b) and (e), with an additional parameter $\phi$ sufficient to uniquely define the location of this fold. New parameters can be shown as dependent, with $l_2=l_1/\sin \phi$ and $\eta_1$ and $\eta_2$ related to $\theta$ with equations given in Gattas and You (2013). The final curved crease module, shown in Figure 1(c) and (f), is then created by specifying a gradient parameter $\varphi$ to define an elliptical curved through the three points of the straight crease reverse fold and projecting this along reflected straight-crease axes. An any specified elliptical curve will form the intersection of some cutting plane and a cylindrical surface, so the generated projected surface forms a reflected conical surface and is thus developable. The final curved-crease element is therefore concisely defined with five parameters: $s$, $\theta$, $l'$, $\phi$, and $\varphi$. For the present paper, modules are used with $s=300\text{mm}$, $\theta=109.3^\circ$, $l'=0.15$, $\phi=66.8^\circ$, and $\varphi=15.5^\circ$.

![Figure 1](image_url)

**Manufacture**

Manufacture of the curved-crease panels was achieved with a recently developed cured-in-place composite manufacturing processing (Hansen et al., 2016). The process takes a flat sheet of fibre and places a slow-curing resin at fold line locations and a fast-curing resin elsewhere. The differential curing time allows a 3D part to be precisely folded after the fast cure resin is set, but prior to slow cure resin set. This process is followed as shown in Figure 2(a) and (b), with a 0.15-0.25mm thick Biotex Flax 100g/m2 2x2 Twill style weave natural fibre bonded with Amperg22 Normal and Slow Epoxy, with 4 and 30-hour cure times, respectively, under vacuum and 20°C
room temperature environment. Silicon dioxide (SiO2) powder was added to the slow cure resin to increase the resin viscosity and thus improve fold line accuracy by minimising resin bleed. A 0.6mm thick Spotted Gum timber veneer was also bonded, shown in Figure 2(c), again for more precise control of folded hinge width than is otherwise possible with FRP alone. Orientation of the grains on the timber veneers was perpendicular to the proposed fold direction to prevent the cracking in folding state. In the foldable state, the fold lines acted as hinges and panel surfaces were elastically bent into their final shape and placed in a jig. Once fully cured, they were held this shape unassisted, Figure 2(d). Final thickness of the cured samples was measured as approximately 1mm.

Figure 2 Manufacture procedures. (a) Slow cured resin in paste applied on the fibre sheet fold locations. (b) Fast cured resin applied elsewhere. (c) Application of timber veneer. (d) Folded and fully cured prototype.

Assembly and Measurement
A plywood timber backboard was used to mount 11 component panels in a modular hexagonal grid as shown in Figure 3. Panels were fixed by fitting triangular flaps into pre-cut slots on the backboard, ensuring precise relative positioning of all panels. The completed assembly was then 3D scanned, with the surface of the panels scanned individually relative to a constant reference plane in space. A FaroArm 3D scanning system was used, which is accurate to between 0.024mm and 0.064mm.

Figure 3 Assembled components. (a) Front elevation. (b) Front perspective. (c) 3D scanning in progress.

RESULTS AND DISCUSSIONS
Global and Local Surface Error
The 3D scan process provided surface positioning data for each of the 11 panels separately, but with a preserved global reference plane. A ‘global’ measure of surface error was obtained by re-assembling 11 scanned reference planes into a single structure and compared globally with the virtual design model, Figure 4(a) and (b). The surface scan data was divided into approximately 97k data extraction points using Rhino/Grasshopper parametric CAD tools, located on anchor points on the design backboard, and the closest distance between the scanned and designed surfaces automatically extracted, see Figure 4(c). A ‘local’ measure of surface error was obtained by comparing individual module scan data to design geometry, Figure 4(d) and (e). Scan data for each module was divided into approximately 40k data extraction points and re-positioned manually to give an approximate best-fit with anchor positions of the virtual geometry. The closest distance between the scanned and designed surfaces was again automatically extracted, as shown in Figure 4(f).

Consistency of Manufactured Panels
Global and averaged local geometric analyses gave a maximum difference between manufactured and design surfaces of 3.79mm and 3.34mm, respectively. This similarity indicates that assembly procedures were accurate. Considering individual module results, shown in Figure 5, all modules showed geometric variation between 2.1% and 3.7%, with percentage values obtained as the maximum absolute difference between manufactured and design geometry, relative to a design radius of 120.3mm. This shows reasonable consistency in the manufacturing method. Physical inspection also showed two trends in where this variation occurred: as a
flattened curvature form and as an outward tilt of corner ends, see Figure 6a and b, respectively. The former is attributed to the neglecting of bending energy in the simplified geometric parametrization and is discussed further in the next section. This latter will be investigated in future papers.

Figure 4 Geometric analyses. Global analysis (a) 3D scanned geometry, (b) 3D scan aligned with design geometry, (c) maximum displacement. Local Analysis (d) 3D scanned panel, (e) 3D scan aligned with design geometry, (f) maximum displacement.

Figure 5 Difference between prototype and design surface geometries.

Figure 6 Examples of observed local geometric variations (a) flattened curvatures and (b) outward tilt at corners.

Comparison of Manufactured and Simplified Design Geometry
The manufactured panels were observed to be relatively consistent in their form and so a comparison of ‘averaged’ manufactured geometry versus design geometry was undertaken to assess the efficacy of the simplified curved-crease design method. Of primary interest is panel curvature, as the simplified method neglects bending energy
considerations in formulating the curved-crease definition. Therefore, to analyse this principal effect, a cross-section analysis was used to extract the curvatures of all 11 manufactured panels at four different locations: two on convex outer surfaces and two on concave inner surfaces as shown in Figure 7a. The extraction plane locations were selected based on those which provided the longest length along the curved geometry and were perpendicular to folded axes. Cross sections were measured in terms of their variation from the constant design radius of 120.3mm and at 19 points, 10 degrees apart, along each curve as shown in Figure 7(b) and (c).

Results are summarised in Figure 8 and it can be seen that, on average, both outer and inner curves have a smaller radius than the design radius toward the centre of the panel and a larger radius towards the outside of the panel. This behaviour is attributed to the assumption of constant curvature made in the simplified design method. Consideration of bending energy, particularly for a module with non-uniform cross section area such as the present one, is therefore critical in prediction of accurate predictions of elastically-bent curved crease components. It should be noted though that the variation shown in Figure 8 is taken relative to the design radius and is relatively small at less than ±4%. However, variation measured relative to the plate thickness would be two orders of magnitude higher. The simplified method can therefore be considered appropriate for applications where global form is critical, such as decorative components, but not for those where centreline geometry is critical, such as structural components.

CONCLUSIONS

This paper has demonstrated an effective manufacturing method for the production of curved-crease components with a consistent surface geometry. It has also found that a simplified design geometry used to model curved-crease components, which does not account for elastic or plastic bending energy, was able to give a prediction of the manufactured surface geometry to within ±4% of design radius, or ±400% of component thickness. This indicates the geometric and fabrication methods are acceptable for applications where global form is critical, such as decorative components, but not for those where centreline geometry is critical, such as structural components.

ABSTRACT

The article presents a digital design and construction system for weaving structure that integrates architectural and structural design. Influenced by architects such as Zaha Hadid and Frank Gehry, a lot of contemporary architectural designs employ a great deal of digital technologies, and explore complex spatial expression and construction of organic curvilinear forms. Despite large amounts of effort that is dedicated into study and optimization of such design, its construction is still expensive. Supported by the contemporary digital technologies, the following study proposed a new weaving structure system, which is composed of long elastic members that are weaved together. The new structure system can be used in construction of continuous curving surfaces of complex topologies. The benefits of this system are as follows: Firstly, it is a design and construction system that has a wide adaptation to different curvilinear geometries. Secondly, the final form is developed from the counterpoises between interacting forces of the weaving elastic members; therefore the result of this structural form-finding process is more rational comparing to a designed geometry that has not been structurally optimized. Thirdly, it greatly reduces the tedious three-dimensional location and fabrication work in the construction of complex curvy surface, and significantly reduces the construction cost.

INTRODUCTION

In recent years, we have witnessed that contemporary digital technologies are exerting a profound impact on architectural design. With digital technologies, the process of architectural creation is no longer a mere organization of space, form and function, but a more comprehensive process of interdisciplinary performance optimization. The creative design of novel building systems with the integration of architectural design, structural engineering and building construction is one of the most important research directions in the field of architecture.

The development of digital technologies equips architects with parametric and generative design capabilities. With the help of 3D modelling software and scripts, quite a lot of unprecedented organic complex forms such as the Taichung Metropolitan Opera House or the Yokohama Port Terminal, were therefore invented or discovered, thus greatly expand the capabilities of architectural design. The structural system and the construction methods used in some projects, nevertheless, do not correspond with its continuous organic shape, which results in undesired difficulty and cost, and obscure the expression of design conception. Hence, given the new trend of architectural design and construction, it is necessary to propose a reasonable structural system which can highly adapt to different organic complex forms.

This paper proposed a new weaving structure system for design and construction. The aim of this research is to develop a holistic system for design, tectonics and construction that integrates architectural design and structural engineering together. The design and construction of the interweaving structure is entirely based on the digital platform. Parametric and generative design methods, structural simulation etc., have been combined to develop the form-finding algorithm, and a construction optimization and supporting program is developed to organize the construction work. Finally some experimental physical weaving structures are constructed to test the system.
RELATED WORK

Researches in several aspects including weaving structure, mesh grid optimization and digital construction method are related to the present work. The following is a brief overview of previous related works.

Not much research has been found on weaving structure in architecture or structural engineering related areas. Some essays mentioned the keyword “weaving structure” or “woven structure” but they don’t correspond to the architectural implication. For example, Toshihiko Okumura et al. (1995) proposed a 3-D woven fabric composite, and for Krasimir Yordzhev et al. (2012) “weaving structure” is a mathematical term referred to combinatorics. Some essays from Chinese researchers focused on “woven building skin” (Yu et al., 2014) “tectonic in woven form” (Cai, 2013) or “woven surface” (Wang, 2010) while in fact most of them are discussing some forms which merely look like weaving. There are some completed projects whose organic envelopes are constructed with interconnecting continuous structural members, such as Haesley Nine Bridges Golf Club House designed by Shigeru Ban Architects, and the Phoenix International Media Center in Beijing designed by BIAD. These works are not the weaving structure we propose since they do not make use of the friction and pre-stress in the bending members. Feng (2007) proposed a FRP woven web structure in which tensile FRP strips are woven into flat roof structure, but the study does not utilize the bending resistance of the members for complex geometry.

Mesh model plays an important role in the optimization method of spatial grid during the generation process of weaving structure. There are considerable related works that inspire us. In the context of computer graphics, mesh optimization is to treat the position and connectivity of vertices with given global functions in order to greatly reduce the number of the vertices and faces. For example, Hoppe et al. (1993) defined this global function as an Energy Function. The resulted mesh grid may be irregular, and a following operation of mesh relaxation is needed (Ohtakey et al., 2001). Meanwhile, in the realm of digital fabrication and construction, some optimization algorithms are well developed. Unlike those mentioned above, the algorithms are used for panelization by optimize the panel segmentation of curvy building façades, generally aiming to equalize the edge length and planarize the mesh faces. Some of the works include the panelling method by Eigensatz et al. (2010), and Area-Equalizing Remeshing by Botsch et al. (2004). These methods are designed exclusively either for speeding up calculation or for the optimization of panels, and they are not suitable for generation and optimization of mesh for weaving structure.

A lot of researches that uses digital tools in fabrication and construction of double curved surfaces of architecture have been carried out. Inspired by the bird’s nest weaving technique, Giulio Brugnaro (2015) manages to construct a weaving grid by rattan using a numerical controlled robotic arm. The work employed an interactive and dynamic digital construction process, resulted in a deformed form with uneven lattice, which is different from the geometrically and structurally optimized grid of our research. But it could be seen from the research that the weaving structure proposed in this paper is highly likely to be constructed by numerical controlled tools.

WEAVING STRUCTURE

Weaving is generally the technique with which the line-like members can be bent and interweaved into 2D or 3D forms. Traditional weaving handicrafts adopt bamboo strips (Fig. 1, left) or rattan. They are useful, economical and artistic, plays an important role in people’s daily life. These weaving structures take advantage of material strength and stiffness: the interweaving rods are dense and bound by the friction between each other that constitute a self-balanced pre-stressed structure system. Although these handicrafts are usually of simple and symmetrical shape such as bottle or basket, weaving technique does have potential in the making of more complex form (Fig. 2, left).

Figure 1 a bamboo tea caddy (left), a design of complex weaving structure (right)
Weaving structure is a kind of spatial structure such as Buckminster Fuller’s geodesic dome. However, the weaving structure makes use of long continuous members rather than short segmented tubes that are connected by rigid or hinge joints as found in many spatial structures (Fig. 2 left). Compared to that, the weaving structure harnesses the pre-stress force inside the bent continuous members to be a self-supporting unity (Fig. 2 right). Since the members can bear bending force, it is possible for the weaving structure to form more complex geometry comparing to pure tensile system such as membrane, and pure compression system such as dome.

Figure 2 spatial structure with bolt ball joints (left) and weaving structure (right)

This paper discusses the overall design and construction process of the weaving structure. Firstly, the 3D digital model of a previously designed geometry is converted and optimized into a mesh model particularly for weaving structure with designated edge length. Then the model is further converted into the model of weaving structure with continuous rods. Afterwards, this structure model is verified and optimized through structural simulation. Later, the construction material and joints are studied, together with a digital program that generate the construction drawing, optimize the workflow, and support the construction process. Finally construction work that requires collaboration of multiple people is carried out. Collaboration is necessary because the weaving order is more complex than that of simple geometry such as bottle or basket.

SPATIAL GRID GENERATION THROUGH REMESHING

It is well known that there are mainly two kinds of mathematical models used to describe almost any 3D shapes: NURBS surface model or polygon mesh model. The advantage of NURBS is that it can describe curved surface smoothly and accurately with limited amount of data, while mesh is good at its flexibility in topology and geometrical similar to weaving lattice for our research. Mesh model is selected for the generation and optimization of the grid of weaving structure, because the aim of weaving structure is to facilitate construction of curved form with complex topology, and mesh edges can be transformed into weaving rods with vertices into joints conveniently.

The weaving structure, nonetheless, has additional requirements for the mesh model: Firstly, the size of each mesh face should be similar to regular triangle with edge length restricted within a certain range. This is an essential step to ensure the structure stability, controlled rod curvature, as well as the formal aesthetics. Secondly, for every vertex in the mesh, the number of edges it connects to should be taken into consideration. Since the actual weaving member is of a certain diameter rather than zero thickness as in the mesh model, too many members around one joint are doomed to unwanted thickness and deformation. Thirdly, it is obvious that the long and continuous weaving members are conducive to the weaving structure. As to one specific vertex, it can be seen that if it connects 2n edges (n is in positive integers), then it can be converted into a joint with n continuous members. If it connects 2n+1 edges, then apart from n continuous members, there will be one additional rod which starts from the joint. Apparently the more loose end there are, the worse the structural integrity will be.

Technically, these problems can be solved based on the Mesh Class referred to the Rhino SDK C# documentation. Before the operation, a constant is set for the standard edge length, which controls the scale of the lattice. Then, an iteration of two operations is performed to reorganize the mesh model.

Insert Vertex

If a mesh edge is much longer than the standard length, it is supposed to be divided into more edges. The operation of ‘insert vertex’ deals with this requirement that traverse the mesh structure and adds all the edges in a list sorted by their length in descending order. For the edges longer than the standard length, if the edge is longer than 1.5 times of the standard edge length, then a vertex is added on the edge and the adjacent faces are split accordingly. It is also viable under non-manifold circumstances (Fig. 3). By this way, in terms of multi-threaded environment, it needs to make sure this method is atomically adding point, i.e. these edges being operated upon should not be interfered by other threads.
**Remove Vertex**

Similarly, there could be a lot of mesh edges that are much shorter than the standard length, so some of the vertices should be removed from the mesh model. If the length is shorter than 0.7 times of the standard edge length, then the two end point of the edge would be merged into one vertex in the middle (Fig. 4). It is easy to conclude that it is also true in the non-manifold situations.

Through the application of these two operations, the original mesh model has been adjusted into a new mesh model. The new model maintains similar spatial form, but the optimized mesh faces’ edge length is closer to the standard length (Fig. 5). The new mesh grid is better aesthetically, and suitable for a weaving structure. Minor manual adjustments are performed to adjust the small flaws on the grid.

**EXTRACTION OF WEAVING MEMBERS**

Weaving structure is composed of continuous rods; therefore, it is necessary to connect the small mesh edges into long continuous polylines that represent the weaving rods. In a weaving structure, the rods should be as straight as possible in order to reduce the curvature, and therefore the corresponding bending stress. The searching and connecting process is as follows: The angles between edges around each vertex are evaluated sequentially, if it is larger than a certain threshold (e.g. 135°), then the two edges of the angle will be connected (Fig. 6, left). Different continuous members are marked with various colours in the model (Fig. 6, right).

**MATERIAL SELECTION AND CONSTRUCTION EXPERIMENT**

Material selection of the weaving structure should consider the strength and deformation capacities. On one hand, the rod should be strong enough to bear various loads, including the pre-stress in the bent rods. On the other hand, the rod should own a large permissible deformation in order to achieve the required curvature. Furthermore, the rod stiffness should not be too small to maintain the natural configuration; meanwhile, the rods should be flexural for construction. If weaving structure is used in construction of small structures, such as pavilions or exhibition facilities, the components should be moulded by hands. A variety of materials had been considered, including bamboo rods, plastic pipes, and carbon or glass fibre reinforced plastics (FRP). In recent experimental construction
tests, glass FRP rod is chosen as the construction material after comparison of several materials. FRP has enough strength for construction, favourable elasticity for bending, and better mechanical characteristics than bamboo. FRP rods have different diameters that allow us to easily choose the proper stiffness.

The interaction of weaving rods and structural form-finding are simulated by a physical simulation engine in the Rhinoceros Grasshopper platform called Kangaroo. The system for simulation is composed of springs that could bear tension and compression, bending resisting hinge that could bear moment force, and particles that could bear gravity and other forces. Although Kangaroo is a simple physical engine, which cannot provide a detailed mechanical simulation, it is enough for the qualitative analysis and optimization of the weaving structure during the design phase.

![Figure 7 Conceptual simulation using Kangaroo (left: axial force, right: bending moment)](image)

Different types of joints are tested including hot melt adhesive (HMA) and nylon cable tie. Nylon cable tie which allows the joints to rotate is chosen, as it creates enough frictions between the weaving rods. Besides, nylon cable tie is also convenient for fabrication in construction.

Several test models have been constructed via FRP rods, whose diameters range from 1.5 mm to 3 mm as shown in Fig. 8. The whole system is proven to be feasible via the design and construction process of the testing models. The experiment also exposed some problems that requires further research. One challenge is that, since the rods with large curvatures are sharply bent, they are able to fracture, such as the three tip circles in the left model shown in Fig. 8. This phenomenon suggests other advanced materials should substitute for these rods, or special methods should be employed to reinforce these rods.

![Figure 8 Experimental models for the weaving structure](image)

**CONCLUSIONS**

Inspired by a variety of traditional handicrafts and supported by contemporary digital technologies, a lightweight weaving structure system is developed aiming to facilitate the construction of complex organic architectural form. This structure system is composed of long continuous rods which are interwoven into a structure entity. The pre-stress force in the bent rods increases the integral stiffness of the structure and gives full play to its material advantages, including light weight and high tenacity. The weaving structure can be used in construction of complex curvilinear forms at a relative low cost. From the construction experiments, this weaving structure system has been proven to be effective and can be applied to light-weight indoor and outdoor structures for exhibition, leisure and recreation.
Due to the complex topology, each woven rod has a complex flowing direction. For the present test, it has to be constructed through collaboration of a big research group. Considering the rapid development in digital fabrication and construction, it might be possible that the weaving structure could be constructed on-site by the numerical controlled robotic arm in the near future.

In conclusion, it is important to note that although the weaving structure is supposed to be used for light-weight structures, the research findings such as form-finding rule of the spatial grid, the design of the joints and digital construction methods, could also provide ideas for large scale structure systems.

ABSTRACT

Bending-active gridshells are formed through active bending of a mat of planar grids assembled from long continuous straight members connected by scissor-like joints that are free to accommodate in-plane rotation. Their unique formation method and simple nodal connection form enable FRP composites to be their appropriate construction material. This paper proposes a form-finding approach for bending-active gridshells formed from FRP tubes within an explicit dynamic framework. The proposed approach treats the target surface geometry of the gridshell as an input into the form-finding procedure. It allows each node to have six degrees of freedom and couples all nodal degrees of freedom except the in-plane rotation for the accurate simulation of the behaviour of the scissor-like joints. Numerical verification is presented to demonstrate the effectiveness of the proposed form-finding approach.

INTRODUCTION

Bending-active gridshells (referred to as gridshells hereafter for brevity) are a particular type of grid structures that are formed through active bending of a mat of planar grids assembled from long continuous straight members connected by scissor-like joints that are free to accommodate in-plane rotation (Figure 1). The concept of gridshells was initially proposed by the famous German engineer Frei Otto half a century ago. Despite their obvious advantages including uniform members/joints, simple connection and the capability of complying with specific free-from surface geometries, only a very small number of gridshells exist worldwide, among them the Multihalle of Mannheim in Germany (Happold and Liddell 1975) and the Downland Museum in the UK (Harris et al. 2003). The majority of existing gridshells were formed from timber laths. The use of pultruded FRP tubes instead of timber laths is a recent and an important advance in the state-of-practice of gridshells (Douthe et al. 2006, 2010; Baverel et al. 2012) because: 1) pultruded FRP tubes have a much higher elastic modulus/strength than timber laths and can readily be manufactured to the desired length; and 2) the unique nodal form of gridshells overcomes the difficulty encountered in the connection of FRP tubes.

An important factor that limits the engineering practice of gridshells is the complexity of their form-finding, which in more specific terms, is the issue of finding the corresponding planar grids configuration that can accurately be deformed into the target surface geometry proposed by architects. The majority of existing form-finding methods for gridshells (e.g. Happold and Liddell 1975; Harris et al. 2003; Douthe et al. 2006; Kuijvenhoven and Hoogenboom 2012; D’Amico et al. 2014) are only capable of finding the deformed grids geometry as an output corresponding to pre-defined planar grids configuration. Even those few methods which treat the target surface geometry proposed by architects as an input and in turn output the corresponding planar grids configuration are mainly subjected to the following two deficiencies: 1) incomplete account for nodal degrees of freedom (DoFs); and 2) coupling of nodal DoFs for the accurate simulation of the behaviour of the scissor-like joints is not properly treated or clearly reported. To overcome these deficiencies, this paper proposes an improved and more general form-finding approach for gridshells within an explicit dynamic framework. The
proposed approach treats the target surface as an input and is applicable to free-form surface geometries. It allows each node to have six DoFs and couples all nodal DoFs except the in-plane rotation to simulate the behaviour of the scissor-like joints.

**GENERAL PROCEDURE OF PROPOSED FORM-FINDING APPROACH**

The proposed form-finding approach comprises five steps (Figure 2) as described below.

**Step 1**: Define the target surface geometry and place the mat of planar grids underneath. The target surface is treated as a rigid geometrical constraint. The mat must have an area larger than the area of the target surface and may have an arbitrary initial shape.

**Step 2**: Apply a fictitious pressure field to the planar grids to force them deform into the target surface geometry until all nodes of the grids inside the target surface are at rest on (in contact with) the target surface.

**Step 3**: Truncate the part of mat of grids that is outside the target surface and fix the so generated end nodes to form the boundary of the gridshell.

**Step 4**: Remove the fictitious pressure field and the rigid surface constraint (contact force) to achieve the final form of the gridshell.

**Step 5**: Generate the configuration of the planar grids in pursuit by releasing the pre-stresses in the final form of the gridshell derived in Step 4.

**EXPLICIT DYNAMIC METHOD FOR 3D BEAM ELEMENTS WITH SIX DOFS PER NODE**

**Motion Equations**

The explicit dynamic method employed in the proposed form-finding approach discretizes a gridshell into a set of particles (nodes) linked by three-dimensional beam elements. The terms *particles* and *nodes* are used
interchangeably in this paper as the particles are also the nodes of the beam elements. Each node of the beam element has six DoFs, including three translational DoFs and three rotational DoFs. The deformation of the gridshell can then be described by the motions of the particles. The motion of an arbitrary particle $\alpha$ follows the Second Newtonian Law,

$$m_\alpha \ddot{x}_\alpha = \Gamma^\text{ext}_\alpha - \Gamma^\text{int}_\alpha - \Gamma^\text{dmp}_\alpha$$

(1a)

$$I_\alpha \ddot{\phi}_\alpha = M^\text{int}_\alpha - M^\text{ext}_\alpha - M^\text{dmp}_\alpha$$

(1b)

where $m_\alpha$ ($I_\alpha$) is the mass (moment of inertia matrix), $\ddot{x}_\alpha$ ($\ddot{\phi}_\alpha$) is the translational (angular) acceleration vector, $\dot{x}_\alpha$ ($\dot{\phi}_\alpha$) is the translational (angular) velocity vector, $x_\alpha$ ($\phi_\alpha$) is the position (rotation) vector and $\Gamma^\text{ext}_\alpha$ ($M^\text{ext}_\alpha$) is the external force (moment). The damping forces $\Gamma^\text{dmp}_\alpha$ ($M^\text{dmp}_\alpha$) are introduced to damp the gridshell to a static equilibrium state, where $\mu$ is the damping factor which can be assigned with a fictitious value as the form-finding issue under consideration is static in nature. $\Gamma^\text{int}_\alpha$ ($M^\text{int}_\alpha$) is the summation of the internal nodal force (moment) exerted by the elements connected with particle $\alpha$.

Based on the central difference method, the velocity and the acceleration of the particle can be expressed by time and displacement

$$x^{n+1}_\alpha = (x^n_\alpha - x^{n-1}_\alpha) / (2\Delta t)$$

(2a)

$$\dot{x}^{n+1}_\alpha = (x^{n+1}_\alpha - 2x^n_\alpha + x^{n-1}_\alpha) / \Delta t^2$$

(2b)

$$\phi^{n+1}_\alpha = (\phi^{n+1}_\alpha - \phi^{n-1}_\alpha) / (2\Delta t)$$

(2c)

$$\ddot{\phi}^{n+1}_\alpha = (\dot{\phi}^{n+1}_\alpha - 2\dot{\phi}^n_\alpha + \dot{\phi}^{n-1}_\alpha) / \Delta t^2$$

(2d)

Substituting Eq. 2 into Eq. 1 yields

$$x^{n+1}_\alpha = c_1 \Delta t^2 (\Gamma^\text{ext}_\alpha - \Gamma^\text{int}_\alpha) + 2c_1 \dot{x}^n_\alpha - c_1 c_2 x^{n-1}_\alpha$$

(3a)

$$\phi^{n+1}_\alpha = c_1 \Delta t^2 (I^\text{int}_\alpha - I^\text{ext}_\alpha) + 2c_1 \dot{\phi}^n_\alpha - c_1 c_2 \phi^{n-1}_\alpha$$

(3b)

where $c_1 = 1 / (0.5 \mu \Delta t + 1)$, $c_2 = 0.5 \mu \Delta t - 1$, $\Delta t$ is the time increment. Eq. 3 allows the displacement of particle $\alpha$ at the current time step to be explicitly derived from known information of previous time steps. More details of the framework of the explicit dynamic method and the formulation of the internal force of the three-dimensional beam elements can be found elsewhere (Yu and Luo 2011a, 2011b).

Nodal Coupling

In a gridshell, the continuous profiles are connected by scissor-like joints which allow free in-plane rotation during the formation process. The behaviour of planar scissor-like joints has been successfully modelled in a previous study (Yu and Luo 2009). However, their behaviour is more complicated in three-dimensional space. As shown in Figure 3, profile $AJB$ and profile $CKD$ connect with each other by node $J$ and node $K$. In the numerical model, these two nodes share the same coordinates. Therefore, the motions of node $J$ and node $K$ possess the following features: 1) their translations are coupled at any time; 2) their out-of-plane rotations are coupled at any time; and 3) their in-plane rotations are independent at any time.

![Figure 3 A scissor-like joint in three-dimensional space](image)

The two profiles are numerically represented by four beam elements (beams 1 to 4 in Figure 3). Since the translations of node $J$ and node $K$ are coupled at any time, these two nodes can be merged into one in the calculations of translations and their nodal masses can thus be expressed as

$$m_{\text{merge}} = m_J + m_K$$

(4)

So are the nodal internal forces and external forces...
For the convenience of dealing with rotational coupling, a tangent plane $\pi$ is defined with a tangent coordinate system $\tilde{\Omega} = \{ \tilde{e}_x, \tilde{e}_y, \tilde{e}_z \}$, where $\tilde{e}_i$ is averaged from the cross products of the four pairs of neighboring beam elements and $\tilde{e}_x$ and $\tilde{e}_y$ can be taken to be an arbitrary pair of orthogonal directions. The rotations can then be conveniently separated into the out-of-plane component and the in-plane component by executing Eq. 3b under the tangent coordinate system. Hence, the moment components of node $J$ and node $K$ ($\tilde{M}_J$ and $\tilde{M}_K$) under the tangent coordinate system can be expressed as

$$
\begin{align*}
\tilde{M}_J &= (M_J^\text{ext} - M_J^\text{int}) \\
\tilde{M}_K &= (M_K^\text{ext} - M_K^\text{int})
\end{align*}
$$

(6)

The two nodes are also merged in the calculations of the out-of-plane rotations but are detached in the calculations of the in-plane rotations. So the moment components become

$$
\begin{align*}
\tilde{M}_\text{merge}^\text{ext} &= (M_J^\text{ext} + M_K^\text{ext}) \\
\tilde{M}_\text{merge}^\text{int} &= (M_J^\text{int} + M_K^\text{int})
\end{align*}
$$

(7)

Likewise, the moment of inertia matrices contributed from beam element $i$ ($i = 1, 2, 3, 4$) also need to be transformed into the tangent coordinate system

$$
\tilde{I}_i' = \tilde{\Omega} \tilde{Q} \tilde{I}_i' \tilde{Q}^T
$$

(8)

where $\tilde{I}_i'$ is the moment of inertia matrix in the local coordinate system and $\tilde{Q}$ is the transformation matrix between local and global coordinate system. With the out-of-plane components being merged, the moment of inertia matrices of the scissor-like joint in and out of the tangent plane are

$$
\begin{align*}
\tilde{I}_\text{in} &= \tilde{I}_i' + \tilde{I}_i'' \\
\tilde{I}_\text{out} &= \tilde{I}_i'' + \tilde{I}_i'''
\end{align*}
$$

(9)

**Verification of the Beam Element**

The classic numerical test of a curved cantilever beam (Bathe and Bolourchi 1979; Moita and Crisfiea 1996) is employed herein to verify the formulation of the three-dimensional beam element when subjected to large deformation. As shown in Figure 4, the cantilever beam initially lies in the X-Y plane in the shape of an arch with a radius of 100 in (2540 mm) and a central angle of $\theta = 45^\circ$. The remaining material and geometrical properties of the cantilever are provided in Figure 4. With one end being fixed and the other end being applied with a vertical load $P=600$ lb (2667N), the cantilever undergoes large axial, bending and twisting deformations due to vertical loading and its curved geometry. The relation between the tip translations and the vertical force is shown in Figure 5 where $u$, $v$ and $w$ are the tip translations along the $x$, $y$ and $z$ directions respectively. It can be seen that the results from the proposed approach are in excellent agreement with those reported in previous studies (Bathe and Bolourchi 1979; Moita and Crisfiea 1996), demonstrating the validity of the formulation of the three-dimensional beam element. The cantilever was discretized into 40 equidistant particles to produce the numerical results in the present study.
FORM-FINDING EXAMPLE

In this Section, a form-finding example is presented to demonstrate the effectiveness of the proposed form-finding approach. In this example, the gridshell was assumed to be formed from pultruded GFRP tubes having an external diameter of 32mm and a wall thickness of 3mm, an elastic modulus $E = 30\text{GPa}$, a transverse shear modulus $G = 3\text{GPa}$ and a density $\rho = 1800\text{kg/m}^3$. The target surface employed in the example is a deep spherical dome (Figure 6a) with a radius $R = 3.25\text{m}$ and a height $h = 4.5\text{m}$. The initial planar grids were assumed to have a dimension of $12\text{m} \times 12\text{m}$ with a grid spacing of $0.5\text{m}$ (Figure 6b).

![Figure 6 A deep spherical dome imposed for gridshell form-finding](image)

Figure 6 A deep spherical dome imposed for gridshell form-finding

Figure 7 shows the final geometry of the gridshell resulted from Step 4 of the form-finding procedure. It should be noted that this final geometry is a very close approximation but not a precise reproduction of the target surface because a very small amount of snap-back of the grids inevitably occurs in Step 4 as a result of the removal of the rigid surface constraint and the pressure field. Figure 8 compares the final geometry of the gridshell with the geometry of the target surface. The comparison indicates that the difference between the two geometries is difficult to be spotted. The difference between the two geometries is further quantified by a careful examination of the distance between typical nodes (nodes 1 to 5 in Figure 8) on the final geometry of the gridshell and the center of the dome. The results of the examination are summarized in Table 1, which indicates that these nodes are located in the very near neighborhood of the target surface. Figure 9 finally shows the planar grids configuration in pursuit after releasing the pre-stresses in the deformed grids. The left and right plots in Figure 9 respectively shows the generated planar grids configuration and its position in the original planar grids.

7. Conclusions

This paper has been concerned with the development of a form-finding approach for bending-active FRP gridshells within an explicit dynamic framework. The continuous members are modelled using three-dimensional beam elements with a complete account for the nodal DoFs (six DoFs per node) so the bending and twisting behaviour of the members can be accurately modelled. The scissor-like joints are modelled using a pair of nodes whose nodal DoFs are all coupled except the in-plane rotation. It should be noted that the final geometry of the gridshell found by the proposed approach is a very close approximation but not a precise reproduction of the target surface because a very small amount of snap-back of the deformed grids inevitably occurs as a result of the removal of the rigid surface constraint and the pressure field in the proposed form-finding procedure.

EXPERIMENTAL ANALYSIS OF A REVERSE ELASTICA POP-UP GEOMETRY

T.U. Lee ¹ and J.M. Gattas ¹

¹ School of the Civil Engineering, The University of Queensland, Australia

ABSTRACT
Pop-up mechanisms are able to generate complex forms from flexible planar materials. They have successfully been used for 3D micro scale engineering applications, but are not yet utilized for building-scale elements due to the difficulty of scaling planar actuation mechanisms. Separately, building elements formed with large, elastic bending deflections are widely used to for light weight and rapid assembly constructions. Commonly termed bending-active structures, their form utilises elastica geometries, which correspond to large bending deformations which have a minimum elastic potential energy. This paper will explore a novel actuation system for large scale pop-up structures that uses a reverse (pre-fabricated) elastica geometry. Experimental analysis is conducted on specimens made from fibre-reinforced-polymers (FRP), to compare elastic force-displacement behaviours of normal and reverse elastica samples under cyclic loading. A concept pop-up structure is also built to show the reverse elastica actuation system in practice.

Pop-up, FRP, Bending-Active Structures, Elastica

INTRODUCTION
Pop-up mechanisms are those that utilize the kinematics of planar sheet folding to ‘pop-up’ a complex 3D shape. The mechanisms have parallels with origami and kirigami, which are the Japanese techniques for folding uncut and cut paper, respectively (Greenberg et al., 2011). Pop-up inspired design has wide potential for use in engineering applications, with several early uses already in existence. Novel deployable systems have been developed by embedding different complex motions and joints in planar origami states (Winder et al., 2009). Three-dimensional microstructures have been designed using layers of 2D planar materials, which are able to be assembled in a short duration, termed lamina emergent mechanisms (LEMs) (Gollnick et al., 2011; Gafford et al., 2013). The properties of LEMs have been studied and include influencing geometry, material properties, and boundary conditions. This knowledge has been used in recent designs to create self-actuating pop-up mechanisms (Jacobsen et al., 2010).

Self-actuating pop-up techniques, or self-pop-ups for short, have been widely applied on micro LEM devices. For example, a pop-up printed circuit microelectromechanical system was used to create a micro scale robot that can self-assemble and operate with simple design motions (Whitney et al., 2011). Self-pop-up through folding has also been achieved by applying global heating on 2D sheet materials to assemble a complex 3D cylindrical origami structure (Miyashita et al., 2013). Those studies have shown that self-pop-ups can successfully be applied on micro scale constructions. However, self-pop-up actuation systems are constrained at larger scale constructions due to the difficulty of scaling planar actuation mechanisms.

Bending-active structures are similar to pop-up mechanisms in that complex forms can be generated from planar materials. They utilize large elastic deformations to form a target profile, and in doing so utilise geometric non-linearities, such as stress-stiffening, to boost structural performance. Large-scale and lightweight constructions can therefore be effectively realized using a bending-active mechanism, if a material is selected which allows suitably large elastic deformations. Timber, fibre-reinforced polymer composites (FRPs), and hybrid materials are commonly used to due to their high flexural strength and low stiffness (Garti, 2015; Lienhard, 2014a).

The non-linear geometry of bending-active elements has led to some challenges in their modelling and design, however a range of techniques have been developed to address this. Particle-spring design methods were proposed for form-finding grid shells consisting of flexible members (Kuijvenhoven, 2012). The theory has contributed to digital form-finding tools such as the Kangaroo physics engine, which can simulate bending behaviors through dynamic relaxation of a spring-particle system (Symeonidou, 2015). Finite element structural analysis techniques have also been used to model flexible elements with uncertain boundary conditions, by using ultra-elastic contraction elements to actuate bending-active regions (Lienhard, 2014b). These simulation
techniques have been applied beyond individual elements to the design of full structures. For example, the Ongreening Pavilion uses a form-finding technique to generate a 3D grid shell composed of individual timber elements bent into an elastica curves (Harding et al., 2014). It is assembled in just 3 days and forms within a given inhabitable space 10m by 8m.

Elastica curves are a key feature of bending-active structures, as they correspond to the minimum bending energy configuration of a planar elastic shell. They have been investigated since the 13th century (Levien, 2008) and the mathematical approaches developed to model the form are still widely utilized today (Pacheco and Pina, 2007; Djondjorov et al., 2008). Elastica geometries are able to be obtained directly by using numerical solvers (Taki, 2007) to evaluate the fundamental equation, or they can be obtained using the same elastic large-displacement methods described above. Elastic bending can also be combined with other deformations to produce new forms of bending-active structures. Examples include spatial structures with twisted and interlaced bending elements (Nabaei et al., 2015); a deployable reflector made from a folded and bent composite curved-crease origami pattern (Pellegrino, 2006); and a pliable structural system inspired by parallel leaf-springs (Tornabell et al., 2014).

This paper investigates the intersection of pop-up mechanisms and bending-actives structures. Specifically, we propose a reverse (pre-fabricated) elastica element that can potentially act as a planar actuation system for large scale self-pop-up structures. First, the design and manufacture procedures for reverse elastica geometries will be developed. Second, an experimental analysis is conducted on normal and reverse elastica FRP samples to compare elastic force-displacement behaviours under cyclic loading. Third, the feasibility of a reverse elastica pop-up system is demonstrated with a concept pop-up structure.

GEOMETRY, MANUFACTURE AND TESTING

Geometry
There are numerous methods to model an elastica curve. This paper shall use the Kangaroo physics engine, which is freely available in the parametric CAD software Rhino/Grasshopper as follows. A straight beam element is specified with pinned-pinned support conditions and with a constant flexural stiffness along the element length. One support is moved in horizontal increments of 10% of the beam length, up to a total displacement of 100% of beam length. The Kangaroo engine simulates beam behaviour using dynamic relaxation of spring-particle system, with axial and rotational spring stiﬀnesses applied to sub-divided beam axes and joints, respectively. The relaxed beam geometry gives the resultant curves shown in Figure 1, and thus a numerical solution to the beam minimum energy configuration under elastic bending. Numerical profiles were validated with physical model data, with physical data obtained as the traced profile of an isotropic polycarbonate rectangular strip deformed in the same way as described for the above numerical simulation. A comparison of simulated and physical prototypes is shown in Figure 1 and it can be seen there is good correspondence.

Manufacture
A reverse elastica curve is one that has bending energy in a deployed state, i.e. it is fabricated in the deployed state such that when it returns to flat, it contains an elastic potential. It is unknown whether normal (straight-to-curved) and reverse (curved-to-straight) elastica beams have the same force-displacement behaviour, and so prototypes of each were manufactured and tested. For manufacture, prototypes were designed with 250mm length and 20mm width. It was calculated that a prototype thickness of approximately 1mm would allow the requisite large elastic displacements if constructed from FRP, and so each prototype was made with 5 layers of GFRP laminated with Ampreg 22 epoxy system. The first model, Type 1, was a flat strip. The second model, Type 2, was the reverse elastica curve and so was built with the profile shown in Figure 2, generated with the Kangaroo engine as describe above.
Testing
To assess the similarities and differences between normal and reverse elastica force-displacement behaviour, three samples of each type were subjected to a quasi-static cyclic displacement test with 10 cycles. Type 1 flat strips were actuated from a straight form into the design elastica curve, as shown in Figure 3(a). Type 2 reverse elastica curves were actuated from the design elastica curve into a straight form, as shown in Figure 3(b). For both, total actuation distance was 175mm. During the cyclic test, received load (N) in relation to the end point displacement (mm) was recorded at a 0.1s time interval. As the actuation between types is in reverse directions, displacement measurements were converted to an absolute percentage of total distance, with 0% representing the flat state and 100% representing the designed elastica curve state, as shown in Figure 4. The shape of the specimens was also recorded during testing with digital photographs.
RESULT AND DISCUSSION

Comparison of Manufactured and Design Geometry

The shape of the specimens under quasi-static cyclic loading was compared with the predicted elastica geometry. Type 1 models matched the elastica geometries simulated in Kangaroo physics throughout the entire process from loading to unloading, with the flat strip maintaining an elastica profile during deformation as shown in Figure 5. This suggests that the design composite material was able to achieve a large deformation with elastic bending behaviour. This conclusion is supported by the load-displacement histories shown in Figure 6a, which follow a reversible, and thus elastic, load path. The reverse elastica Type 2 similarly follows a reversible load path, as shown in Figure 6b, however Type 2 models were not able to return to a perfectly flat state with a 175mm displacement. This can be understood with consideration of averaged force-displacement responses.

Figure 5 Specimens maintained elastica forms under quasi-state cyclic loading (green curves are the simulated elastica profiles).

Figure 6 Experimental data. (a) Type 1 normal strip. (b) Type 2 reverse strip.

Comparison of Normal and Reverse Elastica Geometries

Figure 6 above shows the complete force-displacement time histories for all tested samples. It can be seen that there is good load path reversal and it can be concluded that all samples were loaded in the elastic region throughout testing. Figure 7 below shows the average force-displacement relationship for each type, obtained by averaging the 10 cycles for each sample and then averaging across samples. Type 1 specimens show an initial linear elastic region up to some critical buckling load, after which the response is softened. This is classic non-linear elastic buckling behaviour. Type 2 models, starting at 100%, begin with a softened response and then stiffen as the samples approach the straight, 0% configuration. The magnitude of force change between end states is similar between types, however the path and thus stored energy is different, particularly in the near-
straight region. This is because the Type 2 models start as a post-buckling form and so do not experience the linear elastic region and subsequent bifurcation seen in Type 1 models.

![Figure 7](image.png)

**Figure 7** The average result of a single cycle for both models under quasi-state cyclic loading.

**Self-pop-up Actuation System**

Reverse elastica geometries can be used to develop 3D bending-active structures that store bending energy in a flat state, rather than bent state. Thus, they can be used for structures that are stored in a planar state but can pop-up to a bent configuration, i.e. they can be used as an actuation system for self-pop-ups. A design which utilises this is proposed in Figure 8. Eight reverse elastica strips were fabricated and joined together with hinges at one end of the strips. These strips can be flattened and held back-to-back with clamps, as shown in Figure 8(a). As elastica geometries are minimum energy forms, external energy required to flatten the structure is minimal. Once clamps are removed the lock positions in flat-storage, the flat strips pop-up transform into the reverse elastica form, as shown in Figure 8(b). These can be arranged as shown in Figure 8(c) to form a stable deployed structure.

**CONCLUSIONS**
Pop-up techniques are currently constrained at large scales by the lack of macro-sized, flat-packable actuation systems. This paper has explored an actuation system that is potentially capable of addressing this lack by connecting elastica geometries, pop-up mechanisms, and large-scale bending-actives structures. Reverse elastica geometries were produced using a dynamic relaxation analysis and were manufactured from a GFRP composite. Cyclic testing showed both models exhibited the predicted elastic large-displacement behaviour. Flat-to-curved samples showed a classic non-linear elastic buckling behaviour and curved-to-flat reverse elastica samples only exhibiting a non-linear post-buckling behaviour, i.e. there was no return to an elastic region and no bifurcation. Reverse elastica mechanisms were also able to self-pop-up a simple concept structure.

NATURAL MATERIAL COMPOSITES FOR EARTHQUAKE-RESISTANT STRUCTURES

N. Chouw
Department of Civil and Environmental Engineering, the University of Auckland, Auckland, New Zealand

ABSTRACT

Natural materials such as coconut fibre or flax fabric, are environmentally friendly and can also be used as reinforcement in polymer-concrete composites. Coconut fibre in concrete will not only enhance the ductility of the structural members due to a fibre bridging effect, but it will also increase the material damping due to friction at the interface of widely distributed small cracks. Flax fabric can be used to significantly enhance the tensile property of flax fabric reinforced polymer (FFRP) composite. A combination of FFRP and coconut fibre reinforced concrete (CFRC) as construction materials thus has the merits of the two composites. For earthquake-resistant structures these composite materials do not have the disadvantage of conventional steel-reinforced concrete, because steel corrosion will no longer be an issue. In addition, the structure is lighter. Consequently, FFRP-CFRC structures will experience less impact of earthquake loading because of the lower inertial forces activated in the structure. The natural based structures can also subscribe to a low-damage design philosophy in which the structural members are allowed to partially separate while responding to earthquake loading. An overview of current research on innovative seismic design approaches using natural material composites is presented.

KEYWORDS

Low-damage seismic design, flax FRP, coconut fibre, earthquake-resistant structures.

INTRODUCTION

Current seismic design philosophy tolerates a degree of damage at locations predefined by the designer as long as the safety of inhabitants is assured. Current design specifications reduce construction costs by tolerating plastic deformations at predefined locations (called plastic hinges). Observations of damage to structures following the Canterbury earthquakes (Chouw and Hao, 2012), confirmed that the structures designed to seismic design standards will behave as the designer intended.

Figure 1 shows two adjacent buildings minimal visible damage from the outside. However, inside the buildings RC beam-column joints suffered damage as the designer intended, while the occupants remained safe. However, repair costs are often high (90% of the new building value). In addition, costs accrue because structures and infrastructure are no longer fit for purpose (down time). These costs are considerably difficult to predict.
To avoid these unpredictable costs due to down time of the structures which can easily paralyze the whole city, a low-damage philosophy has been proposed. One possible way to achieve low-damage earthquake-resistant structures is to permit partial separation (uplift) of the footing of the structure, while responding to earthquake loading. Consequently, the structure itself will also temporarily separate from the ground. This separation can lead to significantly less damage, and this has been confirmed by observations after major earthquakes.

The first bridge with the capability to separate at its footings was the South Rangitikei Viaduct, built in the North Island of New Zealand (Beck and Skinner, 1973). The bridge has the ability to perform out-of-plane rocking. Because of the separation at the footings before elastic damage is incurred, rigid-body movements of the bridge structures are activated. Consequently, little or no local deformation along the bridge piers occurs. The impact of the earthquake and the corresponding resulting damage is thus significantly reduce or even entirely avoided.

Chen et al. (2016) presented the most recent research outcomes. The authors focused on the impact of near-source earthquakes on upliftable bridges. This research is especially important because near the earthquake source, the vertical component of the ground surface motions can be much stronger than those components in the horizontal directions. The influence of a simultaneous excitation of high-frequency and strong vertical component and horizontal components has hitherto seen little investigation.

Another example of an upliftable structure is the chimney near the Air New Zealand hanger at Christchurch airport (Figure 2). The chimney can separate at the base when it experiences ground motions larger than a predefined threshold. Despite a number of large earthquakes and more than 10,000 aftershocks following the Canterbury earthquakes, including strong aftershocks such as those on the 22 February 2011 and the 25 May 2012, no structural damage has been observed by the author in their field investigations (Chouw and McCue (2012)).

The beneficial effect of temporary and partial separation at the structural support has been confirmed by Qin et al. (2013) in their physical experiments using a shake table. The consequence of footing separation and subsoil for the structural response and for the response of secondary structures were investigated.

Loo et al. (2012, 2014, 2015 and 2016) focused on the seismic performance of upliftable timber walls. To enhance the overall performance, slip-friction connectors are installed at the bottom corners of the wall. To resist the shear force at the base shear keys are implemented around the middle of the wall base. The frictional sliding activated during the wall loading is used to dissipate the energy induced into the wall from an earthquake. Additionally, the slip-friction connectors permit vertical uplift of the wall, and rigid body movement of the wall occurs during this uplift phase. With the slip-threshold of the connectors appropriately defined damage to the wall is thus minimized or avoided altogether. Timber walls with slip-friction connectors thus compare favourably with conventional shear walls, in which the ductility is activated in the form of plastic behaviour, and hence damage to the nail connections.

Ormeño et al. (2015a and b) investigated the consequence of uplift on the interaction between fluid, storage tank and the supporting soil, during strong earthquakes. The temporary separation at the base of the tank will not only activate rigid-body movements of the wall, but also alter the interaction between the fluid and the tank wall. To enhance the damping behaviour of the whole fluid-structure-soil system slip-friction connectors at the base of the tank were considered. The shake table experiments have confirmed the beneficial influence of uplift on the overall seismic performance of the fluid-structure-soil system, while the slip-friction connectors can be used to control the uplift movements.
NATURAL FIBRE REINFORCED POLYMER-CONCRETE COMPOSITES AS EARTHQUAKE-RESISTANT CONSTRUCTION MATERIALS

Static response

To incorporate natural materials as possible construction materials of future earthquake-resistant structures, the University of Auckland Centre for Earthquake Engineering Research (UACEER) has developed a composite of flax fabric reinforced polymer (FFRP) and coconut fibre reinforced concrete (CFRC). Yan and Chouw (2013a and b, 2014) and Yan et al. (2014, 2015a and b) have performed a number of experiments on FFRP-CFRC composite members. In addition to static and dynamic properties of the structural members, the influence of the surroundings, for example UV and sea water, and the durability of the composite have been investigated.

To reduce the impact of dynamic loadings, Chen and Chouw (2015, 2016a and b) proposed the usage of double FFRP confinements of the FFRP-CFRC composite bridge pier. Because of the inner confinement, the amount of CFRC is reduced and the bridge pier thus has less mass. This results in less activated inertia force. Consequently, the bridge pier experiences less impact from the dynamic load.

Figure 3 shows the influence of coconut fibre, flax fibre and double FFRP confinement on the load bearing capacity of a beam. With coconut fibre the mid-span deflection can be increased by almost 100% (compare the dotted line with the bold dashed line in Figure 3(b)). With FFRP confinement the load bearing capacity can be increased by more than 700%. An additional coconut fibre further increases the load bearing capacity and the ductility of the structure. The consequence of inner confinement of the structure for the load bearing capacity can be seen in Figure 3(c). When reaching certain thresholds, slippages take place at the interface between outer FFRP layer and the concrete, but with double confinement the slippage can be entirely avoided (see dotted line in comparison with the solid line).

Dynamic response

To investigate the seismic response of the FFRP-CFRC bridge pier, the ground motion is simulated based upon the Japanese design spectrum for hard soil condition (JSCE, 2000). Figure 4 shows the design spectrum and the response spectrum of the simulated ground motion with similar frequency content.

Figure 3 Bending test. (a) Set-up, influence of (a) FFRP and CFRC and (b) double FFRP confinement

Figure 4 Japanese design spectrum and response spectrum of the ground acceleration
Despite less concrete being used in the bridge pier with double FFRP confinement, Figure 5 clearly shows that the bridge pier with single (FFRP, solid line) and double (DFFRP, dashed-dotted line) confinement perform very similarly. The periods of the responses show hardly any difference. The result indicates that the inner FFRP confinement can compensate for the reduced concrete component without causing too much change in the dynamic properties of FFRP-CRFC and DFFRP-CFRC composite piers.

**Fibre reinforced lightweight concrete**

To further reduce the impact of dynamic loadings on a structure, lightweight volcanic pumice rocks have been considered as both coarse and fine aggregates (see e.g. Anwar Hossain, 2004, Hassanpour et al., 2012, and Hossain et al., 2011). Figure 7 shows the Opak Fault south of Yogyakarta City in Indonesia. The white marks indicate the pumice rocks observed by the author during his field investigation. Figure 8 shows the behaviour of the lightweight concrete. The pumice aggregates can be clearly seen in Figure 8(a). While the concrete without fibre reinforcement simply splits without resistance, coconut fibres clearly hold the concrete together (Figure 8(b)).
LOW-DAMAGE EARTHQUAKE-RESISTANT STRUCTURES USING NATURAL FIBRE REINFORCEMENT

Partial and temporary separation throughout the structure

To reduce the impact of earthquake loading, interlocking blocks have been developed by UACEER (Ali et al., 2012, 2013a and b, Tang et al., 2014). Coconut fibre is used to enhance the performance of the blocks. Whenever the blocks experience excitations that are stronger than they are designed to endure, the blocks separate from adjacent blocks. Consequently, rigid block movements are activated and the impact of the loading is significantly reduced. Figure 6(a) shows one of the developed block. The holes are for the coconut ropes that limit uplift movement so that dislocations of blocks will not take place. Figures 6(b) and 6(c) show the interlocking block column and wall, respectively. Despite the structures having experienced a number of severe earthquake loadings no damage can be observed.

CONCLUSIONS

A brief overview of research activities at the University of Auckland Centre for Earthquake Engineering Research has been provided. The goal is to develop eco-friendly construction materials that can be used in future low-damage earthquake-resistant structures. To reduce the impact of earthquakes, temporary and partial separation at the base or throughout the structure is permitted. The separation activates rigid body movements of the structural members and thus can eliminate the local deformation of the structure. Reduced or even zero local deformation minimises or completely eliminates excessive stresses building up. Consequently, damage to the structure is minimized. The natural materials considered are flax and coconut fibre and pumice aggregates and these are demonstrated to have significant promise as a construction material in seismic resistant structures.

ABSTRACT

Natural fibres and their fibre reinforced polymer (FRP) composites are light-weight and environmentally-friendly materials which can be used as sustainable construction and building materials. Among different natural fibres, coir has the largest toughness which can be used as reinforcement within concrete (i.e. coir fibre reinforced concrete (CFRC)) to increase concrete mechanical properties. Flax has favorable specific tensile properties which are comparable to those of synthetic E-glass fibres, thus flax fibre reinforced polymer composite (FFRP) can be used in the similar ways of glass FRP as reinforcement of different construction structures. A combination of prefabricated FFRP tube and a CFRC core can be formed an innovative steel-free FFRP-CFRC (i.e. FFRP tube encased CFRC) hybrid structure possessing the advantageous of both components. Current study provides an overview of (1) structural performance of FFRP-CFRC hybrid structures under static and dynamic loadings and (2) use of FFRP as external strengthening material of concrete and timber structures.

KEYWORDS

Flax FRP, coir fibre reinforced concrete, timber, confinement, strengthening

INTRODUCTION

Construction industry is the major and most active sector in the worldwide which accounts for the consumption of large amounts of non-renewable resources and the depletion of large amounts of greenhouse gas emission leading to severe environmental issues (Torgal and Jalali 2011). The severe environmental issues calls for the development of sustainable concrete and structures urgently (Yan and Chouw 2012, Yan 2012). In the past decades, bio-fibre reinforced concrete has been widely investigated because the short fibres were able to improve tensile and flexural strength, toughness and impact resistance when being used within cementitious (Yan and Chouw 2013a,b). Among various fibres, coir, because of its highest toughness and the extremely low cost and availability, is a good fibre reinforcement for concrete material, i.e. coir fibre reinforced concrete, termed as CFRC (Yan et al. 2016a). Recently, utilizing bio-fibres from natural resources to replace synthetic fibres (e.g. carbon/glass) for FRP composites application has gained popularity (Yan et al. 2013a, 2013b, 2013e) due to their economic, environmental and social significances (Yan and Chouw 2014a,b). Among different natural fibres, flax provides the best potential combination of low cost, light weight, and high strength and stiffness for structural applications (Yan and Chouw 2015). The specific mechanical properties of flax fibres are comparable and even superior to those of E-glass fibres (Yan et al. 2015a, Yan et al. 2016). Thus, it is realistic to use flax FRP composites for infrastructure application in the ways similar to the glass FRP composites. For example, flax FRP can be used as external strengthening materials of different structures such as concrete and timber and used in innovative structural systems in the configuration of prefabricated tube, i.e., concrete filled FRP tube (CFFT). A combination of prefabricated flax fabric reinforced polymer composite (FFRP) tube and the CFRC core formed a new representative of CFFT (i.e. FFRP tube encased CFRC, FFRP-CFRC) possessing the merits of both components (Yan and Chouw 2014c). Thus, current study provides an overview on the structural performance of FFRP-CFRC structures under static and dynamic loadings, and the use of FFRP as external strengthening materials of concrete and timber structures.
NATURAL FLAX FIBRE REINFORCED POLYMER COMPOSITES USED IN INNOVATIVE HYBRID STRUCTURE

Figure 1 shows a FFRP-CFRC composite structure subjected to axial compression and four-point bending tests. In the FFRP-CFRC, the pre-fabricated tube made of FFRP acts as permanent formwork for fresh concrete and also provides confinement to concrete. In addition, as a protective shell, the tube can prevent the inner CFRC from outer aggressive environmental attacks. Short monofilament coir fibres are the reinforcement within the concrete core to reduce crack width and amounts and in turn modifies the failure mode of the concrete structure from brittle to ductile as a result of fibre bridging effect, see Figure 1(c) (Yan et al 2014c; Yan et al 2015b).

Figure 1 FFRP-CFRC composite specimens subjected to axial compression (a) and four point bending tests (b) and fibre bridge effect (c)

The axial compressive stress-strain curves of plain concrete (PC) and 4-layer FFRP tube confined plain concrete (FFRP-PC), CFRC and 4-layer FFRP-CFRC are displayed in Figure 2. It is clear that the axial stress-strain responses of both FFRP-PC and FFRP-CFRC specimens show a distinct bi-linear manner, namely, an initial linear response and a second ascending linear response connected by a transition zone (Yan and Chouw 2013a,b). When the applied axial stress is low, the stress-strain response of FFRP-PC or FFRP-CFRC is similar to the unconfined PC or CFRC. When the applied stress approaches the peak strength of the unconfined PC or CFRC, the curve enters a short nonlinear transition region where considerable micro-cracks are propagated and the lateral expansion significantly increased in the concrete. The second linear curve of FFRP-PC or FFRP-CFRC displays an ascending branch, indicating the good confinement of the FFRP tube. The linear response in this region is mainly dominated by the structural behaviour of FFRP composites (Yan and Chouw 2013d, 2013e). The compressive strength of unconfined PC and CFRC is 25.8 MPa and 28.2 MPa and the ultimate axial strain at the peak strength is 0.20% and 0.54%, respectively. It shows that the addition of coir fibre increases the compressive strength and the axial strain because of the fibre bridging effect. The ultimate compressive strength of FFRP-PC and FFRP-CFRC is 53.7 MPa and 56.2 MPa, respectively, corresponding to the confinement effectiveness of 2.08 and 2.0 for FFRP-PC and FFRP-CFRC with the tube thickness of 4 layer flax fabric. The data here indicates that the FFRP tube confinement increases the load carrying capacity of PC and CFRC up to 108% and 100%, respectively. The ultimate axial strain of FFRP-PC and FFRP-CFRC is 2.25% and 2.70%, respectively. So, compared with the ultimate axial strain of PC, the axial strain ratio for FFRP-PC and FFRP-CFRC is 11.3 and 13.5, respectively, indicating that the FFRP tube confinement increases the ductility of PC and CFRC remarkably. Therefore, the FFRP tube confinement increases the load carrying capacity and ductility of concrete significantly.

Figure 2 Axial compressive stress-strain behaviour of FFRP-PC and FFRP-CFRC

The transverse load versus mid-span deflection responses of PC, FFRP-PC, CFRC and FFRP-CFRC under four-point bending test are displayed in Figure 3. The PC specimen exhibited a linear response up to failure showing a pure brittle failure of the concrete. The curve was very short indicating the negligible load carrying capacity and deflection of the specimen. For CFRC, the curve also shows a linear response up to the peak load but it followed by a post-softening response, indicating a ductile behaviour of the specimen. It is believed that the coir fiber inclusion is responsible for this post-peak response. For FFRP tube confined concrete specimens, it can be seen
that the response of the confined concrete specimen is dominated by the strength and stiffness of the FFRP tube. Both the FFRP tube confined PC and CFRC specimens possessed a nonlinear load-deflection response before approaching the peak load. Like that of unconfined PC, the FFRP-PC specimen also exhibited a brittle failure as the result of the non-yielding characteristics of FFRP materials. However, on the other hand, the FFRP-CFRC specimen had a post-softening curve with a ductile response, showing the advantageous of coir fibers. For the confined PC and CFRC, it is clear that there were some sudden load drops in the load-deflection curves, which can be explained by the occurrence of the slippage between the concrete core and the FFRP tube. Slippage between the concrete core and the FFRP tube may compromise the ultimate load carrying capacity of the FFRP and concrete composite column. Therefore, special arrangement should be considered to roughen the inner surface of the FFRP tubes to prevent slippage and may further increase the load carrying capacity of the composite column (Yan and Chouw 2013a).

In general, FFRP-CFRC could provide a good alternative to conventional reinforced concrete (RC) in corrosive environments, e.g. highway bridge piers and girders, marine fender piles, poles and overhead sign structures. These structures are periodically subjected to various dynamic actions from heavy vehicles, wind, ocean waves and earthquakes (Yan et al. 2014b, 2014c). The periodic response of a bridge component to, e.g. wind loading, may lead to material fatigue and thus raise safety concerns. A good understanding the dynamic properties of FRP confined concrete structures, like damping and natural frequencies has industrial significance (Yan and Chouw 2014c). Thus, the PC, CFRC, 4-layer FFRP-PC and 4-layer FFRP-CFRC composite beams subjected to hammer-induced vibration tests were considered. Long cylindrical beams were tested to determine the fundamental frequencies of the transversal, longitudinal and torsional vibrations for calculating the dynamic modulus of elasticity and Poisson’s ratio followed ASTM C215 and for determining the damping ratio (Yan and Chouw 2014c). The tested results indicated that with the addition of coir fibre to CFRC, the damping ratio, in the transversal, longitudinal and torsional vibration modes, increases by 362% (from 0.79% to 3.65%), 301% (from 0.93% to 3.73%) and 280% (from 0.86% to 3.27%), respectively, compared with the PC. This data indicates that coir fibre inclusion has a significant influence on the damping of the CFRC composite (Yan and Chouw 2014c). Test results also showed a similar increase pattern of both FFRP-PC and FFRP-CFRC at all the three vibration modes. With an increase in tube thickness from 2-layer to 4-layer flax fabrics, the damping ratios of both FFRP confined PC and CFRC increase. In CFRC, the coir fibre inclusion produces more interfaces and stress transition zones in the cementitious matrix. During vibrations, more energy is dissipated due to the internal friction between the coir fibres and the matrix where more fibre/cementitious matrix interfaces are involved. In addition, concrete is a brittle material with extensive potential micro-cracks and these cracks may open and close during vibration, and the matrix interacts with the fibre surface, resulting in energy loss (Yan et al. 2016b). For FFRP confined concrete, FFRP tube introduces new interfaces between the tube and the concrete core, which may also be responsible for dissipating energy by friction during the vibration, thereby increasing the damping ratio of FFRP confined concrete. Therefore, both coir fibre and FFRP tube improve the damping ratio of the FFRP tube confined CFRC, thus reducing the effect of dynamic loading on the structure.

Due to the excellent dynamic properties obtained from vibration tests, it is expected that the FFRP-CFRC has potential to be seismic-resistant structure, thus, the seismic performance of FFRP-CFRC columns as bridge pier subjected to earthquake loadings was considered using a shake table (Figure 4). Earthquake loadings based on Japanese Design Spectrum for medium soil were considered. Four different sets of earthquake loading (i.e. set 1, 6, 12 and 18) with three different scale factors (i.e. 0.5, 0.8 and 1.0) were applied. Figure 5(a) shows the relative top displacement of FFRP-CFRC columns under one of the simulated ground motions and Figure 5(b) shows the summarized maximum top relative displacement for all the load cases. It can be seen that the maximum top relative displacement in set 6 is even larger than the 5% allowable drift for seismic design of building frames in most design codes, indicating the potential of this FFRP-CFRC as seismic-resistant structure (Yan et al 2014d).

NATURAL FLAX FIBRE REINFORCED POLYMER COMPOSITES AS EXTERNAL STRENGTHENING MATERIALS

For timber structure

Another use of natural FFRP composite as reinforcement is to be external strengthening materials of conventional construction and building materials. For example, FFRP composites in the configuration of = plates can be used external reinforcement of timber structure placed at the bottom section of the wood beams. Figure 6(a) shows the failure modes of 1-, 2- and 3-layer flax FRP plate strengthened wood beams (Douglas fir) under four-point bending and Figure 6(b) shows the micrograph of the flax FRP and wood interface using the Scanning Electronic Microscope (SEM) study. It is clear that all the wood beams strengthened with 1-, 2- and 3-layer FFRP failed with the rupture of the FFRP and wood beam at the middle span. No delamination or debonding failure was observed for tested beams, indicating the good compatibility of FFRP and wood beams. The SEM study also indicates the good interfacial bond between the FFRP and the wood beams. The flexural test results showed that the average peak lateral load of the un-strengthened wood beam obtained from three identical specimens was 3.3 kN, while the value of 1-, 2-, and 3-layer flax FRP strengthened beams was 4.5 kN, 5.5 kN and 6.2 kN, respectively. For the energy under the area of the load-deflection curves, that of un-strengthened wood beam was 20.5 J and the energy of 1-, 2- and 3-layer FFRP strengthened beams was 40.0 J, 67.5 J and 104.4 J, corresponding to an increase of 94.9%, 229.2% and 409.0%, respectively. The FFRP external reinforcement also enhanced the ultimate deflection of the beams significantly, with an increase of 36.2%, 32.1% and 76.2% respectively for the beams with 1-, 2- and 3-layer FFRP strengthening. However, it should be pointed out that the use of FFRP strengthening does not change the failure pattern of the wood, which is still a brittle failure.
For concrete structure

Natural FFRP composites can also be used as external strengthening materials of concrete structures (Huang et al. 2016). Figure 7 shows the relationship between the ultimate compressive strength of the plain concrete confined by FFRP wrappings obtained from uni-axial compression. As can be seen, the increase in ultimate compressive strength is almost proportional to an increase in the number of FFRP wrappings. For the unconfined PC, the average ultimate stress was 20 MPa, while that of the 2-, 4-, and 6-layer FFRP wrapping confined plain concrete was 28 MPa, 37 MPa and 49 MPa, respectively (Yan 2016). Thus, FFRP wrapping is an effective external strengthening material to improve the load carrying capacity of concrete column.

Figure 8 shows the load-deflection responses of PC and CFRC beams strengthened without and with 6-layer FFRP composite plates under three-point (3PB) and four-point (4PB) bending tests. It is clear that the use of FFRP strengthening increased the peak load, deflection and the energy capability of both PC and CFRC beams significantly, i.e. under 4PB, the peak load of 6-layer FFRP strengthened CFRC was 31 kN while that of CFRC without strengthening was only 6.2 kN. Furthermore, the use of FFRP strengthening changed the post-peak response of both PC and CFRC beams. For both PC and CFRC beams without FFRP strengthening, the failure was brittle while the strengthened beams showed somehow a ductile behavior (Yan et al 2015b).
CONCLUSIONS

This study provided a brief overview of using natural flax fibre reinforced polymer composites used in innovative hybrid structure and used as external strengthening materials of concrete and timber structures. In general, the FFRP-CFRP hybrid structures showed their potential to be axial, flexural and seismic-resistant structural members. As external strengthening materials, the use of FFRP in different configurations can improved the ultimate load carrying capacity, deformation and energy dissipation capacity of concrete and timber structures effectively.

ABSTRACT
This paper reports an experimental investigation on flexural strengthening of RC beams with natural flax fabric reinforced polymer (FFRP) composite plates. The experimental variables considered are FRP thickness (4 and 6 layer), the internal steel rebar ratio (0.223% and 0.503%) and the pre-cracking of RC beams (i.e. by applied 80% yielding load of control RC beam before the application of FFRP plates). This study shows that FFRP plates strengthening increased load, deflection and ductility of RC beams remarkably. The enhancement in load and ductility is more pronounced for RC beams with lower steel ratio. All the FFRP strengthened RC beams exhibited a similar failure pattern, namely, initial steel yielding and then rupture of the FRP plates. There was no obvious effect of pre-cracking on the load of the FFRP strengthened RC beams, showing that the effectiveness of FFRP external strengthening materials for retrofitting damaged RC beams (e.g. after earthquake-attack). In addition, the experimental results are compared with the predictions based on the equations given in ACI 440.2R-08 for beams strengthened with synthetic FRP composites.

INTRODUCTION
Nowadays, because of the increased environmental concern, there is an increasing tendency to use natural fibres to replace synthetic glass or carbon fibres as reinforcement materials of FRP composites for civil engineering applications (Dittenber and GangaRao 2012; Yan and Chouw 2013a; Yan et al. 2014a; Cevallos et al. 2015). The advantages of natural fibres are the dependence on non-renewable energy/material sources, lower pollutant emissions, lower cost and greenhouse gas emissions, enhanced energy recovery and biodegradability (Yan and Chouw 2013b). Among natural fibres, flax is widely used fibre reinforcement for FRP because it offers the best potential combination of low cost, light weight, and high strength and stiffness for structural applications (Yan et al. 2014b). Thus, a series of studies were conducted on the structural performance of natural flax FRP composite (FFRP) tube encased coir fibre reinforced concrete hybrid structures (Yan and Chouw 2013b, 2013c, 2013d; Yan et al. 2014c). Previous studies (Yan and Chouw 2013b, 2013c, 2013d; Yan and Chouw 2014; Yan et al. 2014c) showed a good potential of FFRP tube confined concrete as axial, flexural and impact-resistant structural members. The composite structure also showed better structural performance (i.e. energy dissipation and load carrying capabilities) than conventional steel reinforced concrete (Yan and Chouw 2013d). To date, few studies have been considered using FFRP plates as external strengthening materials of RC members. Whether the environmentally-friendly and cheap FFRP composite is effectively for strengthening of existing deficiently-designed RC structures and/or for retrofitting of damaged RC structures after earthquake-attack is a matter of interest. Therefore, this study investigates the flexural performance of RC beams strengthened with externally bonded FFRP plates.

EXPERIMENTAL SECTION
In this study, eight RC beams were constructed. All the beams had a rectangular cross section, with a length of 2000 mm, width of 150 mm and depth of 300 mm. For the beams with FFRP strengthening, three of beams were strengthened with 4 layers of FFRP and the other three beams were strengthened with 6 layers of FFRP. To evaluate the effect of steel reinforcement ratio, two types of steel reinforcement ratio were used: 0.223% and
0.503%, respectively. In addition, two RC beams (FB-5 and FB-6) were pre-cracked by applying 80% of the yield load (this load level can lead to a few small cracks of RC beams but do not cause total loss of load carrying capacity of the RC beams) of the control beam. After pre-cracking, the two RC beams with micro-cracks were then strengthened with FFRP laminates so as to investigate the feasibility of FFRP as external strengthening used to retrofit damaged RC structures after earthquakes.

For dimension of the RC beams is 2000 mm in length, 150 mm in width and 300 mm in height. The length of FFRP sheets used is 1700 mm and the width of the FFRP sheet is 140 mm. The FFRP sheets were glued at the bottom of the pre-treated RC beams with the epoxy resin adhesive. To have the FFRP with a proper workability, three U-shaped FFRP bands were added at both ends of the beam to prevent the main FFRP plate at the bottom of the beam from debonding. The U-shaped FFRP bands (60 mm in width and 700 mm in length) had one layer of FFRP and spaced at 30 mm.

The clear span of the specimens was 1800 mm and the span of the beam between the two loading points was 600 mm. The beams were loaded in four-point bending and tested until failure with a hydraulic actuator. It should be noted that the hydraulic actuator applied concentrated loading on the midpoint of a rigid steel spreader beam. In order to obtain the FRP strain at mid-span, nine strain gauges were stalled on the surface of FRP sheet, which were connected to a data acquisition system to monitor the strain during loading. Moreover, five displacement transducers were used to measure deflection at five different locations in each span, at mid-point, two loading points, and both ends of the beam.

RESULTS AND DIACUSSION

In general, the failure of the tested beams can be divided into two modes. The control beams (CB-1 and CB-2) failed with steel yielding, followed by concrete crushing (Mode I). While the FFRP reinforced beams (FB-1–FB-6) failed with steel yielding, followed by FFRP rupture (Mode II). The capacity of crack load, yield load, ultimate load, deflection at yield load, deflection at ultimate load, deflection at failure, failure mode, ductility index and the energy absorption capacities are listed in Table 1.

Load-Deflection Behaviour and Load-FFRP Strain Relationships

From Figure 1 (a) and Table 1, it is clear that the FFRP reinforcement increases the ultimate load capacity of all the strengthened beams in varying degrees. The specimen FB-1 with 4-layers FFRP and steel reinforcement ratio of 0.223%, compared to the specimen CB-1 with the same steel reinforcement ratio, the ultimate load increases 67.7% from 46.3 kN to 77.7 kN, while the specimen FB-2 with 6-layers FFRP and steel reinforcement ratio of 0.503%, compared to the specimen CB-1 without FFRP but with same steel ratio, it increases 105.1% from 46.3 kN to 95.0 kN. It can be concluded that more layers of FFRP strengthening lead to higher ultimate load capacity of the beams, when comparing the values of these 3 groups: FB-1 and FB-2, FB-3 and FB-4, FB-5 and FB-6. In addition, the increase in ultimate load of specimen FB-3 and FB-4, compared to the specimen CB-2 without FFRP, are 15.5% (from 142.3 kN to 164.3 kN) and 21.1% (from142.3 kN to 172.3 kN), respectively. It should be noted that the steel reinforcement ratio of specimens FB-3 and FB-4 (0.223%) is lower than FB-1 and FB-2 (0.503%). This data here indicates that the increase in the ultimate load capacity for RC beam with low-reinforcement ratio due to FFRP strengthening is larger than that of beam with high-reinforcement ratio. Additionally, it can be seen that the pre-cracking has no obvious effect on the ultimate load carrying capacity of FFRP strengthened beams.
For the deflection behavior, the test results show that specimen FB-2 with 6 layers FFRP has the largest deflection among all specimens. Compared to the control specimen CB-1, the deflection at failure of specimen FB-1 and FB-2 increases 92.3% and 147.4%, respectively. The deflection at failure of FB-3 (22.1 mm) and FB-4 (22.3 mm) are 16.5% and 17.6%, respectively, larger than that of the control specimen CB-2 (19.0 mm). Moreover, the deflection at failure of FB-5 (17.9 mm) and FB-6 (23.9 mm) are slightly higher than of the corresponding deflection of FB-1 and FB-2, respectively. From Figure 1 (a), it is obvious that all FFRP reinforced specimens show a brittle failure in post-peak response with a sharp drop in load with the deflection. This implies the failure of FFRP strengthened beam is determined by the brittle characteristics of FFRP laminates. It also should be pointed out that the same increase in load increment contributes to a larger growth in deflection of the strengthened beams after the yield load.

Figure 1 (b) shows the load-FRP strain relationship at the mid-span of all 6 FFRP reinforced specimens. Compared to FB-1, the strain for FB-2 specimen increases only 2.3%. FB-4 increases 52.0% compared to the strain of FB-3. FB-6 increases 77.8% compared to that of FB-5. This indicates that more layers of FFRP strengthening correspond to a larger ultimate strain. Observing FB-2 (1.34%) and FB-6 (1.60%), pre-cracking slightly increases the ultimate strain. In addition, it is obvious that all specimens, except the pre-cracking specimen FB-5 and FB-6, have a similar and large initial slope. And with load increase, the slope decreases gradually in different speed, which shows that the strain grows faster and faster and the FFRP carries larger and larger load. It is noteworthy that all specimens, except for FB-5, present obvious elastic recovery (the FRP strain decreased rapidly) after reached the ultimate strain in the load-strain curves and that no debonding was observed in test process in all specimens. Similar tends of load-FRP strain relationship were also found in other strain gauges. This is attributed by the fact that the FFRP ruptured, followed with a rapid decrease in strain.

![Figure 1 (a) Load-deflection responses, and (b) mid-span load-FRP strain relationship](image_url)
Ductility Indices and Energy Absorption Capacities

As for ductility, the ductility index $\mu_{dy}$ is calculated with the mid-span deflection at yield load ($\delta_y$) and the mid-span deflection at ultimate load ($\delta_u$). From Table 1, it is clear that all the FFRP strengthened specimens have higher ductility index than the control specimens and the pre-cracking specimens have the highest ductility index. Thus, the FFRP reinforcement has a significant effect on the improvement of ductility for RC beams. In this study, the energy absorption is calculated using the area under the load-deflection curve to measure the ductility. Among all the specimens, FB-4 has the largest energy absorption (2844.2 kN-mm), while the control specimen CB-1 has the smallest energy absorption (369.7 kN-mm). Obviously, the energy absorption of FB-1 (1196.9 kN-mm) and FB-2 (1853.9 kN-mm) is much larger than that of CB-1. The beam FB-3 (2720.7 kN-mm) and FB-4 (2844.2 kN-mm) has slightly small increase compared to that of CB-2 (2055.1 kN-mm) in energy absorption, respectively. In addition, the specimen FB-5 (1094.8 kN-mm) and FB-6 (1821.8 kN-mm) are slightly smaller than FB-1 and FB-2 in energy absorption due to the influence of pre-cracking. Thus, FFRP strengthening is beneficial for the increase of ductility and energy absorption in RC beams.

Prediction of Ultimate Load-Carrying Capacity Based on ACI 440.2R-08

Table 2 listed the experimental ultimate load ($P_{eu}$) and the predicted ultimate load ($P_{up}$) of FFRP reinforced composite beams from ACI 440.2R-08 (ACI 440.2R-08). It is obvious that all the values of $P_{up}$ / $P_{eu}$ are less than 1, which means that the predicted ultimate load are smaller than that of specimen obtained from the experimental results. The difference between the predicted results and the experimental results ranges from 3.0% to 40.0% for all the strengthened beams. Specimen FB-1, FB-2, FB-5 and FB-6 with 4 layers FFRP laminates have slightly smaller differences between the predicted results and the experimental results, while the specimen FB-3 and FB-4 with 6 layers FFRP laminates have larger differences. In general, the ACI 440.2R-08 design guidelines is relatively conservative with a margin for the ultimate load capacity of FFRP reinforced beams.

Comparison with RC Beams with Externally Bonded Synthetic FRP Plates

Table 3 gives the physical and tensile properties of some typical natural fibres and synthetic fibres reported in the literature. It shows that the tensile strength and modulus of flax fibre are larger compared with the tensile strength and modulus of other typical natural fibres like sisal, hemp and jute fibres. The tensile strength and modulus of flax fibre are close to those of E-glass fibres, but still much lower than those of carbon fibres. However, the elongation at failure of flax fibre is larger than that of E-glass or carbon fibre. Regarding the cost, flax fibre is much than that of E-glass or carbon fibre. In addition, the energy consumption for production of one ton of fibre is 2750 MJ, which is only 8.7% and 0.8% that of E-glass and carbon fibre, respectively. However, the use of natural flax fibres is more cost-effective and energy-effective compared with that of E-glass or carbon fibre.

For axial compression, the confinement effectiveness and confinement ratio of natural flax FRP tube confined concrete were compared with those of G/CFRP confined concrete from study of Yan and Chouw (Yan and Chouw 2014b). The tensile properties of G/CFRP composites used in these studies varies from 381 to 4400 MPa and 38.1 to 580 GPa. The compressive strength of the unconfined concrete (25.7 MPa) for FRP confined concrete is close to those (26.2 MPa to 29.8 MPa) used for G/CFRP confined concrete (Pessiki et al. 1997; Wang and Cheong, 2001 and Shehata 2002). The confinement effectiveness and confinement ratio of G/CFRP confined concrete varies from 1.11 to 2.96 and from 0.033 to 0.604. The obtained confinement effectiveness and confinement ratio of FFRP confined concrete are 1.46-2.08 and 0.210-0.566, respectively. Therefore, in axial compression, the confinement performance of natural FFRP on concrete is close to that of G/CFRP on concrete, even the tensile properties of FFRP composites are much lower than those of G/CFRP composites.

For flexural behaviour, Rahimi and Hutchinson (Rahimi and Hutchinson 2001) investigated RC beams strengthened with externally bonded GFRP, CFRP and mild steel plates by four-point bending. Compared with
the ultimate load of the control RC beam with internal steel reinforcement of 1.68%, the increase in ultimate load due to 4-layer CFRP, 6-layer CFRP, 12-layer GFRP and 3-mm thick steel plate strengthening is 28.0%, 73.3%, 48.2% and 40.9%, respectively. For FFRP strengthened RC beams in this study, compared with the ultimate load (463 kN) of control RC beam with internal steel reinforcement of 0.223%, the increase in ultimate load of RC beams due to 4-layer and 6-layer FFRP plate strengthening is 67.8% and 105.2%, respectively. Compared with the ultimate load (142.3 kN) of control RC beam with internal steel reinforcement of 0.503%, the increase in ultimate load of RC beams due to 4-layer and 6-layer FFRP plate strengthening is 15.5% and 21.1%, respectively. Compared the enhancement in ultimate load of RC beams due to externally bonded CFRP, CFRP and steel plates given in Ref. (Rahimi and Hutchinson 2001) with that due to externally bonded FFRP plate in this study, it can be seen that the improvement in ultimate load of RC beams with similar dimension due to externally bonded natural FFRP plates is comparable to that due to externally bonded GFRP and CFRP and is close to that due to externally bonded CFRP plates. However, it is true that the tensile strength and modulus of natural FFRP plates are significantly lower compared with those of CFRP, GFRP and steel.

**CONCLUSIONS**

1. FFRP strengthening increases the deflection of the specimens remarkably. The increase in deflection is more propounded for beams with a lower steel reinforcement ratio. In addition, beams with more FFRP layers have larger deflection.

2. Both ductility and energy absorption increase significantly due to FFRP strengthening compared to the control beams. The increase in ductility and energy absorption is larger in low-reinforcement ratio beams than that in high-reinforcement ratio beams.

3. The pre-cracking by applying 80% of yield load of the control beam slightly increases the deflection at failure, ductility of the beam and ultimate FRP strain of the strengthened beams, but has no obvious effect on the failure mode, ultimate load capacity and energy absorption.

4. The experimental results of ultimate load-carrying capacity are in general agreement with the predictions that computed according to ACI 440.2R-08 design guidelines. However, the ACI 440.2R-08 design guidelines are relatively conservative with the margin ranged from 3.0% to 40.0%, especially for high-reinforcement ratio beams. When the number of FFRP layer increases, the predictions become less accurate.

5. The comparison with RC beams having similar dimension with externally bonded GFRP, CFRP and steel plates indicates that the enhancement in ultimate lateral load carrying capacity due to natural FFRP plates is close to comparable to the GFRP, CFRP and steel plate strengthened beams, although the tensile strength and modulus of FFRP composites are significantly lower than those of CFRP, GFRP and steel.

In general, this study reveals that natural flax fabric reinforced polymer composites as an environmentally-friendly external reinforcement material can be used to retrofit and/or strengthen exiting deficiently-designed and/or damaged RC structures, which might be further extended for the existing masonry and wood structures.

ABSTRACT

Jute-NFRP is remarkably less expensive than conventional FRP, such as CFRP and ARFP, and is less harmful to the environment. This study aims to observe the shear behaviour of RC beams jacketed by Jute fibre sheets, and to develop a new model of shear strength prediction of such RC beams. In the experimental program, a total of six RC beams were tested under a three-point bending load. One control beam was designed with insufficient shear reinforcement. To investigate enhancement of shear strength, five RC beams were strengthened by jacketing one to five layers of Jute-NFRP in shear direction. From the experimental results, shear strength of Jute-NFRP strengthened beams increased in number of NFRP layers. In addition, by shifting the failure mode from brittle shear failure to more ductile failure, it can be demonstrated that Jute-NFRP jacketing is effective for enhancing the shear strength of RC beams approximately 80.2-204%. The experimental results in terms of shear strength were compared with those from existing predicting equations.

KEYWORDS

FRP jacketing, RC beams, natural fibre, jute fibre, shear strengthening, shear strength prediction.

INTRODUCTION

Several reinforced concrete (RC) structures without properly designed shear reinforcement are susceptible to catastrophic shear collapse under severe loading. In recent years, Fibre Reinforced Polymer (FRP) sheets have become increasingly in use for shear strengthening RC structures owing to their high stiffness, strength-to-weight ratios and design flexibility (Vistasp and Lei 2000). Conventional FRPs such as Carbon FRP (CFRP) and Aramid FRP (AFRP) are effective in enhancing shear strength, but their applications in structures is limited mainly by their high initial cost and relatively high environmental impact (Mohanty et al. 2000). Instead of those synthetic FRPs, use of Natural Fibre Reinforced Polymer (NFRP) such as Jute FRP has gained popularity in engineering applications since they are more cost effective and environmental friendly while maintaining high mechanical properties comparable to those of CFRP and Glass FRP (GFRP) used as reinforcement (Sen and Reddy 2013). Although Jute NFRP can be applied in concrete structures, its structural performance for strengthening RC structures has not been clearly investigated to ensure its structural application and safety.

Jute-NFRP sheets usually contain fibres in two orthogonal directions, termed as warp and weft directions. It was found in this study that tensile strength, elastic modulus and fracturing strain are different in the different fibre direction (Tidarut 2015). In the weft direction, their tensile strength and stiffness tend to be stronger than that in the warp direction. This research is therefore aimed to study shear strengthening of RC beams jacketed by Jute-NFRP in only WEFT direction owing to its high strength and stiffness. To examine the structural performances of RC beams jacketed by Jute-NFRP, a total six rectangular beams were prepared including one control specimen without Jute-NFRP jacketing. Five specimens were jacketed with U-wrap shape in which the weft direction was set normal to the member axis with one to five number of Jute-NFRP’s layers. From the experimental results, beams with jute-NFRP jacketing all failed in shear, with improving shear strength. This proved that jute-NFRP effectively increase shear strength with increasing number of layers. This fact proved that Jute-NFRP can
effectively increase shear strength. In addition, the experimental shear strength of RC beams was compared with that obtained from design equation of JSCE code in order to investigate its applicability.

EXPERIMENTAL PROGRAMS

Material Properties

Concrete and Steel Reinforcement

Ready-mixed concrete with the compressive strength of 34 MPa at 14 days was used in the experiment. Steel moulds were prepared, and the size was adjusted with wooden plates placed perpendicularly to the mould’s bottom. Longitudinal reinforcement with diameter of 25 mm had yielding strength of 400 MPa, whereas stirrup with diameter of 6 mm had yielding strength of 240 MPa. Table 1 summarizes the properties of steel reinforcement.

Jute-NFRP and Epoxy Resin

Tensile properties of Jute fibres are imperative in order to consider them as reinforcement. According to Horsangchai et al. 2016, coupon test of Jute-NFRP was conducted considering fibre alignment in both warp and weft directions with fibre density of 1.41 g/cm³. Coupon specimens for WARP and WEFT were denoted as WARP1 to WARP5 and WEFT1 to WEFT5, respectively. From the coupon test, tensile strength, elastic modulus and rupture strain were obtained for ten coupon specimens are shown in Table 2 and Figure 1. The properties of the epoxy resin used in the test to uniformly gather the fibres are shown in Table 3.

RC Beam Test

All six beams were tested under static loading until their failure. Each beam had a shear span \( (a) \) of 500 mm, and cross section of 150 mm × 300 mm \((b \times h)\) with chamfering corner of 13 mm in radius to prevent rupture of fibre sheet and stress concentration at the corners. The shear-span to effective ratio \((a/d)\) was 2.0, representing normal RC beams. In Figure 2, two longitudinal reinforcements were placed parallel to each other in the compression zone, whereas two layers of two longitudinal reinforcements were placed in the tension zone. The stirrups were placed along the main steel reinforcements with spacing of 150 mm. In all six beams, the longitudinal reinforcement and stirrup ratios were 5.14% and 0.28% respectively, and volumetric ratio of Jute-NFRP sheet varied from 0.24% to 1.19% with increasing number of Jute-NFRP layers. The parameters were the number of jute-NFRP layers. Table 2 shows the details of six beams. Strain gauges were attached on stirrups, longitudinal reinforcement and jute-NFRP sheets to measure their strains, especially along where shear cracks were expected to occur. Linear Variable Differential Transducer (LVDT) was used to measure vertical deformation at mid-span. Figure 3 shows the preparation of RC beams and Table 4 shows the details of tested RC beam. The RC beams were denoted as Control for unstrengthened one and WEFT1-WEFT5 for strengthened ones with 1 to 5 layers of Jute-NFRP.

* Note that \( a/d \) = shear-span to effective ratio, \( \rho_{st} \) = longitudinal reinforcement ratio, \( \rho_w \) = stirrup ratio, \( \rho_f \) = Jute-NFRP sheet’s ratio
EXPERIMENTAL RESULTS

Failure Modes
Failure modes before and after removing Jute-NFRP sheets are shown in Figure 4. Figures on the left side show failure modes before removal of Jute-NFRP, and those on the right show failure modes after removal of Jute-NFRP. The control beam failed in anchorage failure with some minor shear cracks. It may be because the main longitudinal reinforcement did not have enough anchorage or hooked length and such reinforcement significantly moved during the loading test. For WEFT 1 and WEFT2, they failed in shear with rupture of Jute-NFRP along the shear cracks. It can also be seen that Jute-NFRP strengthened beams did not fail in anchorage failure since the Jute-NFRP attachment could prevent the movement of the longitudinal reinforcements inside. For WEFT3, WEFT4 and WEFT5, they failed in shear compression failure while no major cracks were observed on the beams’ surfaces and Jute-NFRP sheets. However, some minor cracks were seen on the beams.

![Figure 4 Failure modes of RC beams](image)

Shear Force Components
Relationships between total shear force and vertical deformation at mid-span of RC beams are shown in Figure 5a. Shear strengths of Jute-NFRP jacketed beams are enhanced when increasing the number of Jute-NFRP layers. Deformations at the peak load also increase gradually when increasing the number of layers of Jute-NFRP. Maximum total shear strength and corresponding deformation of strengthened beams are higher than those of control beam, as shown in Fig. 5a. The enhanced total shear strength increases with the amount of Jute-NFRP, by varying from 80.2% to 204% for WEFT1 to WEFT5. This total shear force ($V_{tot}$) consists of shear forces carried by concrete ($V_c$), stirrup ($V_s$) and NFRP sheet ($V_f$), as shown in Eq. (1). Shear forces carried by stirrup and FRP sheet are calculated using strains of stirrup and FRP sheet measured along shear crack, as shown in Figure 2 (see...
strain gauges in circles). Shear force carried by concrete \( (V_c) \) can be obtained by subtracting the shear force carried by stirrup and FRP from the total shear force with \( (V_{tot} - V_s - V_f) \). Figure 5b shows shear forces carried by stirrups and deformations.

Figure 5b shows the relationship between shear force carried by stirrup \( (V_s) \) and deformation at mid-span. Beams with more NFRP layers show smaller \( V_s \)-value at the same deformation. This is because the NFRP delayed the elongation and yielding of stirrups. On the other hand, \( V_s \)-behavior did not fully correspond to number of layers, namely different behavior between 1-2 layers and 3-5 layers. This is owing to the difference of failure mode. WEFT1 and WEFT2 exhibited shear failure, whereas WEFT3, WEFT4 and WEFT5 failed in shear compression failure. This shear compression failure does not show major cracks as shear failure does. In other words, crack opening tends to be smaller in shear compression failure than that of shear failure, resulting in the difference of stirrup elongation. Stirrups in beams with larger number of layers showed larger deformation. It can be observed from \( V_s \)-behavior also that more number of NFRP layers give larger ductility to RC beams.

**Shear forces carried by Jute-NFRP and Concrete**

Figure 6a shows the relationship between shear strength carried by Jute-NFRP \( (V_f) \) and deformation at mid-span. Steady increase in \( V_f \)-value with layer increase can be observed from layers 1 to 4. However, WEFT5 shows small \( V_f \)-value because the strain measured from strain gauges on the fiber sheet could not record the local large strain, so called localization of strain. Other than that, it can be concluded that more layers of NFRP could effectively contribute to shear forces carried by Jute-NFRP and ductility as peak shifts in larger deformation.

Figure 6b shows the relationship between shear strength carried by concrete \( (V_c) \) and deformation at mid-span. \( V_c \)-value tends to be larger when increasing number of NFRP layers. This is because NFRP confined the beam, and more layers of NFRP contributed to larger confinement effect. Observed crack opening is also delayed owing to NFRP. \( V_c \)-value constantly increased with more layers of NFRP, except WEFT4 specimen. It may be due to debonding failure occurring at the compression failure zone. Such debonding could propagate depending on bonding strength of NFRP, which varies in each specimen. Furthermore, \( V_c \)-value is calculated by subtraction of \( V_s \) and \( V_f \) from \( V_{tot} \). It can be explained that as \( V_f \) increased in WEFT3 to WEFT4 while \( V_{tot} \) did not increase, leading to decrease in \( V_c \)-value.

**DISCUSSIONS ON APPLICABILITY OF EXISTING DESIGN EQUATIONS**

To predict shear strength of beam strengthened by Jute-NFRP, shear strength obtained from experiment and JSCE code (2002) are compared. Total shear strength can be calculated from Eq. (1). The concrete and stirrup contributions to shear strength can be calculated as follows:

\[
V_c = 0.2\sqrt{f'_c/1000/d\sqrt{100}}\rho_w (bd) \quad (1)
\]

\[
V_s = A_w f_{we} (\sin \alpha + \cos \alpha) z / s \quad (2)
\]

where \( f'_c \) is the compressive strength of concrete; \( b \) is the width of member; \( d \) is the effective depth of member; \( \rho_w \) is the ratio of transverse steel reinforcement; \( A_w \) is the cross-sectional area of transverse steel reinforcement; \( f_{we} \) is the yielding strength of transverse reinforcement; \( \alpha \) is the angle of transverse steel reinforcement to the member’s axis; and \( z \) is \( d/1.15 \); \( s \) is the spacing of shear reinforcement. The shear contribution provided by FRP sheet is its tensile capacity and is computed based on the shear reinforcing efficiency of the FRP sheet \( (K) \) as shown in Eq. (3).
\[ V_f = KA_f f_{\mu} (\sin \alpha_f + \cos \alpha_f) \frac{\rho_v}{s_f} \]

where \( K = 1.68 - 0.67R \) in which \( 0.4 \leq K \leq 0.8 \) and \( R = \left( \frac{f_{\mu}}{E_f} \right)^{\frac{1}{14}} \left( \frac{f_{\mu}}{E_f} \right)^{\frac{2}{13}} \) in which \( 0.5 \leq R \leq 2.0 \); \( A_f \) is the cross-sectional area of the FRP sheet; \( f_{\mu} \) is the design tensile strength of the FRP sheet (N/mm²); \( s_f \) is the spacing of the FRP sheet; \( E_f \) is the modulus of elasticity of the FRP sheet (kN/mm²); \( \rho_v \) is the volumetric ratio of the FRP sheet; and \( \alpha_f \) is the angle of the FRP sheet to the member axis.

Comparison of shear strength between JSCE code and experiment is shown in Table 5 and Figure 7. \( V_{\text{tot}} \) of JSCE code is quite conservative (range of error = -23.2% to +6.0%). It can be seen that each shear component (e.g., \( V_c \), \( V_s \), and \( V_f \)) also show discrepancies between experimental and predicted values. For shear forces carried by concrete \( (V_c) \), the predicted values are underestimated when compared to the experimental ones. This is partly because the \( V_c \)-equation of JSCE does not consider the confinement effect by jacketing sheet. On the contrary, predicted shear forces carried by Jute-NFRP \( (V_f) \) show overestimated values since the K-factor in JSCE code is based on behavior of conventional FRP such as CFRP and AFRP. In conclusion, the predicting equation for \( V_c \) and \( V_f \) should be modified in case of NFRP for higher accuracy in the future research work.

Figure 7 Comparison between shear strength from experiment and JSCE code (2002)

**CONCLUSIONS**

1. Jute-NFRP is an ideal and effective material to strengthen RC beams with low cost. It enhances shear strength of RC beams. However, more study should be performed in terms of the in-depth behavior of each shear force components.

2. Increasing the number of Jute-NFRP sheet layer can increase the total shear strength and concrete shear strength. The enhancements of total shear strength are from 80.2% to 204% for WEFT1 to WEFT5 beams.

3. The design equation in JSCE code slightly underestimates the shear strength of Jute-NFRP strengthened beams with range of error between -23.2% and +6.0%. However, each shear component, especially shear forces carried by concrete \( V_c \) and shear forces carried by NFRP \( V_f \) should also be revised taking into account confinement effect and various types of NFRP.

ABSTRACT

This paper presents the results of an experimental program on RC beams reinforced by natural composite (Flax technic fiber) for shear resistance by External Bonding method (EB) and modeling results by finite element method in using Abaqus software. A total of 11 beams divided in two groups with the same geometry and with different concrete strength was tested. The composite’s strain was monitored by using strain gauges bonded on high stress zone associated with digital image correlation (DIC) method. The beams have a rectangular section and a 2m span. The following parameters were investigated: (i) ratio of reinforcement by FRP (continuous and non-continuous), (ii) interaction between FRP and transverse steel (stirrup). The results show that the shear resistance capacity of beams reinforced by Flax technic composite significantly increases, from 11% to 28%. The results also show that the presence of stirrups decreases the contribution of composite to the shear resistance of beams. On the modeling using finite element method, the results showed a good similarity / convergence with experimental results of control beams and also of reinforced beams with the perfect bonding interface of composite-concrete. The results of the correlation image method also present good agreement with modeling results obtained by Abaqus.

FRP, RC beams, shear strengthening, Flax technic, natural composite.

INTRODUCTION

In the construction, the composite materials are very popular for the reinforcement of structural or for repairing old structures of external bonding method. The current composite materials which were used for reinforcement of structure are: Carbon-fiber-reinforced polymer (CFRP), Glass-fiber-reinforced polymer (GFRP)… This type of composite presents several advantages like: corrosion resistance, high resistance, easy for application on structure… However, these materials are of petrol origin, thus the production has an unfavorable impact on the environment, and these materials are not recyclable and request millions years for degradation. Today, to answer the question of sustainable development requirement, it is necessary to find a new eco-friendly material that can replace these materials. In collaboration with the project FABILIN at laboratory of composites materials for construction (LMC²), the high-performance flax fiber was studied in this paper. This material was already used in several domains: automobile industries, airline industries to replace some elements of automobiles, planes…

To check the efficiency of Flax fiber on reinforcement of RC structures, the program of test is done on shear strengthening RC beams reinforced by this fiber by external bonding method. The principal objective of this study is the evaluation of the capacity of Flax fiber in shear reinforcement of RC beams. These investigated parameters are: (i) ratio of reinforcement of FRP (continuous vs non-continuous), (ii) strength of concrete, (iii) interaction of FRP and transverse steel (stirrup).

RESEARCH SIGNIFICANCE

The shear reinforcement of RC beams by external CFRP or GFRP bonding method was investigated by several authors (Teng et al., 2009), (Khalifa et al., 1998), (Khalifa and Nanni, 2000),… The failure mode obtained in these experiments was often by debonding of composite reinforcement, so it limit the full used of the high-capacity of CFRP and GFRP. By using natural composites materials for reinforcement RC structure, some studies investigated the flexure reinforcement of RC beam (Bharath and Reddy, 2015),(Sen and Reddy, 2013),(Sandeep kumar et al.,
The results showed a significant enhancement of flexure capacity RC beam. This study will conduct on the shear reinforcement of RC beams by using flax technic fiber.

**EXPERIMENTAL PROGRAM**

**Description of specimens**

A total of 11 samples beams which was divided in two groups (group A and group B) were tested in flexion of three points. All beams have the same geometric configuration: 2m of span, rectangular section 150x250mm², the loading point was found from 0.5m of support for high shear force in this part which considered as zone of the test (Figure 1), the force part of 1.5m length was reinforced with stirrups Ø6 of 50mm spacing to ensure that there is no shear failure in this part. to ensure that there is no flexure failure of control beams during the test, three bars Ø20 was used for longitudinal reinforcement. The differences for each beams were the spacing of stirrups in the zone of test, no stirrups and stirrups of 150mm spacing for group A (A0 and A150), and stirrups at 180mm for all beams of group B (B180); and the strength of concrete for group A and group B were 40MPa and 30MPa respectively.

![Figure 1](image-url) a) Geometry of test, b) Cross section with stirrups, c) Cross section with no stirrups, d) Cross section with FRP

One beam of each series is tested as control beam, and the remaining beams were reinforced by flax technic fiber in using external bonding method –U jacket, and tested as reinforced beams. The configuration of each beam are showed in Table 1:

<table>
<thead>
<tr>
<th>Table 1 Configuration of all beams</th>
</tr>
</thead>
<tbody>
<tr>
<td><img src="image-url" alt="Diagram of beams" /></td>
</tr>
</tbody>
</table>

Note: for reinforced beams, example beam A150-200-3LFRP means: A150-group of beam and spacing of stirrups in zone of test, 200: spacing of sheet composite (‘’cont’’ mean reinforcement continuous), 3LFRP: number of layers LFRP.

**Materials**

Concrete used is prepared in laboratory, standard compression tests on control cylinders revealed a 28-day concrete compressive strength of 40MPa on average for group A and 30MPa on average for group B. The steel reinforcing bars (Ø20, Ø6, and Ø10) is tested in tension according to ASTM A 370 with modulus of elasticity of
200 GPa and yield stress of 520 MPa on average. The mechanical properties of flax technic fiber are provided by tensile test and are showed in Table 2. There are three types of flax’s fibers used for reinforcement: sheet bidirectional 90° (S600 is used for beams A0-cont-2LFRP, A150-cont-2LFRP) and sheet bidirectional 45° (BD700 is used for beam B180-cont-2LFRP-45°) for continuous reinforcement, and strip of 100mm large of tissue unidirectional (UD220) for reinforcement non-continuous. The mechanical properties of composite are tested by tensile test according ISO 527-1. The obtained results are showed in the Table 3.

Test setup and instrumentation

All beams were tested by three points bending test in using hydraulic jack which having a capacity of 500kN. The test was conducted under displacement controlled rate of 1mm/min. The displacements of mid-span and loading point were captured in using LVDT sensors. All data is acquired and recorded in acquisition system VIHAY 5000.

Results and discussion

In Table 4, the contributions in shear resistance of beam from concrete, transverse steel reinforcement, and LFRP reinforcement at ultimate load were showed. Note that the values in this table were obtained based on following assumptions of Eurocode 2: a) the shear resistance of concrete is constant regardless the presence of stirrups or LFRP, b) the shear resistance of stirrups is constant whether the beam is reinforced by LFRP or not. For group A, the results show that the presence of LFRP reinforcement enhance significantly the shear resistance of beam. The maximum gain of the shear contribution of LFRP is 24% on beam A0-cont-2LFRP without stirrups reinforcement and with only reinforced continuous by LFRP. For beams with stirrups reinforcement, the shear gain is 15% for beam A150-cont-2LFRP (with LFRP continuous), and 11% for both A150-150-3LFRP and A150-200-3LFRP (with strip of LFRP). The presence of stirrups decreased the contribution of LFRP for shear resistance of beam. This observation was confirmed in researches of (Mofidi, 2012), (Bousselham and Chaallal, 2006),…For group B, the contribution of LFRP for shear resistance of beams is again confirmed: 28% on beam B180-cont-2LFRP-45° with LFRP reinforcement continuous, and 10%, 19%, 15% on beams B180-200-2LFRP, B180-200-4LFRP, B180-150-4LFRP respectively. For the failure mode, all beams were failed by shear excluding two beams A150-cont-2LFRP and A150-150-3LFRP which failed by flexure.

Figure 2 Load - displacement (group A)  
Figure 3 Load - displacement (group B)
Figure 2 and Figure 3 present the relation between load and displacement for group A and B respectively. At the first elastic phase, all beams have similar values of rigidity. For group A, the shear crack starts at the load about of 75kN with an angle 40° to the beam’s axis. Beams A0-Ref and A0-cont-2LFRP without stirrups reinforcement shows the brittle behavior; as soon as the load reaches the ultimate load, the failure occurs. However, in series A150, with the addition reinforcement of stirrups, the post-failure behavior is more ductile. So with the stirrups reinforcement, post-failure behavior of the beam changes to more ductile mode. This result validates what was observed by (Mofidi, 2012). For group B with stirrups reinforcement of 180mm spacing, all results show a similar elastic behavior up to loading of 55kN. When shear cracks start, the rigidity of beams changes. In this test, the load then continues to increase up to failure.

All beams, reinforced by LFRP, which are failed by shear, present the deboning of FRP (pulling some minor part of concrete away with). No rupture of LFRP is observed.

### MODELING

#### Geometric and materials.

In this part, only modeling results of four beams of group A: control beams and reinforced beams by LFRP continuous are presented in using finite elements method using Abaqus software. Two under-software: Abaqus/Standard (implicit) and Abaqus/explicit are used for modeling of quasi-static problem for comparison of results.

The 3D model is used for three-point-bending test of RC beams under bi-axial loading. The boundary condition and force applications are predefined and the symmetries of geometry and load are used to simulate the model structure and thus save computing times. For concrete, elements type C3D4 with linear function is chosen from Abaqus element library. T3D2 truss-elements-lying embedded in the concrete volume-model stirrups and longitudinal bars. Concrete represent the “host element” in the applied concept of “embedded elements”. Thus no bond slip between reinforced and concrete is assumed. FRP is modeled as elements type S3R with using the perfect bonding with concrete surface. For the boundary condition, verticals direction constraints were blocked at two lines where the supports are on. Loading is applied by displacement controlled with function “smooth step” on surface of loading point to avoid dynamic effect on Abaqus/Explicit. The step time in Abaqus/Explicit is chosen 0.1s to assure the quasi-static problem.

The complex, nonlinear behavior of concrete is described by elastic-yielding damage model ‘concrete damage plasticity’. This model requires the following material functions: stress-strain relations for the uni-axial behaviors under compressive as well as tensile loading including cyclic un-and reloading, and functions for the evolution of the damage variables under compressive and tensile loading. The compressive strength is as in the experimental work: 40MPa. $E_c$ and $f_{ct}$ were calculated by Eurocode:

$$E_c = 22 \left( \frac{f_{cm}}{10} \right)^{0.3}$$  \hspace{1cm}  (1)$$f_{ct} = 0.30 f_c^{2/3}$$  \hspace{1cm}  (2)

The stress–strain relationship proposed by (Wang and Hsu, 2001) is used to model the uni-axial compressive stress–strain curve (Eq.3, Eq.4) and tensile stress–strain curve (Eq.5, Eq.6) for concrete:

1484
\[
\sigma_c = f_{cm} \left[ 2 \left( \frac{\epsilon_c}{\epsilon_{c1}} \right) - \left( \frac{\epsilon_c}{\epsilon_{c1}} \right)^2 \right] \text{ if } \frac{\epsilon_c}{\epsilon_{c1}} \leq 1
\]

(3) \[ \sigma_c = f_{cm} \left[ 1 - \left( \frac{\epsilon_c}{\epsilon_{c1}} - 1 \right)^2 \right] \text{ if } \frac{\epsilon_c}{\epsilon_{c1}} \leq 1 \]

(4)

\[ \sigma = E \epsilon, \text{ si } \epsilon \leq \epsilon_{\text{rupture}} \]

(5) \[ \sigma = f_{ct} \left( \frac{\epsilon_{\text{rupture}}}{E} \right), \text{ si } \epsilon \geq \epsilon_{\text{rupture}} \]

(6)

The behavior of steel reinforcement is assumed perfect elasto-yielding and behavior of LFRP is considered elastic behavior up to failure.

**Results and discussion**

The load-displacement curves obtained for the control beams and the retrofitted beams from experimental and FEM analysis are shown in Figure 4, Figure 5, Figure 6, and Figure 7. Two different methods of calculus is retained implicit and explicit. There is good agreement between explicit method and implicit method results and also between FEM and experimental results for the control beams. For the retrofitted beams by LFRP, the FEM analysis shows a good coherence with experimental results.

![Figure 8 Failure mode: a) A0-Ref, b) A150-Ref](image)
Figure 8 shows the failure mode of control beams: A0-Ref and A150-Ref for the numerical and experimental results. In general, the cracks obtained in the experiments and in the modeling are similar, which indicates that the model can capture the mechanisms of failure in the beams. For the retrofitted beams, the cracks cannot capture by photo because of composite glued on surface of beams. However, the composite’s strain can be measured by the correlation image method. The photos were captured during the test an analyzed with software Icasoft which based on analyses of pixel matrix. Figure 9 shows the result of correction of image and numerical result for the strain of composite. The spec of strain on composite obtained by numerical analysis and of correlation image method are similar. The maximum strain on composite of numerical analysis and correction of image method are 1.1% and 1.0% respectively.

**CONCLUSION**

In this study, Flax technic fiber presents a significant effect in the shear reinforcement of RC beam. The modeling by FEM-Abaqus shows good agreement with experimental results. The following conclusions can be drawn from this study:

- The shear reinforcement by Flax technic composite enhances a significant of capacity of shear resistance of RC beams from 11% to 28%.
- The reinforcement of stirrups decreases the contribution of composite in shear resistance of beams, and changes the post-failure behavior of beams.
- The FEM model can capture the mechanisms of fracture in the control beams and also in the reinforced beam by FRP with perfect bonding interface.

ABSTRACT

This study aims to establish an in-depth understanding of the compressive behaviour of concrete confined with NFRP. The coupon test of the Jute, Hemp and Cotton NFRP was conducted to obtain its elastic modulus and tensile strength. A total of 63 concrete cylinders were jacketed by the Jute NFRP with a varying number of layers (1 to 6 layers) and the fibre alignment in only the WEFT direction. From the experimental results, the compressive strength of the confined concrete in WEFT direction significantly increases to up to 28%, 42%, and 25% for Cotton, Jute and Hemp confinement, respectively. This proves that NFRP is effective and suitable to enhance the confinement effect of concrete, especially Jute-NFRP.

INTRODUCTION

During the Mae Lao Earthquake in Thailand (Mw 6.3), many reinforced concrete (RC) structures designed without seismic codes collapsed catastrophically due to insufficient confinement (see Figure 1). One of the most effective methods to increase such confinement effect is to strengthen structures using fibre reinforced polymers (FRPs) because of their light weight, high corrosion resistance and easy installation. Conventional FRP such as Carbon FRP (CFRP) and Glass FRP (GFRP) can significantly increase strength and ductility of structures. However, such FRPs are considered expensive (e.g., 22 US dollars/kg), causing them to be inappropriate for low-cost buildings. As a result, alternative FRPs made of natural fibres such as Natural FRP (NFRP) are necessary for developing countries since they are cheaper and available in local areas (Cook 1968; Cronier et al. 2005; Takasaki et al. 2013; Tara and Jagannatha 2011; Sabbie et al. 2015). Some of the common natural fibres widely produced in Thailand are jute, hemp and cotton fibres for agriculture and textile industries. These fibres are not only economical (0.45 US dollars/kg) but also environmentally friendly. To date, such NFRP has not been widely implemented in engineering applications due to a lack of intensive study on its structural performance.

This paper aims to investigate the tensile behaviour of three types of NFRP coupons, namely Cotton, Jute and Hemp. Therefore, a total of 30 coupon specimens of Cotton, Jute and Hemp NFRP with WARP and WEFT fibre directions was tested based on JSCE-E541 standard (2000). Another goal of this paper is to evaluate the behaviour of concrete confined by those NFRPs and the enhanced compressive strength due to confinement. A total of 63 concrete cylinders with 100 mm-diameter and 200 mm-height was tested and confined by the NFRP with a varying number of layers (1 to 6 layers) and the fibre alignment in only the WEFT direction. Then, all concrete cylinders were loaded under the axial compression test until they failed. It is found that the compressive strength of confined concrete increased significantly up to 28%, 42%, and 25% for Cotton, Jute and Hemp confinement, respectively. The stress-strain relationships of confined concrete showed bi-linear curves, depending on the number of NFRP layer. All NFRP coupons exhibited an approximately bilinear stress-strain relationship (Figure 4b). The average values of the tensile strength of the Hemp-NFRP in WEFT direction was the highest (179 MPa), whereas the
elastic modulus of the Jute-NFRP in WEFT direction was the largest (16,350 MPa). The ultimate strain of the Cotton-NFRP in WARP direction was the largest (5.2%).

**EXPERIMENTAL PROGRAM**

**Tensile coupon test**

To investigate tensile properties of NFRP, a total of 30 coupon specimens of Cotton, Jute and Hemp NFRP with WARP and WEFT fibre directions was tested based on JSCE-E541 standard (2000), as shown in Figure 2. The coupon specimens were denoted with prefix letters “C” for Cotton, “J” for Jute, and “H” for Hemp (see Table 2). All coupon specimens were coated with epoxy resin, and cured for a week. Grips were attached at the both edges of specimens to prevent from a slippage between specimen and the wedge grip of the tensile machine. An image measurement method was used to capture the tensile strain of each NFRP coupon (Figure 2).

**Concrete cylinders and Instrumentation**

A total of 63 concrete cylinders was casted in three batches consisting 1) Group-1 with Cotton-NFRP confinement (denoted as C1 to C6), 2) Group-2 with Jute-NFRP confinement (denoted as J1 to J6), and 3) Group-3 with Hemp-NFRP confinement (denoted as H1 to H6). In each Group, there were 3 control specimens with a diameter of 100 mm and a height of 200 mm (denoted as Control 1 to Control 3 for the 1st batch to the 3rd batch). The compressive strength was designed to be 21 MPa at 28 days, using normal strength cement with coarse aggregate having maximum size of 20 mm. The NFRP only in WEFT direction were wrapped on the concrete’s surface with overlapping zone of quarter of diameter (see Figure 3a). Strain gauges were mounted on the NFRP surface at the mid-height in vertical and horizontal directions. All cylinder concretes were tested under monotonic concentric compression using Universal Testing Machine (see Figure 3b).

**RESULTS AND DISCUSSION**

**Coupon test results**

From the coupon test, tensile strength, elastic modulus and rupture strain of 30 coupon specimens were obtained. Table 2 summarizes the average tensile properties of all three types of NFRP composites, including their elastic modulus, rupture strain, and tensile strength. There are two values of elastic modulus, namely the initial elastic modulus ($E_1$) for the 1st region and the 2nd stage elastic modulus ($E_2$) for the 2nd region. The NFRP composites failed in either mid-height or end-grip of the specimens (Figure 4a). All NFRP coupons exhibited an
approximately bilinear stress-strain relationships, considering the average values of each NFRP coupons (Figure 4b). The average values of the tensile strength of the Hemp-NFRP in WEFT direction was the highest (179 MPa), whereas the elastic modulus of the Jute-NFRP in WEFT direction was the largest (16,350 MPa). The ultimate strain of the Cotton-NFRP in WARP direction was the largest (5.2%).

Figure 4 Failure modes and average stress-strain relationships of cotton, jute, and hemp NFRP coupon specimens

Figure 5 Failure modes of confined concrete cylinders
Concrete cylinders

Failure modes

Failure modes of confined concrete cylinders tested under monotonic loading are shown in Figure 5. For the first batch of specimens, all the NFRP-confined concretes failed by tensile rupture of the NFRP with a loud noise at the ultimate state. In some Cotton-NFRP and Jute-NFRP confined concretes, slippage between NFRP layers can be observed (see C5, C6, J5 and J6 in Figures 5a and 5b).

Stress-strain relationships

Figure 6 presents the compressive stress-strain curves in both lateral and axial directions for all unconfined and confined concrete cylinders. Both the compressive strength and the ultimate axial strain were significantly enhanced in confined concrete cylinders. Overall stress-strain relationships of NFRP confined concrete cylinders exhibit a bilinear shape. In the 1st region, the stress–strain behaviour of NFRP confined concrete cylinders is slightly similar to the corresponding unconfined ones. In the 2nd region, the curve enters the nonlinear transition region where considerable micro-cracks are propagated in concrete and the lateral expansion significantly increased. The NFRP then starts to confine the concrete core, leading to an increase in compressive strength and ductility of concrete. However, such enhancement can develop at a certain level, depending on the number of NFRP layer. With lower amount of NFRP, confined concrete could exhibit a softening behaviour. On the other hand, they could exhibit an ascending behaviour with higher amount of NFRP. The lateral tensile stress in the NFRP also increases when axial stress increases. Once this lateral stress exceeds the ultimate tensile strength of NFRP obtained from the flat coupon tensile test failure of the NFRP tube starts.

Figure 6 Stress-strain relationships of NFRP confined concrete

Figure 6a shows the stress-strain behaviour of Cotton-NFRP confined concrete cylinders. When applying 1 to 5 layers of Cotton-NFRP, the stress-strain curve after the peak strength shows a rapid softening (e.g. C1-C5) owing to the low confinement. When applying Cotton-NFRP to 6 layers (C6), the confinement increases so that the
stress-strain curve after the peak exhibits an ascending linear behaviour until the fracture of NFRP (see Figure 6a). For Jute-NFRP confined concrete, the stress-strain behaviour also shows significant enhance of compressive strength (see Figure 6b). The softening region after peak strength can be observed in J1-J4, whereas the ascending region after the peak strength can be seen in J5-J6. However, the Hemp-NFRP confined concrete (H1-H6) exhibit only softening behaviour after the peak strength because of a small tensile stiffness $E_{frp} (1.63 \text{ GPa-mm})$ than Cotton-NFRP (2.00 GPa-mm) and Jute-NFRP (2.94 GPa-mm) and premature fracture, leading to insufficient confinement effect.

Overall, the increment in compressive strength of concrete increase significantly up to 28%, 42%, and 25% for Cotton, Jute and Hemp confinement, respectively. It can also be observed that the lateral rupture strain of NFRP jackets measured in compression tests was remarkably lower than the ultimate tensile strain of NFRP coupon specimens. According to Lam and Teng (2004) and Dai et al. (2011), such difference was owing to the deformation non-uniformity of cracked concrete.

Figure 7 presents the comparison between the compressive strength from test and model. Using a linear regression, it is concluded that the compressive strength predicted by current existing model is unconservative, which is approximately 1.42 times of the tested values (see Figure 7). Therefore, the modified equations for several types of NFRP are crucially required in the future research program.

Modelling of compressive strength

For confined concrete design, the ultimate axial compressive strength is one of the significant parameters for engineering design. According to Dai et al. (2011), the compressive strength model was proposed based on Teng and Lam’s model (2003). Dai et al. (2011) proposed the model which is appropriate for both conventional FRPs (e.g., CFRP and AFRP) and large rupture strain FRP (LRS-FRP) such as PET-FRP and PEN-FRP, as shown below:

$$ f'_{cc} = f'_{cu} + 3.5\sigma_l $$

where $f'_{cc}$ = confined compressive strength; $f'_{cu}$ = unconfined compressive strength; and $\sigma_l$ = confining pressure (or lateral stress) of the FRP jacket.
\[
\sigma_i = \frac{\sigma_{b,\text{rup}} t_{frp}}{R}
\]

where \(\sigma_{b,\text{rup}}\) = hoop stress of FRP jacket \((= E_{frp} \varepsilon_i)\); \(t_{frp}\) = nominal thickness of the FRP jacket; and \(R\) = radius of the concrete core; \(E_{frp}\) = secant modulus of NFRP obtained from coupon test; \(\varepsilon_i\) = hoop or lateral strain of NFRP at peak strength obtained from coupon test.

Table 3 shows a comparison between the predicted and the experimental results for the NFRP-confined concretes. The compressive strength equations proposed by Dai et al. (2011) can successfully estimate the strength in the concrete specimens confined with a small amount of NFRP confinement, namely 1 or 2 layers (with percent error of 9.3% to 26.3%). Meanwhile, the model overestimates compressive strength of confined concrete with a larger amount of NFRP, especially C4-C6 (with percent error of 100.2% to 127.6%). This is because the model was generated based on an interpretation of the existing test data of conventional FRP, PEN-FRP and PET-FRP confined concrete.

CONCLUSIONS

This study experimentally investigated the compressive behaviour of Cotton, Jute, and Hemp NFRP confined concrete cylinders (wrapped only in the WEFT direction). The study can be summarized as follows:

1) All NFRP coupons exhibited an approximately bilinear stress-strain relationship in terms of average values. The average values of the tensile strength of the Hemp-NFRP in WEFT direction was the highest (179 MPa), whereas the elastic modulus of the Jute-NFRP in WEFT direction was the largest (16,350 MPa). The ultimate strain of the Cotton-NFRP in WARP direction was the largest (5.2%).

2) In axial compression, NFRP confinement significantly enhances the compressive strength and ductility for confined concrete. The enhancement in strength and ductility increases with an increase in amount of NFRP. The compressive strength of confined concrete increases significantly up to 28%, 42%, and 25% for Cotton, Jute and Hemp confinement, respectively.

3) Cotton-NFRP (with 1-5 layers) and Jute-NFRP (with 1-4 layers) confined concretes under compression exhibit bi-linear stress-strain behaviour with a linear-ascending branch at the first stage, following by softening branch at the second region. When increasing Cotton-NFRP to 6 layers and Jute-NFRP to 5-6 layers, the second regions show ascending behaviour owing to sufficient confinement level. However, only softening behaviour in the second region was observed in Hemp-NFRP confined concrete because of its low elastic modulus and premature fracture.

4) Dai et al.’s model can successfully predict the ultimate compressive strength of NFRP confined cylinders with lower amount of NFRP layer (1 to 2 layers). However, the model is unable to predict the ultimate strength of confined concretes with higher amount of NFRP. The compressive strength predicted by current existing model is unconservative, which is approximately 1.42 times of the tested values. The modified equations for several types of NFRP will be proposed in the future research program.
