ORGANIZERS OF MINI-SYMPOSIA AND SPECIAL SESSIONS

Mini-symposium on Near-Surface Mounted FRP for Structural Strengthening
Zhang, Shi-Shun University of Wollongong Australia
Sena-Cruz, Jose University of Minho Portugal

Mini-symposium on Seismic Retrofit of RC Structures with FRP Composites
Ilki, Alper Istanbul Technical University Turkey
Ferrier, Emmanuel University of Claude Bernard Lyon 1 France

Mini-symposium on Prestressed FRP for Strengthening and New Constructions
El-Hacha, Raafat University of Calgary Canada
Rojib, Hothifa University of Calgary Canada

Mini-symposium on Strengthening of Steel Structures with FRP
Deng, Jun Guangdong University of Technology China
Yang, Yongxin Central Research Institute of Building and Construction Co., Ltd, MCC Group China

Mini-symposium on FRP-Concrete Hybrid Structures
Feng, Peng Tsinghua University China
Yu, Tao University of Wollongong Australia

Mini-symposium on FRP Sandwich Structures in Bridge and Building Construction
Keller, Thomas Swiss Federal Institute of Technology, Lausanne (EPFL) Switzerland

Mini-symposium on Structures Incorporating FRP Composites under Impact/Blast Loading
Remennikov, Alex University of Wollongong Australia
Huo, Jingsi Huaqiao University China

Special Session on FRP Composites in Spatial Structures
Jiang, Tao Zhejiang University China
Gattas, Joe University of Queensland Australia

Special Session on Natural Fibre Composites in Construction
Xian, Gui-Jun Harbin Institute of Technology China
Yan, Libo Technical University of Braunschweig Germany
The Eighth International Conference on Fibre-Reinforced Polymer (FRP) Composites in Civil Engineering (CICE 2016) was held at The Hong Kong Polytechnic University (PolyU), Hong Kong, China on 14-16 December 2016. It marked the 15th anniversary of the CICE conference series, which is the official conference series of the International Institute for FRP in Construction (IIFC). Since its launch in 2001 in Hong Kong, the CICE conference series has previously travelled to Adelaide (2004), Miami (2006), Zurich (2008), Beijing (2010), Rome (2012) and Vancouver (2014). The CICE 2016 conference was jointly organized by the Department of Civil and Environmental Engineering (CEE) and the Research Institute for Sustainable Urban Development (RISUD) of PolyU.

The first CICE conference, held in 2001, was organised by the same department, which was then known as the Department of Civil and Structural Engineering, and also had Prof. J.G. Teng as the Chair of the Organizing Committee. It was at CICE 2001 when a meeting was called by Prof. Teng to explore the establishment of a world-wide learned society for the FRP-construction community, which led to the founding of the International Institute for FRP in Construction (IIFC) in 2003. The CICE conference has been associated with the IIFC as its official conference series since 2003, and the IIFC is now very firmly the premier international learned society for the FRP-construction community. Given this background, it was a special pleasure to have CICE 2016 held on the PolyU campus to commemorate its 15th anniversary when PolyU celebrates its 80th anniversary.

Following the well-established tradition of the series, CICE 2016 provided an international forum for all concerned with the application of FRP composites in civil engineering to exchange recent advances in both research and practice and strengthen international collaboration for the future development of the field. The conference programme comprised about 240 presentations, including 8 Keynote Lectures, 7 Mini-symposia, 2 Special Sessions, and the IIFC Best PhD Thesis Competition in two sessions, in addition to presentations arising from free submissions. The IIFC Best PhD Thesis Competition, which is a new scheme launched recently by the IIFC as a component of the CICE conference, aims to promote research excellence among our new generation of researchers. The proceedings of the conference consist of two parts: (i) a printed volume that contains the abstracts of all papers accepted by the conference; (ii) a USB disk that contains all full papers (or abstracts if full papers were not submitted). It is hoped that this hybrid format can strike a good balance between ease of access and size of the volume. The papers were contributed by researchers from 31 countries around the world and cover a wide range of themes as indicated by the mini-symposium/special session titles and section headings (see Table of Contents).

The success of the conference was due to the support and efforts of many individuals and organizations. On behalf of the Organizing Committee, we would like to thank all authors for their careful preparation of the manuscripts, all Keynote and Invited Speakers for sharing their work and insight at the conference, and all mini-symposium/special session organizers for mobilizing researchers in their specialised areas to attend the conference. All papers submitted for the conference were reviewed by members of the International Scientific Committee and the Organising Committee as well as other experts in the field. The two Committees, as well as the mini-symposium/special session organisers, also generated widespread interest in and support for the conference. We are grateful to all of them for their important contributions to the conference.
In addition to sharing the paper review task, members of the Organising Committee were also most generous with their time in the organization work. As Chairman and Co-Chairman of the Organising Committee, we are indebted to all of them. Special thanks go to the Executive Members of the Organising Committee, including Dr Chiara CECCATO, Dr Wan-Yang GAO, Dr Guan LIN, Mr Yi-Nan YANG and Miss Anisha Tsang (Conference Secretary), who all toiled through a protracted period to ensure the success of the conference.

We have had the pleasure of working closely with the IIFC, the official sponsor of the CICE conference series. The selection of papers for the Best Paper Awards and the IIFC Best PhD Thesis Award Competition were organised mainly through the efforts of the IIFC. We are grateful to the IIFC, particularly its Executive Committee under the leadership of Prof. Jian-Fei Chen, the IIFC President, for their strong support and valuable advice during the organization of the conference. It has been our pleasure to contribute to the continued success of the IIFC.

Thanks are also due to Prof. William Lam, Head of the Department of Civil and Environmental Engineering, for his support to the conference, including the provision of technical and secretarial support at the conference. We are also grateful to the wider community of PolyU for all the support we have received from them.

This conference was held at a time when PolyU had already launched a year-long celebration of its 80th anniversary. The university was established as a Government Trade School in 1937, and has evolved over the past eight decades into one of the top universities in Asia with internationally recognised excellence in civil engineering and many other disciplines. We were pleased to dedicate this conference to the 80th anniversary of PolyU.

Jin-Guang TENG
Chairman, Organizing Committee

and

Jian-Guo DAI
Co-chairman, Organizing Committee
# TABLE OF CONTENTS

| International Scientific Committee | i |
| Conference Organizing Committee | v |
| Organizers of Mini-Symposia and Special Sessions | vi |
| Preface | vii |
| Table of Contents | ix |

## Keynote Lectures

1. **Debonding Failures in FRP-Strengthened RC Structures: Recent Advances and Research Needs**  
   J.F. Chen, G.M. Chen and J.G. Teng  
2. **Durability of FRP Rebars in Aggressive Environments**  
   Brahim Benmokrane and Ahmed H. Ali  
3. **Longevity Design of Major Structures Strengthened/Reinforced with FRP Composites**  
   Zhishen Wu (Recipient of the IIFC Distinguished Lecture) and Xin Wang  
4. **FRP Sandwich Structures in Bridge and Building Construction**  
   T. Keller  
5. **Bio-Based FRP Composites – Do They Have a Place in Construction?**  
   A. Fam and K. Mak  
6. **Future Building – Carbon for Bridges, Roofs and Facades**  
   M. Schlaich and Y. Liu  
7. **Reducing the Cost of FRP RC Research and Development**  
   D.J. Oehlers and P. Visintin  
8. **Fire Behaviour of FRP Structures**  
   J.R. Correia (Recipient of the IIFC Distinguished Young Researcher Award)

## Bond Behaviour

1. **Direct Measurement of Traction-Separation Law of Concrete/Epoxy Interfaces Under Mode-I Loading**  
   Shahrooz Amidi and Jialai Wang  
2. **Assessment of the Bond Quality Between Concrete and FRP Strengthening Systems Using a Novel Nondestructive Test**  
   A. Billon, F. Taillade, M. Quiertant, J.M. Hénault, R. Maurin, J.C. Renaud, E. Merliot and K. Benzarti  
3. **Defect Criticality in FRP/Concrete Bond Joint – A Finite Element Study**  
   C. Tuakta and C. Yoopom  
4. **Effect of Concrete Strength and Amount of Polyurea Resin on Concrete-Strand Sheet Bond**  
   M. Arazoe, A. Kobayashi, Y. Takahashi and Y. Sato  
5. **Improvement of Debonding Behavior Among Low Strength Concrete and Externally Bonded CFRP**  
   M. Lunardelli, T. Leusmann and H. Budelmann  
6. **Experimental Study on Bond Behavior of Externally Bonded BFRP Sheets-Concrete Joints Under Sustained Loading**  
   K. Iwashita, Z.D. Tang, T. Yamauchi, O. Kondo and H. Takami

Xi Chen, Xiangmin Li, Qingfeng Xu, Lingzhu Chen, Rundong Gao and Zhuolin Wang

NUMERICAL ANALYSIS OF RC BEAMS STRENGTHENED WITH PRESTRESSED CFRP LAMINATES
R. Kotynia, S. Serega and K. Lasek

EXPERIMENTAL STUDY OF INTERMEDIATE CRACK DEBONDING FAILURE IN FRP-STRENGTHENED CONCRETE BEAMS
T. Mohammadi, B. Wan and K.A. Harries

COMPREHENSIVE ASSESSMENT OF THE CFRP DEBONDING PROCESS IN STRENGTHENED RC BEAMS BY IRT
A. Bykov, I. Shardakov and A. Shestakov

EFFECT OF U-SHAPE FRP ANCHORAGE ON THE SEPARATION OF BEAM-TYPE CANTILEVER STRENGTHENED WITH CFRP LAMINATE

CFRP STRENGTHENING OF RC BEAMS USING A DUCTILE ANCHORAGE SYSTEM
J.W. Schmidt, J. Krabbe, N.O. Sørensen, K.D. Hertz, P. Goltermann and G. Sas

NUMERICAL ANALYSIS OF BENDING AND SHEAR IN LARGE-SCALE PRE-TENSIONED CONCRETE BRIDGE GIRDERS STRENGTHENED WITH PRE-STRESSED CFRP LAMINATES

CONTRIBUTION OF EXTERNALLY BONDED FRP TO FLEXURAL CAPACITY OF REINFORCED MASONRY WALLS SUBJECTED TO OUT-OF-PLANE LOAD
Z. Aljaberi and J.J. Myers

EXTERNAL STRENGTHENING OF MASONRY SEMICIRCULAR ARCHES BY MONOLAYER PREPREG COMPOSITES
F. Cakir, H. Uysal and K.M. Mosalam

INVESTIGATION OF THE SHEAR BEHAVIOUR OF CONCRETE SLABS STRENGTHENED WITH ETS FRP BARS
X.G. Wang, Y. Zheng, J.B. Yang and C.M. Ma

EFFECT OF SHEAR SPAN-DEPTH RATIO ON BEHAVIOR OF RC BEAMS SHEAR-STRENGTHENED WITH VARIOUS FRP WRAPPING CONFIGURATIONS
W.W. Li and Christopher K.Y. Leung

EXPERIMENTAL INVESTIGATION OF RC BEAMS STRENGTHENED IN SHEAR WITH EXTERNALLY BONDED COMPOSITES
J.H. Gonzalez-Libreros, C. Sabau, L.H. Sneed, C. Pellegrino and G. Sas

A NEW SHEAR STRENGTH MODEL FOR RC DEEP BEAMS STRENGTHENED WITH FRP COMPOSITES
G.L. Wang, M.Z. Chen and W.S. Ding

SHEAR STRENGTHENING OF CONTINUOUS REINFORCED CONCRETE T-BEAMS USING DEEP EMBEDMENT TECHNIQUE
V. Raicev, T.J. Ibell, A.P. Darby, M. Evernden and JJ Orr

SIZE EFFECT IN RC BEAMS SHEAR-STRENGTHENED WITH FRP
W.N. Liu, P.Y. Zhou, G.M. Chen, J.G. Teng and J.F. Chen

A NEW CLOSED-STIRRUP TECHNOLOGY FOR SHEAR STRENGTHENING OF RC T-BEAMS USING CFRP LAMINATES AND ROPE
Georges El-Saikaly, Simon Bourget and Omar Chaallal

AN EXPERIMENTAL INVESTIGATION ON THE SPLAY PORTION OF EMBEDDED FRP TENSION ANCHORS
Ravi Kanitkar, Scott T. Smith and Chris Lewis

FORCE-BASED MODEL FOR STRAIGHT FRP ANCHORS EXHIBITING FIBRE RUPTURE FAILURE MODE
E. del Rey Castillo, M. Griffith and J.M. Ingham
REINFORCEMENT OF OLD STEEL STRUCTURES BY CFRP BONDING – EXPERIMENTAL DETERMINATION OF MODIFIED MODE I STRESS INTENSITY FACTOR
E. Lepretre, S. Chataigner, L. Dieng and L. Gailet

DEVELOPMENT OF REPAIR AND STRENGTHENING METHOD OF STEEL MEMBERS USING VARTM TECHNOLOGY
H. Nakamura, R. Kondo, T. Matsui and Y. Matsumoto

FATIGUE LIFE EXTENSION OF A STEEL PLATE WITH AN EDGE CRACK BY CFRP PLATES BONDING
R. Matsumoto, M. Takemura, T. Ishikawa, Y. Hiratsuka and H. Kawano

FRCM for Strengthening and New Construction

ON TENSILE BEHAVIOR OF FRCM MATERIALS: AN OVERVIEW
B. Ferracuti and F. Nerilli

INFLUENCE OF THE FIBER TYPE AND MATRIX AGE ON THE BONDING OF FRCM COMPOSITE STRIPS APPLIED TO CONCRETE SUBSTRATES
C. Sabau, J.H. Gonzalez-Libreros, L.H. Sneed, G. Sas and C. Pellegrino

SHEAR STRENGTHENING OF RC BEAMS WITH FRCM: WHAT DO WE KNOW SO FAR?
J.H. Gonzalez-Libreros, C. Sabau, L.H. Sneed, C. Pellegrino and G. Sas

STRENGTHENING OF SHEAR DEFICIENT REINFORCED CONCRETE BEAMS WITH TEXTILE REINFORCED MORTAR (TRM)
A. Khan and F. Masood

BONDING BEHAVIOUR AND SHEAR STRENGTHENING EFFECT OF CFRP GRID WITH PCM SHOTCRETE METHOD FOR RC MEMBER
Rui Guo, Shinichi Hino, Shigetada Hatakeyama, Atsuya Komori and Kenshi Taniguchi

STRENGTHENED REINFORCED CONCRETE BEAMS USING FIBER REINFORCED POLYMER GRID AND ULTRA HIGH TOUGHNESS CEMENTITIOUS COMPOSITE
Yuzhou Zheng, Wenwei Wang and Khalid M. Mosalam

EXPERIMENTAL STUDY ON THE MECHANICAL BEHAVIOUR OF CIRCULAR REINFORCED CONCRETE COLUMNS STRENGTHENED WITH FRP TEXTILE AND ECC
Zhong-Feng Zhu and Wen-Wei Wang

THE BEHAVIOR BETWEEN CFRP GRID AND STIRRUP IN RC BEAMS STRENGTHENED BY CFRP GRID AND SPRAYED MORTAR
N.L. Vu, K. Uji and V.D. Tran

TEXTILE REINFORCED MORTAR VERSUS FRP FOR CONFINED CONCRETE: BEHAVIOUR AT ELEVATED TEMPERATURES
G. Cerniauskas, Z. Tetta, D. Bournas and L.A. Bisby

DIAGONAL SHEAR TESTS OF FULL SCALE FRM-STRENGTHENED LIMESTONE MASONRY WALLS
F. Micelli, M.S. Sciolti, A. Dudine, M. Leone and M.A. Aiello

DURABILITY PERFORMANCE OF FRCM COMPOSITE BONDED TO CONCRETE UNDER DIFFERENT ENVIRONMENTAL AGING CONDITIONS
Z.R. Aljazaeri and J.J. Myers

FILIGREE TEXTILE-REINFORCED CONCRETE CONSTRUCTIONS
S. Rempel, N. Will, J. Hegger and J. Bielak

FRP Composites in New Construction

SHEAR TESTING OF GFRP BARS
P. Arczewska, M.A. Polak and A. Penlidis
EXPERIMENTAL INVESTIGATION OF THE SHEAR RESISTANCE OF GFRP COMPOSITE BARS
C. Tan, J. Xu and R. Aboutaha 538

BEARING STRENGTH OF SMALL-DIAMETER SELF-TAPPING FASTENERS IN HYBRID STEEL-FRP CONNECTIONS
T.R. Gentry, J. Anwar, M. Chen and D. Scott 544

INFLUENCE OF USING PITCH-BASED ULTRA-HIGH MODULUS CARBON FIBRES ON THE STRUCTURAL BEHAVIOUR OF FRP REINFORCED CONCRETE SLABS
P. Reiter, B. Zwingmann, Y. Liu and M. Schlaich 551

DEVELOPMENT OF BRAIDED BASALT FRP REBAR FOR REINFORCEMENT OF CONCRETE STRUCTURES
S. Antonopoulou, C. McNally and G. Byrne 557

AXIAL BEHAVIOUR OF CIRCULAR GEOPOLYMER CONCRETE COLUMNS REINFORCED WITH GFRP BARS AND SPIRALS
G.B. Maranan, A.C. Manalo, B. Benmokrane, W.M. Karunasena and P.A. Mendis 563

BEHAVIOUR OF ULTRA HIGH PERFORMANCE STEEL FIBRE CONCRETE REINFORCED WITH POLYMER MATERIALS UNDER COMPRESSION AND FLEXURAL LOADINGS
M. Singh, M.S. Mohamed Ali, A.H. Sheikh, M. Griffith and P. Visintin 569

EXPERIMENTAL AND NUMERICAL STUDY ON THE SHEAR BEHAVIOUR OF GEOMETRICALLY SIMILAR FRP RC BEAMS
Szymon Cholostiakov, Matteo Di Benedetti, Maurizio Guadagnini, Chandan Gowda, Joaquim Barros and Emanuele Zappa 575

AN EXPERIMENTAL STUDY ABOUT THE SHEAR BEHAVIOR OF HIGH STRENGTH CONCRETE BEAMS REINFORCED WITH FRP BARS
H.O.A. Said, Y.A. Hassanean and A.M.A. Moussa 581

STUDY OF THE STRUCTURAL BEHAVIOUR OF ECC FOR LINK SLABS

REUSE OF WASTE GFRP COMPOSITES AS COARSE AGGREGATES FOR CONCRETE
L.C. Bank, A. Yazdanbakhsh, C. Chen and Y. Tian 593

A NOVEL DESIGN: CFRP CONTINUOUS WINDED BAND SYSTEM
Y. Liu, B. Zwingmann and M. Schlaich 599

NEW FRONTIERS FOR THE USE OF FRP REINFORCEMENT IN GEOMETRICALLY COMPLEX CONCRETE STRUCTURES
Saverio Spadea, John Orr and Antonio Nanni 605

PERFORMANCE AND STRENGTH OF PULTRUDED GFRP ANGLE STRUTS SUBJECT TO CONCENTRIC COMPRESSION
D.C.T. Cardoso and B.S. Togashi 612

CHARACTERIZATION OF ROTATIONAL BEHAVIOR OF WEB-FLANGE JUNCTIONS OF PULTRUDED GFRP BRIDGE DECKS
S. Yanes-Armas, J. De Castro and T. Keller 618

EXPERIMENTAL STUDY OF PULTRUDED GFRP BRIDGE DECK WITH DOUBLE CELLS

FLEXURE STABILITY OF PULTRUDED GFRP I-SHAPES
J.D. Vieira, T.Q. Liu and K.A. Harries 630

COMPARISON OF BOLTED AND BONDED CONNECTIONS BETWEEN GFRP PULTRUDED PROFILES AND CONCRETE USING DIC
S. Bel, A. Koziak and B. Jurkiewicz 636

STATIC PERFORMANCE OF AN ALL-COMPOSITE MODULAR COMPOSITE BEAM UNDER POSITIVE AND NEGATIVE BENDING SCENARIOS
Sindu Satasivam, Colin Caprani and Yu Bai 642
INVESTIGATION INTO THE BEHAVIOR OF REINFORCED CONCRETE BEAMS RETROFITTED WITH FRP FABRICS SUBJECT TO BLAST LOADING 760
M. Saloo, M.Z. Kabir and M.R. Khedmati

Performance in Severe Environments 767

STRENGTHENING EFFECT OF DAMAGED RC BEAM RETROFITTED WITH FRP SHEET DETERIORATED BY SALT ATTACK 768
A. Kamiharako, T. Miura and S. Fukashi

PERFORMANCE OF CFRP-STRENGTHENED CONCRETE IN H2SO4 774
Yongcheng Ji, Yail J. Kim and Jong sung Sim

FLEXURAL BEHAVIOR OF CFRP-REINFORCED CONCRETE BEAMS ATTACKED BY ACID RAIN 780
H.Y. Luan, A. Chen and Y.F. Fan

COMPREHENSIVE BEHAVIOUR OF CFRP-WRAPPED CONCRETE EXPOSED TO CYCLIC WET-DRY ENVIRONMENT 786
Y.C. Guo, J.F. Chen, J.H. Xie and Y.H. Huang

TENSILE PROPERTIES OF BASALT-FIBRE REINFORCED POLYMERS (BFRP) BARS WITHIN SEAWATER AND SEA SAND CONCRETE ENVIRONMENT 791

AN EXPERIMENTAL STUDY ON THE THERMOMECHANICAL AND RESIDUAL BEHAVIOUR OF THE PULTRUDED CARBON FIBER REINFORCED POLYMER LAMINATE SUBJECT TO HIGH TEMPERATURE LOADING 797
P.L. Nguyen, X.H. Vu and E. Ferrier

NUMERICAL ANALYSIS OF THE POST-FIRE STRENGTH OF FRP REINFORCED BRIDGE DECKS 804
H. Hajiloo and M.F. Green

TENSILE PROPERTIES OF GFRP BARS AFTER EXPOSURE TO HIGH TEMPERATURES 810
C.C. Li, J.F. Chen and Y.L. Wang

TEMPERATURE EFFECT ON THE MECHANICAL PROPERTIES OF FRP-WOOD COMPOSITE 816
Ao Zhou and Denvid Lau

TEMPERATURE EFFECTS ON CONCRETE SANDWICH PANELS REINFORCED WITH GLASS FIBRE REINFORCED POLYMERS (GFRP) 821
A. Schmitt, M. Haffke, V. Carvelli and M. Pahn

LONG TERM PERFORMANCE OF GFRP BARS UNDER THE COMBINED EFFECTS OF SUSTAINED LOAD AND SEVERE ENVIRONMENTS 828
Hamed Fergani, Matteo Di Benedetti, Maurizio Guadagnini, Cyril Lynsdale and Cristina Mias

TENSILE PROPERTIES OF CFRP PLATES UNDER HIGH STRAIN RATES 835
Alaa Al-Mosawe, Riadh Al-Mahaidi and Xiao-Ling Zhao

EFFECT OF SHEET VOLUME ON IMPACT RESISTANT CAPACITY OF RC BEAM STRENGTHENED WITH CFRP SHEET 841
Y. Kurihashi, H. Mikami, M. Komuro and N. Kishi

DURABILITY OF DRY AND IMPREGNATED REINFORCEMENT FIBRES EXPOSED TO DIFFERENT ALKALINE ENVIRONMENTS 848
F. Micelli, M. Orsini, A. Dudine and M.A. Aiello

Field Applications 855

A REVIEW OF GEOTECHNICAL APPLICATION OF FIBER REINFORCED POLYMER MATERIALS 856
J.L. Zhou, X. Zhang, H.S. Jiang, M. Bolton and E. Oh
A REVIEW ON DEVELOPMENT AND APPLICATIONS OF HYBRID COMPOSITE PLATE (HCP): A ROBUST RETROFITTING SOLUTION FOR RC MEMBERS
E. Esmaeeli

UPGRADING THE DUNDAS POINT BOARDWALK, APPLECROSS WITH THE USE OF GFRP BAR REINFORCED CONCRETE COLUMNS AND FOOTINGS
J. Brown

FLEXURAL DESIGN OF LIGHT RAIL GUIDEWAY GIRDERS USING ULTRA-HIGH-PERFORMANCE FIBRE-REINFORCED CONCRETE AND GLASS-FIBRE-REINFORCED POLYMER
D. Hubbell and P. Gauvreau

EXPERIMENTAL AND NUMERICAL ANALYSIS OF AN FRP LIGHTHOUSE SUBJECTED TO FREE VIBRATIONS
J.D. Jiménez-Vicaria, P. Sánchez-Sierra, E. Navarro-Lera and C. Paulotto

DURABILITY ASSESSMENT OF FRP BARS EXTRACTED FROM EXISTING FRP BRIDGE STRUCTURES EXPOSED TO FIELD CONDITIONS
W. Wang and J.J. Myers

BRIDGE RETROFIT WITH FRP MATERIALS – FIFTEEN YEARS OF EXPERIENCE
I.E. Harik and A. Peiris

DEVELOPMENT OF GFRP TRUSSED INSPECTION PATH WITH 10-M LONG SPAN
Y. Ishii, H. Nakamura, K. Koizumi, Y. Furuya, H. Nakai and M. Nishida

STRUCTURAL STRENGTHENING OF BRIDGE STRUCTURE USING FRP AND ITS LONG TERM PERFORMANCE – A CASE STUDY
Faye Qiao, Gary Lee, Kevin Tang, Jinsong Wang and Scott Arnold

Mini-symposium on Near-Surface Mounted FRP for Structural Strengthening

BOND ON NSM CFRP SYSTEMS: RECENT CONTRIBUTIONS OF UMINHO ON DURABILITY, QUALITY CONTROL AND DESIGN
(Invited Presentation)
J. Sena-Cruz, P. Fernandes, M. Coelho, P. Silva, J. Granja, A. Benedetti, M. Azenha and L. Neves

FATIGUE BEHAVIOR OF NSM CFRP-STRENGTHENED REINFORCED CONCRETE BEAMS
C. Chen and L. Cheng

BEHAVIOUR OF CONCRETE BRIDGE DECK SLABS STRENGTHENED WITH NSM FRP BARS
Y. Zheng, L.P. Xia and C.M. Ma

BOND BEHAVIOUR OF NSM CFRP-CONCRETE SYSTEMS: ADHESIVE AND CFRP CROSS-SECTION INFLUENCES
J. Cruz, A. Borojевич, J. Sena-Cruz, E. Pereira, P. Fernandes, P. Silva and A. Kwiecien

EXPERIMENTAL INVESTIGATION OF RC SLABS STRENGTHENED WITH NSM CFRP SYSTEM SUBJECTED TO ELEVATED TEMPERATURES UP TO 80 °C
P. Silva, G. Escusa, J. Sena-Cruz and M. Azenha

ASSESSMENT OF CURRENT GUIDELINE FORMULATIONS FOR FLEXURAL STRENGTHENING OF REINFORCED CONCRETE BEAMS USING NSM REINFORCEMENT
T. D’Antino, A. Limonta and M.A. Pisani

FIRE RESISTANCE OF RC MEMBERS STRENGTHENED WITH NEAR-SURFACE-MOUNTED FRP BARS
Hong Zhu, Kai Zhang, Guanlin Zhu, Yan Liu, Xiaowei Wang and Geliang Chen

INTERACTION FORCES IN RC BEAMS STRENGTHENED WITH NSM FRP ROUND BARS
S.S. Zhang and T. Yu
THREE-DIMENSIONAL FINITE ELEMENT MODELING OF BOND FOR NEAR SURFACE MOUNTED CFRP IN CONCRETE  
L. Zhang and L. Cheng  
960

THE TORSIONAL STRENGTHENING OF RC BEAMS USING THE NSM FRP TECHNIQUE WITH FRP ROPE  
G. Al-Bayati, R. Al-Mahadi and R. Kalfat  
966

FIRE BEHAVIOUR OF NSM-CFRP-STRENGTHENED REINFORCED CONCRETE BEAMS. EXPERIMENTAL AND NUMERICAL STUDY  
J.P. Firmo, J.R. Correia and M. Arruda  
972

Mini-symposium on Seismic Retrofit of RC Structures with FRP Composites  
979

DESIGN MODELS FOR THE STRENGTH, THE STIFFNESS AND THE CYCLIC DEFORMATION CAPACITY OF RC MEMBERS RETROFITTED WITH FRP  
(Invited Presentation)  
M.N. Fardis  
980

CYCLIC STRESS-STRAIN MODEL FOR STEEL REBARS IN FRP-CONFINED CONCRETE CONSIDERING BUCKLING EFFECT  
Y.L. Bai and J.G. Dai  
990

SEISMIC RETROFITTING OF REINFORCED CONCRETE STRUCTURES USING COMPOSITES: FRENCH GUIDELINE  
E. Ferrier, M. Laurent and M. Quiertant  
994

SEISMIC RESPONSE OF AFRP RETROFITTED PRE-DAMAGED AND UNDAMAGED SUBSTANDARD RC COLUMNS IN WEAK-AXIS DIRECTION  
E.C. Seyhan, I. Saribas, C. Goksu and A. Ilki  
999

EXPERIMENTAL AND THEORETICAL INVESTIGATION OF THE SEISMIC BEHAVIOUR OF RC BEAM-COLUMN JOINTS  
Angelo Masi, Giuseppe Santarsiero, Francesco Fabbrocino, Gian Piero Lignola and Gerardo Mario Verderame  
1005

A HYBRID FRP-BASED SYSTEM FOR SEISMIC UPGRADING OF R.C. COLUMNS: EXPERIMENTAL RESULTS AND MICROPLANE BASED NUMERICAL SIMULATIONS  
G. Cersosimo and N. Nisticò  
1012

UNIQUE USAGE OF FRP SHEET TO STRENGTHEN RC WALLS  
S. Kono, H. Watanabe, M. Sakashita, K. Fujikake and H. Tanaka  
1018

RELOCATING THE PLASTIC HINGE AT BEAM COLUMN JOINT INTERFACE INTO THE BEAM IN CFRP STRENGTHENING  
M.K. Rahman, O.S. Arowojolu, M.H. Baluch, A.H. Gadhib and M. Al-Osta  
1024

RESILIENCE RESERVE OF RC COLUMNS EXTERNALLY CONFINED WITH COMPOSITE ROPE OR FRP SHEET UNDER SEISMIC OVERLOADS  
T.C. Rousakis  
1033

ANALYSES OF PLASTIC HINGE REGIONS IN FRP-CONFINED RC COLUMNS UNDER CYCLIC LOADING  
F. Yuan and Y.F. Wu  
1039

SEISMIC RETROFITTING OF RC WALLS EXTERNALLY STRENGTHENED BY FLAX-FRP STRIPS  
E. Ferrier, L. Michel, G. Di Luccio and E. Martinelli  
1045

STRENGTHENING OF RC SHEAR WALLS WITH CFRP STRIPS  
S. Altin, Ö. Anil, Y. Kopraman and M.E. Kara  
1052
FRP PRESTRESSING SYSTEMS FOR FLEXURAL STRENGTHENING OF STRUCTURAL ELEMENTS – A REVIEW

(Invited Presentation)
R. El-Hacha and H. Rojob

TWO EXAMPLES OF POST-TENSIONED CFRP CABLES IN BRIDGE CONSTRUCTION: ONE IN REHABILITATION, ONE IN NEW CONSTRUCTION

U. Meier, R. Brönnimann and P. Anderegg

PRESTRESSING SYSTEM OF MULTI-PLY FRP SHEETS FOR STRUCTURAL STRENGTHENING

C.Y. Zhou, J. Liu and L. Xie

EXPERIMENTAL INVESTIGATION ON RC BEAMS WITH PRESTRESSED NSM SYSTEM

H. Lee, W. Jung and W. Chung

PRESTRESSED NSM CFRP FOR STRENGTHENING A CONSTRUCTED BRIDGE: ANCHORAGE BEHAVIOR FROM MACRO TO MICROSCALE PERSPECTIVES

Y.J. Kim, Y. Ji, J. Kang, J. Park and W. Jung

DEFORMABILITY OF PRETENSIONED PC BEAMS WITH BFRP REINFORCEMENT

M. Mirshekari, T. Donchev, D. Petkova and M. Limbachiya

FATIGUE REPAIR OF METALLIC STRUCTURES WITH A THERMALLY-ACTIVATED SHAPE MEMORY ALLOY (SMA)/ CARBON FIBER REINFORCED POLYMER (CFRP) PATCH

B. Zheng and M. Dawood

PRESTRESSED CFRP FOR FLEXURAL STRENGTHENING OF LARGE-SCALE RC BEAMS VERSUS SELF-PRESTRESSING SMA – A COMPARISON

H. Rojob and R. El-Hacha

FATIGUE LIFE IMPROVEMENT OF INITIALLY CRACKED STEEL PLATES USING CFRP/SMA COMPOSITES EMBEDDED WITH NITI SHAPE-MEMORY ALLOY WIRES

A. Abdy and R. Al-Mahaidi

PRESTRESSING SYSTEMS FOR STRENGTHENING OF CONCRETE AND METALLIC STRUCTURES: RECENT DEVELOPMENTS AT EMPA, SWITZERLAND

M. Motavalli, E. Ghafoori, M. Shahverdi, J. Michels and C. Czaderski

REPAIR OF FATIGUE CRACKS IN STEEL MEMBERS BY UTILISING PRESTRESSED CFRP PATCHES

R. Emdad, R. Al-Mahaidi and X.L. Zhao

NUMERICAL STUDY ON FATIGUE BEHAVIOR OF STEEL PANELS WITH INCLINED CRACK REPAIRED BY PRESTRESSED FRP

N.X. Zhang and T. Chen

DURABILITY OF STEEL BEAMS STRENGTHENED WITH CFRP PLATE

(Invited Presentation)
J. Deng and Y. Xie

EXPERIMENTAL STUDY ON INTERFACIAL BONDING BEHAVIORS BETWEEN ECC AND CONCRETE

Jun Tian and Wen-wei Wang

ANALYSIS OF BUCKLING BEHAVIORS OF CFRP-ALUMINUM HYBRID COLUMNS

L.L. Hu, P. Feng, P. Qian and L.P. Ye

EXPERIMENTAL STUDY ON THE FATIGUE BEHAVIOUR OF CRACKED STEEL BEAMS STRENGTHENED BY DIFFERENT HIGH STRENGTH MATERIALS

ABSTRACT

The external bonding of fibre-reinforced polymer (FRP) reinforcement to reinforced concrete (RC) structures is now widely accepted as a mainstream strengthening technology. In such FRP-strengthened RC structures, the bonded interface between FRP and concrete plays a key role and debonding of the bonded FRP system from the concrete substrate due to interfacial shear and/or peeling stresses often governs their strength. Although a great number of studies have been undertaken on these structures, reliable numerical simulation of debonding failures has only become possible in recent years. This presentation will provide a review of recent advances in understanding and predicting debonding failures in FRP-strengthened RC structures; it will also examine the key research needs in the area. Special attention will be given to the major challenges encountered in the numerical simulation of debonding failures in FRP-strengthened RC structures and the appropriate use of dynamic solution methods in capturing the complex debonding failure process.

ABSTRACT
Fibre-reinforced-polymer (FRP) bars are being used increasingly as internal reinforcement in concrete structures. Despite research and product certification, FRP durability—especially under severe environmental conditions—stands out as the most critical research topic. The lack of appropriate data poses a major obstacle to broader acceptance and mass implementation of FRPs. This paper summarizes the most significant research work published on durability related to FRP internal reinforcement in concrete members. The durability of this type of reinforcement has been extensively investigated over the last two decades. A comprehensive review of the literature, including the degradation mechanisms, accelerated tests for long-term performance, and the effects of environment parameters such as moisture, salt solutions, and alkaline on FRP durability, will be presented and discussed.

KEYWORDS
Durability, FRP bar, environment effect, long-term behavior, reinforced concrete.

INTRODUCTION
The corrosion of steel in concrete has been identified as one of the leading causes of deterioration and structural deficiency (Figure 1a). Repair and restoration costs in the US, Canada, and the majority of European countries constitute a high percentage of total national expenditures on infrastructure. Estimates indicate that the United States spends billions of dollars annually to repair and replace bridge substructures such as piers ($2 billion) and marine piling systems ($1 billion) (Benmokrane et al. 2016). In addition, the U.S. Federal Highway Administration (FHWA) estimates that eliminating the nation’s bridge deficient backlog by 2028 would require an investment of $20.5 billion annually because of corroded steel reinforcement. Canada’s deficit for its municipality infrastructure, which represents 70% of the country’s total infrastructure, was estimated to be $60 billion in 2004, and is expected to grow at $2 billion per year. A relatively recent solution, receiving global attention, is the use of fiber-reinforced-polymer (FRP) composites as cost-effective alternatives to conventional construction materials. Due to their corrosion resistance, light weight, and high strength, FRPs have been widely used in civil infrastructure throughout the world for the last 20 years (Ali et al. 2016). FRP composite materials, consisting of strong, stiff fibers (such as carbon, glass and aramid) impregnated with polymeric resins (such as polyesters, vinyl esters, or epoxies) are being increasingly used in civil-infrastructure applications. Even if FRP reinforcement seems to be a promising solution for corrosion problems, the main issues confronting designers and engineers with respect to using FRP composite materials are their durability qualities and long-term behavior, particularly in civil infrastructure subject to severe environmental conditions. Figures 1(b) and 2 show typical GFRP reinforcing bar and its use in a concrete deck slab, respectively. Despite the fact that the structural integrity of composite bars has been certified, the industry still needs long-term durability data for the material in order for FRP to gain wider acceptance for use in infrastructure applications (Harries et al. 2003). Compared to the large amount of work on the durability of FRP composites originating in the aerospace, chemical, and military industries, there is only a small but growing amount of research concerned with the durability of FRP composites in civil-infrastructure applications. This paper summarizes recent research on various aspects of the durability of FRP composites for use as internal reinforcement for concrete structures. The main topics investigated are related to the effect of different environmental conditions on FRP reinforcement, with the paramount issues being the effects of moisture, alkalis, and saline environments. Most of these parameters have been extensively investigated, and the results can be found elsewhere (Benmokrane et al. 2006, 2011, 2016; Ali et al. 2015; Almusallam et al. 2013).
OVERVIEW

FRPs are heterogeneous combinations (fibre and resin matrix) separated by a distinct interface. The constituents maintain their identities, but the combination produces properties and characteristics beyond that of the constituents, yet highly dependent on fibre–resin cohesion. The resin system acts as a matrix bonding the fibres and spreading the load among individual fibres. It also protects them from abrasion, impact, and environmental conditions. The fibre–resin interface is of paramount importance, requiring sound adhesion to ensure optimal load transfer and long-term performance. This multiphase structure should be taken into account when investigating FRP durability.

FRP-bar durability is a concern for a few reasons. First, FRP bars are still “new materials” compared to traditional steel bars. Second, FRP-bar innovation is ongoing with a need to verify the durability of new materials and seek new FRP bars with higher durability. Third, design codes and building/transportation authorities currently specify a 75- to 150-year life: FRP durability needs to be demonstrated.

Unlike steel, FRP bars are resistant to electrochemical corrosion, although the literature indicates that they could deteriorate due to certain physical (e.g., cyclic or sustained loading, moisture diffusion, and temperature) and chemical (e.g., alkalinity) effects. The degree or rate of damage/deterioration—and its reduced strength, stiffness, and durability—depends on many factors such as fibre type and volume, resin matrix, fibre–matrix interface, manufacturing process, and exposure environments. Degradation processes in FRP bars are typically denoted as fibre dominated; matrix dominated; and interface dominated.

DURABILITY CONCERNS

Although FRPs are resistant to electrochemical corrosion, which severely affects steel, FRP performance can be degraded due to environmental, physical, or chemical conditions, leading to loss of strength and stiffness. The literature (Robert et al. 2009; Robert and Benmokrane 2010) indicates that the FRP performance deteriorates due to certain physical (e.g., cyclic or sustained loading, moisture diffusion, extreme temperature variations) or chemical (e.g., alkalinity) exposure. The degree of damage/deterioration depends on a variety of factors such as fiber type and volume, resin matrix, manufacturing process (curing rate, thermal micro-cracks, porosity, non-impregnated fibers, void content), and exposure environments (Ali et al. 2015). Furthermore, adding FRP composites to concrete structures complicates the durability performance of FRP-reinforced concrete structures.
due to the combined effect of FRP composites, interface, concrete, and various environmental and mechanical conditions. Hence, the whole process of assessing the durability of FRPs, in association with concrete structures, is a very complex and multidimensional task. The necessity of a broad assessment of the durability of FRP composites in association with concrete, and as an individual material, cannot be overemphasized. The following sections attempt to look at various durability aspects of FRP composites, FRP-reinforced concrete members, and the bond between FRP and concrete. To focus on the complexity of the analysis, our discussion focuses solely on three factors influencing durability: fluids (moisture; chemical solutions), alkalinity/salinity, and freeze/thaw cycles.

**Fluids and Moisture**

Concrete containing internal FRP reinforcement is commonly exposed to alternating wet/dry cycles, natural weathering, and sometimes corrosive media. Even if concrete provides an excellent first line of defense, its permeability is high enough to eventually transport moisture and other corrosive elements to the internal reinforcement. In recent decades, the effect of fluids on the performance of FRP composites has been one of the most studied subjects related to composite durability. In general, the sorption of fluids by FRPs depends on fluid types (water, acids, bases), fluid concentration, temperature, external applied stress, type of fiber and resin, interphase, molding process, and state of the material (damage, curing conditions). Ben Daly et al. (2007) showed that the moisture-diffusion process in pultruded composites and the saturation level attained could be related to the presence of fillers and additives in the polymer matrix. It has been proven that the sorption rate is controlled by the matrix’s chemical structure (degree and type of cross-linking, presence of voids), interface/interphase, and manufacturing process. Consequently, researchers have attempted to control the diffusion process by using resin matrices of lower permeability (Benmokrane 2000), modifying the interphase region by using suitable sizing chemistry, or selecting an appropriate molding process to reduce void content. Moreover, moisture ingress can degrade the resin through chemical attack (hydrolysis) or a drop in glass transition temperature. For this reason, fluids affect dominant matrix properties, such as the transverse and shear strengths of FRP composites, and these properties decrease more and more with increased exposure time and temperature.

Glass fibers are particularly sensitive to fluid ingress, since they react to chemical and physical attacks. The level of degradation depends on fiber composition, fluid type and concentration, and exposed temperature. Extensive studies have been conducted on this topic (Chen et al. 2007; Robert et al. 2011, 2010, Robert and Benmokrane, 2010, 2013, 2015). Carbon fibers are not affected by fluid ingress, but the resin matrix is usually affected, the performance of this composite is nevertheless affected. In the case of unidirectional carbon composites, this usually leads to reduced compressive and shear strength, with little impact on tensile strength, since it is especially dominated by the fibers, which are not affected by fluids. Hancox and Mayer (1994) reported minimal weight gain and strength loss for carbon/epoxy specimens exposed to 65% humidity for over four months and to boiling water for over three weeks. Aramid fibers are affected by fluids, mostly at higher temperatures. AFRP composites saturated in water have been reported to lose 35% of their flexural strength at room temperature and up to 55% if stressed and under wet/dry thermal cycles.

**Alkaline and Saline Environments**

The concrete environment is characterized by high alkalinity, with a pH between 12 and 13 depending on the concrete design mixture and the type of cement used (Benmokrane et al., 2006). This alkaline environment damages glass fibers through loss in toughness and strength and increased embrittlement. In general, carbon fibers exhibit the best alkaline resistance, followed by aramid and glass fibers. Glass fibers are damaged due to the combination of two processes: (1) chemical attack on the glass fibers by the alkaline cement environment, and (2) concentration and growth of hydration products between individual filaments. Fiber embrittlement results from nucleation of calcium hydroxide on the fiber surface. The hydroxylation can cause fiber surface pitting and roughness, flaws that severely reduce fibers properties in the presence of moisture. In addition, the calcium, sodium and potassium ions in the concrete pore solution are highly aggressive towards glass fibers. Therefore, the degradation of glass fibers is not only caused by the high pH level, but by the combination of alkali salts, pH, and moisture. Aramid fibers show strength degradation in an alkaline environment. Kevlar 29 exposed to 10% sodium hydroxide solution for 1000 hours loses 74% of its strength. High-modulus aramids such as Kevlar 49 demonstrates better alkaline resistance. Carbon fibers are not supposed to be affected by alkaline solution at any concentration or by water temperatures up to boiling (Judd 1971; Benmokrane et al. 2016). Judd (1971) reported that carbon fibers were resistant to alkaline solutions at all concentrations and all temperatures up to boiling. Carbon tow immersed for 257 days in a very basic 50% sodium hydroxide solution showed variations in strength and elastic modulus of only around 15%. Katsuki and Uomoto (1995) used electron probe microscopy to track the ingress of alkali ions (sodium ions) into aramid-, carbon-, and glass-reinforced vinyl-ester rods. Sodium ions penetrated into the GFRP radially over time. No degradation was noticed in AFRP or CFRP rods immersed for 60 days compared
to GFRP rods. Chin et al. (2001) used energy dispersive X-ray analysis to observe that appreciable amounts of sodium, potassium, and calcium were found within isopolyester specimens exposed to pore solution at 60°C for 60 days. They also noticed, however, no evidence of ion ingress in the vinyl-ester specimen.

Chu and Karbhari (2002) and Chu et al. (2004) conducted studies on characterizing and modeling the effects of moisture and alkalis on E-glass/vinyl-ester composite strips at different temperatures (23°C, 40°C, 60°C, and 80°C). The tensile-strength degradation levels between 35% and 62% of the initial strength. The test results of Gaona’s durability study (2003) conducted on bare GFRP bars showed that the tensile strength of the tested GFRP bars decreased over time when the bars were in direct contact with solutions simulating concrete interstitial solution. Losses up to 24% were measured for bars conditioned in an alkaline solution with a high pH value (12) at 35°C for 50 weeks. Wang (2005) conducted 330 accelerated aging tests on different diameters of E-glass/vinyl-ester reinforcing bars. The samples were conditioned in alkaline solution (pH of 12.6–12.8) and distilled water at 23°C, 40°C and 60°C for 150 and 300 days. No fiber defects were observed in any of the 150-day samples, although matrix cracks were noted in the 300-day samples. Al-Zahrani (2007) investigated degradation in the residual tensile strength of three types of GFRP bars in aggressive solutions. Bare bars were conditioned in four solutions (alkaline, alkaline + seawater, alkaline + sabkha, and acidic) at three different temperatures for 3–12 months. The maximum reduction in the tensile strength ranged between 27% and 71% in the alkaline environment and sabkha at 60°C. In the case of thermal variation and outdoor exposure, the reduction ranged from 5% to 21%. Kim et al. (2008) conducted a short-term durability test on two types of commercially available bare GFRP bars (E-glass/vinyl-ester) under four different environmental conditions (moisture, chloride, alkali, and freeze/thaw cycling) for up to 132 days. In addition to the room temperature (25°C), elevated temperatures of 40°C and 80°C were employed to accelerate the degradation of the GFRP bars. They concluded that an alkaline environment had greater impact on the degradation of the tensile strength of GFRP bars than the other influencing factors.

Robert et al. (2013) studied the mechanical, durability, and microstructural characterization of unstressed glass-fiber-reinforced-polymer (GFRP) reinforcing bars exposed to a concrete environment and saline solutions under accelerating conditions. These conditionings were used to simulate the effect of seawater and deicing salts on GFRP bars. The results revealed no significant differences in the durability of the concrete-wraped GFRP bars, whether immersed in saline solution or tap water; the GFRP bars in saline solution evidenced very high long-term durability. Benmokrane et al. (2016) conducted a recent study on the durability performance of carbon-fiber-composite-cable (CFCC) tendons exposed to elevated temperature and alkaline environment. Specimens were exposed to alkaline solutions for 1000, 3000, 5000, and 7000 hours at elevated temperatures (22°C, 40°C, 50°C, and 60°C) to accelerate the effect of the concrete environment. The durability performance of the CFCC tendons was assessed by conducting tensile tests on the specimens after different exposure times. The test results revealed a 7.17% reduction in tensile strength after 7000 h of immersion in the alkaline solution at 60°C. The tensile-strength reduction was attributed to the development of microcracks in the epoxy resin as the result of existing defects in the material.

**Durability of GFRP Bars Embedded in Concrete**

Few research studies have investigated the durability of GFRP bars embedded in concrete. Al-Zahrani (2007) subjected small concrete prism specimens (10 x 10 x 100 cm) reinforced with a single embedded centrally GFRP bar to continuous wetting at 30°C in potable water, seawater, sabkha solution, or outdoors for 6–24 months. He observed that the strength reductions were much lower than in the case of bare bars. This reduction ranged between 10% and 35% after 24 months of exposure. The researcher concluded that this behavior could be attributed to the limited availability of moisture around the bars and the lower temperature of the conditioning solutions, which was 30°C for the embedded bars and 60°C for the bare bars. Chen et al. (2007) conducted another durability study on GFRP bars in which bare FRP bars and bars embedded in concrete were exposed to five different solutions. The results showed significant strength loss from the accelerated exposure of both bare and embedded GFRP bars, especially with the solutions at 60°C. Continuous immersion resulted in greater degradation than exposure to wetting/drying cycles. In contrast, freeze/thaw cycles combined with solution exposure produced little degradation in the GFRP bars. Robert et al. (2009) conducted a study on the durability of GFRP bars in moist concrete in which sand-coated GFRP bars with a nominal diameter of 12.7 mm were embedded in concrete and exposed to tap water at 23°C, 40°C, and 50°C for 60 to 240 days. The tensile test results showed decreases in tensile strength of 10% and 16%, respectively, compared to the original tensile strength, after 240 days of exposure at 40°C and 50°C.

In a 2005 field study conducted by Mufti et al., concrete cores were taken from five in-service concrete bridge structures across Canada reinforced with GFRP bars and ranging in age from six to eight years. On the basis of a microscopic and chemical analysis involving simulated laboratory studies with alkaline solutions, they concluded that the concerns about the durability of GFRP in alkaline concrete were unfounded. Recently, the performance of the GFRP bars was assessed by conducting tensile tests on the bars extracted from the concrete prisms after...
exposure to different conditions (Almusallam et al. 2013). In addition, scanning electron microscopy was used to investigate the bar degradation mechanism. The test results after 18 months of specimen exposure showed that both the tap water at 50°C and the alkaline solution at 50°C produced the greatest reductions in the tensile strength of the bars. The two field conditions evidenced almost no degradation in the tensile properties of the bars (Almusallam et al. 2013).

Freezing and Freeze/Thaw Cycles

In general, freezing and freeze/thaw exposures do not affect fibers, although such exposure can affect the resin and the fiber/resin interface. Most studies on this subject were conducted on aerospace materials. The literature indicates that freezing and thawing has very limited impact on pultruded FRP composites. Lord and Dutta (1988) produced an extensive review on material degradation due to low temperatures and freeze/thaw cycles. In general, at low temperatures, complex residual stress arises within FRP composites as a result of matrix stiffening and mismatch of thermal expansion coefficients of the matrix and resin as well as of the FRP and concrete. Residual stresses can cause microcracks in the matrix and fiber/matrix interface, which can grow under low-temperature thermal cycling and coalesce to form transverse matrix cracks and fiber/matrix debonding, leading to degradation of FRP composites. The presence of deicing salt under wet conditions with subsequent freeze/thaw cycling can cause microcrack formation and gradual degradation due to crystal formation and increased salt concentration, in addition to moisture effects that include swelling and drying.

In general, the literature shows that unidirectional tensile strengths decreased in the -10°C to -40°C range, whereas the off-axis and transverse strengths may increase due to matrix hardening. Increasing freeze/thaw cycles have been shown to accentuate residual stresses, resulting in increased crack severity and density. An apparent increase in matrix brittleness and decrease in tensile strength has also been reported (Bennmokrane et al. 1998). In contrast, Shao and Koudi (2002) showed that samples from pultruded GFRP sheets saturated in water provided excellent resistance to freeze/thaw cycles. The authors observed nearly no changes in tensile properties of the FRP composites after 564 cycles between 4.4°C and -17.2°C, even when the samples were saturated with water. Mashima and Iwamoto (1993) studied the change in bond characteristics due to freeze/thaw action on nonmetallic reinforcement composed of synthetic fibers such as carbon, aramid, and vinylon. The bond strength was measured by pullout testing after 200 freeze/thaw cycles. Testing of the 10 x 10 x 10 cm cubic specimens began after 14 days of curing in water at 20°C. Four types of CFRP, GFRP, and AFRP rods and steel reinforcing bars were used in the study. It was determined that the bond strength of the glass-, vinylon-, and carbon-FRP rods were not influenced by freeze/thaw cycles, but the aramid-FRP rods (both braided and coiled types) evidenced a gradual reduction in bond strength of up to about 20% with progressive freezing and thawing. Alves et al. (2010) investigated the durability of FRP bonding to concrete elements subjected simultaneously to 250 freeze/thaw cycles and sustained load. The test results revealed that the combined conditions increased the GFRP–concrete bond strength.

DURABILITY OF GFRP-REINFORCED CONCRETE IN FIELD STRUCTURES

In 2004, ISIS Canada, a Canadian Network of Centres of Excellence, launched a major study to obtain field data on the durability of GFRP in concrete exposed to natural environments. The objective of the study was to provide performance data on a GFRP that has been used in several structures across Canada. Concrete cores containing the GFRP were removed from several five- to eight-year-old exposed structures, and the GFRP’s physical and chemical compositions were analyzed at the microscopic level (first round of tests).

Five ISIS Canada field demonstration structures built in five different provinces (Hall’s Harbor Wharf in Nova Scotia, Joffre Bridge in Quebec, Chatham Bridge in Ontario, Crowchild Trail Bridge in Alberta, Waterloo Creek Bridge in British Columbia) exposed to a wide range of environmental conditions were chosen, (see Figure 3). Their selection reflects a wide range of environmental conditions that are representative of the Canadian climate. Three research teams from four Canadian universities independently performed microanalyses of the GFRP and surrounding concrete. They used a variety of analytical methods to (a) investigate whether or not the GFRP in the concrete field structures had been attacked by alkalis and (b) compare the composition of the GFRP removed from in-service structures to that of control specimens, which were saved from the projects and not exposed to the concrete environment (see Figure 4).

Direct comparisons were carried out with “virgin” GFRP rods preserved under controlled laboratory conditions. The results indicate that no deterioration of the GFRP took place in any of the field demonstration structures included in this study, and that no chemical degradation processes occurred within the GFRP due to concrete alkalinity. The overall conclusion was that the GFRP is durable in concrete. The outcome of this work led to the second edition of the CHBDC allowing GFRP as primary reinforcement and prestressing tendons in concrete structures (CSA S6-14).
In 2009, core specimens of GFRP reinforcement (second round of tests) were collected from three structures of the field demonstration projects studied in the earlier rounds of tests in 2004. These three structures are: Hall’s Harbor Wharf in Nova Scotia, Joffre Bridge in Quebec, and Crowchild Trail Bridge in Alberta. Analytical methods including Scanning Electron Microscopy (SEM), Energy Dispersive X-ray (EDX), Optical Microscopy (OM), Differential Scanning Calorimetry (DSC) and Fourier Transform Infrared Spectroscopy (FTIS) were used to assess the condition of GFRP after 10 to 13 years of exposure to concrete. These analyses were performed to provide further information on the durability of GFRP in field environments as opposed to simulated alkaline environments. These conclusions pertain to the durability of GFRP reinforcement that has been used in Hall’s Harbor Wharf, Joffre Bridge and Crowchild Trail Bridge for a period of concrete exposure ranging between 5 and 13 years: 1) Results from OM did not show any sign of gaps or debonding between the GFRP reinforcing bars and the surrounding concrete in all of the three structures examined. The results also suggest that there were no cracks, slits or fissures in the concrete, indicating that the bond was preserved between the materials; 2) The results from DSC indicate that the structure of the polymer matrix of GFRP reinforcement was not significantly disrupted by exposure to the environment. Neither hydrolysis nor significant changes in the glass transition temperature of the matrix took place after exposure to the combined effects of concrete alkaline environment and the external natural environmental exposure for 10-13 years; 3) The FTIS analyses support the results from the DSC analyses and OM examinations; 4) Micrographs from the SEM analyses did not reveal any signs of physical damage to the fibers, polymer or fiber/matrix interface. The result brings confirmation to the fact that the structures were not exposed to the detrimental effects of alkali attack from the surrounding concrete; 5) Accordingly, results from the EDX analyses do not show traces of alkaline solution within the cross-section of the reinforcement for any of the structures considered.

CONCLUSIONS
Applications of FRP rebar in different concrete structures have proven to be very successful to date. Based on investigational findings, the durability performance of FRP materials is very good in comparison with other, more conventional, construction materials. Field studies have proven that Glass FRP (GFRP) bars are durable in concrete environment and in-service structures. GFRP is the preferred material for concrete reinforcement in North America due to its economical competitiveness and durability.
Future Research

The reported studies show that the fibre–resin interface is of paramount importance, requiring sound adhesion to ensure optimal load transfer and long-term performance. Also, there has been very little research on the synergistic effects (e.g., moisture and load) of the long-term properties of FRP bars; synergistic effects are not typically addressed in current codes and testing standards. Significant effort should be undertaken to study the synergistic effects between environmental factors and loads on both the material and structural scales. Analyzing the interaction between moisture/temperature/stress and damage development will help in developing synergistic models incorporating material variability and in assessing the applicability of Arrhenius-type models. The Arrhenius concept assumes that a single mechanism controls material degradation at all temperatures (below the material’s glass-transition temperature). A new degradation model providing for changing degradation mechanisms over time (due to stress or other environmental factors) needs to be developed for better service-life prediction. With new knowledge and data on the durability of FRP bars, the current design factors and stress limits in codes could be reassessed to economically use FRP bars as concrete reinforcement. Finally, recent ongoing efforts into developing and innovating FRP-bar technology has focused on using new fibres (e.g., basalt fibers, ceramic fibers), high-performance resin systems with low permeability, and new materials such as nanocomposites. These advanced materials are expected to yield benefits over existing FRP bars, while being significantly more cost-effective, yet research is needed to establish and assess their durability.

ABSTRACT

Fiber-reinforced polymer (FRP) composites have been developed as advanced structural materials to achieve high performance and longevity in major structures. However, due to insufficient studies on the evaluation of the service life of FRPs under various conditions, long-term behavior of FRP strengthened/reinforced structures, and the life cycle design of FRPs in major structures has not been well developed. Focusing on the above limitations, the authors’ team has conducted a series of innovative research over the past ten years on developing advanced basalt FRP composites and various stable composite products. Subsequently, are proposing evaluation methods addressing long-term behavior of FRPs under cyclic and sustained load and their enhancement through hybridization, matrix modification, and pretension treatment. Based on the understanding of the long-term behavior of FRP composites, further evaluation of the long-term interface behavior of FRP strengthened concrete structure and their enhancement are herein proposed for the longevity design of strengthening existing RC structures. Meanwhile, to address the longevity design of new construction with FRPs, the philosophy and the methods to realize high performance and longevity of FRP cable supported bridges are introduced.

Advancement of FRP, hybridization, durability, damage controllability, lightweight, longevity.

INTRODUCTION

Fiber-reinforced polymer (FRP) composites are widely known for their high strength, light weight, corrosion and fatigue resistant, and ease of construction in comparison with the conventional steel and concrete materials. In the 1980s, the FRP materials began to be used in the field of civil engineering due to the stimulation of “Concrete Crisis”, which was mainly caused by the problems with steel reinforcement corrosion in concrete structures (Wu et al. 2010). In the mid-1990s, since Japan's Kobe earthquake resulted in a great deal of civil transportation infrastructure disasters, FRP quickly developed into an important means for seismic reinforcement. Since then, structural application of FRPs has been widely studied and explored and extensive research has been carried out in the area of critical physical and in-service properties of FRP and their reinforcement applications (Bakis and Bank 2002; Keller 2003; Hollyway 2010; Wu et al. 2014). The incorporation of FRPs has evolved from the initial retrofitting and reconstruction to building new structures. A wide range of FRP products have developed from FRP fabric/plates, to a variety of forms of fiber composite bars/cables, grids and profiles. The range and the forms of application of FRP’s are being more and more widely explored on internal reinforcements, externally bonded reinforcements, and structural shapes and bridge decks. In addition, preliminary studies of FRPs as a separate structural unit, such as FRP tube truss structures, FRP woven structure, FRP cable large span cable-stayed structure, FRP profile Bridge panel and box girders, have also found applications and new grounds. These structures can significantly reduce the weight of the original structure, enhance the durability and long-term safety of the structure, and can reach the span requirements that cannot be achieved by conventional materials (Meier 1987).

However, although in some aspects the structures with FRP reinforcements exhibit apparent advantages in comparison with structures made with conventional materials, the FRP reinforcements still have not become a major structural material and are not yet being used in major engineering constructions. One of the most significant problems is that although FRP is regarded as the superior material for long-term behavior, there is still a lack of understanding the gap between how to properly design and evaluate FRPs in strengthened or reinforced structures based on service life design. Meanwhile, the insufficient study on the high performance to cost of FRP composites,
Aside from conventional CFRPs, and how to control and design their service life according to structural requirements is also a challenge.

On the other hand, from the perspective of the cost minimization of full life cycle (LCC) of infrastructure, understanding how to control and design for proper service life is a critical factor for building a resource-saving, energy saving and environmental-friendly society. The maintenance and upgrading costs in traditional design life (50-100 years) of large infrastructure systems have become a serious obstacle to the sustainable development of nations. The demand of long service cycle of the infrastructure and the problems of steel corrosion continue to result in huge financial losses world-wide. For instance, in mid-1990s, the infrastructure investment budget of Japan reached 50 trillion yen, and the amount of the investment budget has continued to decrease after 2005. In the future this budget can only be maintained at a scale of 30 trillion yen, while it only meets existing project managements, maintenance, repair and update requirements.

Europe, the U.S., Japan and other developed countries have proposed to implement the design philosophy of minimizing the full life cycle cost (LCC), including construction, custody, use, dismantling the economic costs and environmental costs, early stage of project construction or reinforcement of the social costs, etc., in order to reduce the huge costs of infrastructure maintenance management. Long life design (more than 100 years) has been recognized as one of the most effective methods in order to significantly reduce the upgrading costs, while also largely reducing the resource consumption. Therefore, construction based on longevity design can significantly lower the LCC of structures during their real service life, which greatly benefits sustainable development.

By focusing on the above background work on FRP research and applications, and the longevity design demands for major engineering structures, the evaluation and advancement of FRP composites and their strengthened/reinforced structures will be introduced in this paper.

**LONG-TERM BEHAVIOR OF FRP COMPOSITES**

Long-term behavior of FRP composites mainly depends on the fatigue behavior under cyclic load and creep behavior under sustained load. These two key governing factors can control the service life of structures subjected to the cyclic or working load at high stress level. In the following section these two issues are discussed separately.

**Fatigue behavior**

Fatigue behavior is a key issue and sometimes the controlling factor for the service life in several applications of FRPs in construction under cyclic load, such as FRP cables in cable-supported bridges. However, fatigue behavior of FRP differs from conventional metal materials due to the complex composition of fibers, matrix and interfaces. Thus, focusing on the longevity design of structures, for instance, service life from 100 to 300 years, how to properly evaluate the fatigue behavior of FRPs under long cycles and how to consider the environmental impacts on the fatigue life are necessary and form the basis for structural longevity design. The latest research on fatigue behavior of basalt FRPs as pre-stressing members, is herein introduced. The main focus in this research includes the micro fatigue behavior, macro fatigue performance and the consideration of environmental impacts.

**Fatigue degradation mechanism of FRPs**

*Fatigue-SEM testing device*

A system that can simultaneously perform the fatigue loading test and SEM observation as shown in Figure 1 was developed to clearly identify the damage evolution and its mechanism during the fatigue loading. For transferring the fatigue load to the specimens, a pair of steel wedges was attached to the fatigue servo system and pre-tightened with the specimen. Aluminum shims were used between the wedges and the specimens to smoothen the stiffness change between them and to minimize the risk of grip failure during fatigue testing (Zhao et al. 2016). By using this technique the effect of defects and selecting standardized products for fatigue test can also be excluded.

![Figure 1 Fatigue-SEM testing device setup. (a) SEM Servopulser; (b) Layout diagram of gripping device](image-url)
Fatigue damage propagation under different max stress

The damage propagation patterns during fatigue loading vary under different max stress levels. At high stress level, the fracture of the specimens takes place in the form of progressive fiber breaking, similar to static tensile fracture. At modest stress levels, the short matrix cracks propagate transversely over a few fibers, or along the interface of fiber and matrix, resulting in the initiation of progressive interface debonding. Furthermore, at low stress level, only discontinuous interface debonding occurs due to the propagation of micro cracks in matrix (Zhao et al. 2016).

Fatigue damage propagation under different stress ratios

Fatigue failure mode also depends on the stress ratio. Figure 2 shows three typical failure surfaces at the stress level of 75% for specimens of R=0.8, 0.5 and 0.1 respectively. It can be clearly seen that the control mode of damage is a discontinuous interface debonding at the stress level of 75% for R=0.8. However, the failure modes shift into fibers wearing out and even breaking when the stress ratios decrease.

Fatigue behavior under 2 million and 10 million

A bi-linear phenomenological fatigue model (Harik et al. 2002) is adopted to describe the effect of different property degradation rates (Zhao et al. 2016), as shown in Figure 3. It can be seen that the slopes of the linear and bi-linear lines are not consistent, which indicates the three different failure mechanisms under different periods of cycles, as shown in Figure 4. The prediction with data up to 2×10⁶ cycles is lower than that with all data, which indicates that the degradation rate under fatigue load slows down after 2×10⁶ cycles.

Fatigue life prediction by constant life

As a method for predicting fatigue life, CLD diagrams (Figure 5) are linear or nonlinear interpolation schemes between experimentally obtained S–N curves (like Figure 6) in the mean stress (σ_m)-stress amplitude (σ_a) coordinate system. These diagrams are widely used for demonstrating the effect of stress ratio on the fatigue life and generalizing the predictions for arbitrary stress ratios. Lines through the origin represent data for a specific stress ratio (S-N curves). Lines connecting data points corresponding to a specific fatigue life for different stress ratios are also derived to allow (by interpolation between known data) the prediction of S-N curves at additional R-ratios.
Fatigue behavior of macro FRP composites

Based on the aforementioned damage evolution and mechanism of FRPs under cyclic load, fatigue behavior of FRP tendons, which is a typical form in engineering application, were investigated (Wang et al. 2015a). Following the practical use of FRP tendons, firstly, the applied stress ranges varied from 0.05 \( f_u \) to 0.14 \( f_u \), and the minimum stress level remained constant at 0.35 \( f_u \), to simulate the moderate and severe working conditions in service (El Refai 2013). Secondly, the maximum stress levels applied ranged from 0.6 \( f_u \) to 0.8 \( f_u \) to examine the potential maximum stress for BFRP tendons with a constant stress range of 0.05 \( f_u \) (the maximum stress range in cable-supported bridge Wang et al. (2014a)). Slightly different from the above meso mechanism, the failure mode of FRP tendons is mainly caused by the fiber-matrix interface debonding, which is induced by the propagation of micro cracks in matrix. The stress range greatly affects the fatigue life of BFRP tendons even under relatively low stress levels. Specimens, with a stress range limit of 0.05 \( f_u \) (85 MPa), and a maximum fatigue stress level up to 0.6 \( f_u \), survived after two million cycles (Figure 7). The fatigue behavior of BFRP tendon fulfills the structural requirements of cable-supported bridge structures.

Fatigue behavior of FRP under multi field coupling
Under high stress range

Initial interface damage is introduced after corrosion under marine environment (Figure 8). After one week in the salt solution, only discontinuous interface debonding was observed among the regions of fiber breaking within 50000 fatigue cycles. The interface damage became serious with the aging duration. Long and continuous interface debonding occurred in the specimen after six-weeks in the salt solution within 50000 fatigue cycles. Thus, Marine water action destroys the adhesion between the fibers and the matrix. This interface damage could result in early interface debonding during the fatigue loading.
Under practical stress range

Based on the above fatigue research of BFRP tendon, fiber-matrix interface debonding is the main cause of FRP under practical stress range (0.05 f₀). The fatigue strength degradation of BFRP tendon under a marine environment is mainly caused by the debonding of the fiber-matrix due to Si-O-Si chemical bond hydrolyzation (Figure 9). However, experimental results showed that fatigue strength reduction of BFRP tendons aged at relatively low temperature (25 or 40 °C) was limited (less than 10 %).

Under temperature acceleration

SEM analysis (Figure 10) showed that specimens aged at a high temperature (55 °C) for 63 d exhibited larger corrosive areas and more corrosive channels than the specimens in the other groups. The infiltration of hydrones in the salt solution was accelerated by high temperature, leading to more serious hydrolyzation of the Si-O-Si chemical bond between the fiber and the matrix. However, the fatigue strength of specimens aged at 55 °C for 63 d is 0.52 f₀, which still fulfills the requirements of prestressing application.

Figure 9 Mechanism of fatigue degradation  Figure 10 SEM analysis  Figure 11 Fatigue strength prediction

Prediction of fatigue strength

Using Arrhenius equation, the degradation laws of BFRP tendon can be predicted during the entire service life. The values of the fatigue strength of BFRP tendons were predicted to be 0.41, 0.43 and 0.45 f₀ at northern latitudes of 20°, 40° and 60°, respectively, after aging in marine environments for 100 years, as show in Figure 11. These results provide guidance for the fatigue design of BFRP tendons utilized under a marine environment.

Enhancement of fatigue behavior

Due to the high cost, it is difficult to accept CFRP for a wide range of applications in construction, although it possesses superior properties compared with other FRPs. In order to enhance the utilization efficiency of high performance to cost FRP composites, one of the effective ways is to hybridize basalt or glass fibers with high fatigue resistance fibers like carbon. It is apparently shown that the fatigue behavior can be significantly enhanced by hybridization of carbon and basalt fibers. On the contrary, negative effect on the fatigue behavior was observed for hybridization with carbon and glass fibers (Figure 12 and 13). The interfacial behavior between fibers and matrix plays a critical function in fatigue behavior enhancement (Wu et al. 2010).

Figure 12 S-N curves of different FRPs  Figure 13 Mechanism of hybrid effect

In order to enhance the fatigue and anti-corrosion behavior of FRP composites, matrix modification methods, like rubber particle toughening and Nano-kaolinite clay modifying, can be used. The increases of fatigue life of FRP were observed by modified matrix (Manjunatha et al. 2010). As it is clarified above that cracking in the matrix is the initiation of fatigue damage under service load, the control of matrix cracking is expected to enhance fatigue life of FRP composites.
Creep behavior

Creep is defined as the strain increase of material under sustained stress over a long time. When subjected to a relatively high stress, a creep rupture may take place in the material, which should be avoided in prestressing applications. Due to the viscoelastic properties of FRPs, their creep behavior should be taken into consideration when designed to be used at a sustained stress. Authors’ previous researches on the evaluation of creep behavior of FRP and the enhancement method are introduced below.

Creep development

The relationship of strain and sustained time showed obviously different characteristics upon different levels of stress (Shi et al. 2015a). Under low stress, it was characterized by a first stage of rapid increase of strain and a second stage of long stable low rate of strain increase. Under moderate stress, creep rupture occurred after the second stage. Under high stress, an unstable strain increase in the second stage was characterized (Figure 15). The initial stage of rapid increase of strain was caused by the non-uniformity of fibers in the FRP composite, which causes continuous fracture of fibers under high stress or stress redistribution among the fibers under moderate and low level of stresses (Wang et al. 2014b).

Evaluation of creep and relaxation behavior

Creep behavior is generally evaluated for two aspects: creep rupture stress and creep strain increment rate. As shown in Figure 16, the creep rupture stresses of CFRP and AFRP are 0.7 \(f_u\) and 0.55 \(f_u\) (ACI 440.4R), respectively, making them potentially feasible for prestressing use. However, GFRP is considered unsuitable for prestressing applications, since its creep rupture stress is only 0.29 \(f_u\) (ACI 440.4R). Newly developed basalt FRPs possess a satisfactory creep rupture stress equal to 0.54 \(f_u\) (Shi et al. 2015a), which allows that competitive with CFRP and AFRP in creep behavior. In terms of 1000 h creep strain increment, CFRP performs the lowest among FRPs (Figure 17). The corresponding value of BFRP (1.5 %) is slightly higher than CFRP. The increment rates of AFRP and GFRP are relatively large (7 % and 5 %, respectively). Larger creep strain increment causes larger relaxation loss, which is adverse for prestressing members.

In terms of relaxation behavior, CFRP has only 3 % one-million-hour relaxation rate, which is the lowest among all types of FRPs. However, AFRP performs excessive relaxation rate (12.5 %), which makes it unsuitable for prestressing applications (Zou et al. 2003). The corresponding value of BFRP was predicted to be 6.7 % under initial stress of 0.5 \(f_u\) (Shi et al. 2016). This level of relaxation rate is acceptable in prestressing applications.
Creep behavior under multi field coupling

Marine environment has a negligible effect on the creep strain of FRP tendons at ambient temperature, but a high temperature up to 55 °C accelerates the creep deformation conspicuously (Shi et al. 2015b). At relatively low temperatures such as 25 or 40 °C, the creep rupture behavior of BFRP, after aging in marine environment, shows no degradation, as shown in Figure 18. The largest reduction of creep rupture stress occurs at aging temperature of 40 °C and duration of 9 w, which is only 7%. This phenomenon shows good consistency with the result of fatigue behavior in marine environment. The results demonstrate the feasibility of BFRP tendons applied as prestressing components in marine environment.

Enhancement of creep behavior

The uneven fibers in FRP can be straightened and redistributed during the pretension process because of the viscoelastic deformation of resin, thus, creep behavior can be enhanced through a two-stage pretension treatment during and after production (Figure 19). Authors’ previous research showed that pretension level of 0.6 $f_u$ and duration of 3 h is the optimized pretension condition for BFRP (Wang et al. 2015b). As shown in Figure 20, the creep strain increment rate of FRP was reduced by more than 50% through pretension treatment. Furthermore, the one million-hour creep rupture stress of the pretension-treated BFRP tendons is effectively increased from the original 0.59 $f_u$ to 0.63 $f_u$ (based on experimental fitting) and from 0.52 $f_u$ to 0.54 $f_u$ (according to the reliability analysis). The enhanced creep rupture limit promotes more sufficient use of BFRP tendons (Shi et al. 2015a).

LONG-TERM BEHAVIOR OF FRP-CONCRETE INTERFACE

Debonding of the external FRP is a main failure mode in structures strengthened by FRP. Thus, the long-term behavior of FRP-concrete interface is a key factor controlling the service life of these types of structures. In this respect, authors have done a series of studies, which are presented as follows.
Failure modes

The failure mode of FRP-concrete interface (Figure 21) depends on the loading type and level. At higher fatigue loading levels, fracture propagates along concrete layer. This failure mode is dominated by concrete damage (micro cracks) accumulation. In contrast, at low fatigue loading levels or creep load, interfacial failure develops along the adhesive, which is controlled by the adhesive creep deformation.

Modelling of long-term behavior of FRP-concrete interface

Wu and Diab (2009) proposed some modelling methods to simulate the long-term behavior of FRP-concrete interface. Time-dependent (fatigue and creep) fracture process of the FRP-concrete interfaces was divided into two stages: (1) a debonding initiation stage, which relies on a linear viscoelastic model (Figure 22 (a)) controlled by the time of creep or total number of fatigue cycles and the properties of the adhesive layer; and (2) a time-dependent debonding propagation stage which depends on a bond-slip model (Figure 22 (b)) and a damage accumulation factor.

Throughout the experimental results, the above models showed their ability to predict the debonding and crack propagation along FRP-concrete interface not only under low fatigue and sustained loadings, but also under high loadings (Figure 23). Furthermore, these models gave the opportunity to numerically study the creep and fatigue performance of structures externally strengthened with CFRP sheets taking into account the deterioration effect of FRP-concrete interface.
Degradation of FRP-concrete interface with long-term aging

Water molecules break the hydron bond and VDW of resin/SiO$_2$, leading to lower fracture energy of interface and degradation of bond behavior. As shown in Figure 24, before aging, the failure takes place in concrete, while after aging in water for 360 days, the failure occurs in the adhesive. Degradation of the interface can be clearly demonstrated from the fracture energy with respect to aging duration (Pan et al. 2015).

Enhancement of FRP-concrete interface

Polymer treatment (Figure 25) can enhance concrete layer, assuring its bonding behavior with the adhesive under long-term fatigue load. With polymer treatment, failure of FRP-concrete interface takes place in the concrete layer, rather than in the adhesive. The bond-slip curve of interface is also significantly higher than the one without polymer treatment (Figure 26). Thus, polymer treatment improves the long-term behavior of interface.

LONGEVITY DESIGN OF FRP CABLE SUPPORTED BRIDGES

In cable supported bridges, the steel cables can induce spanning limitation and decrease in safety and service life due to their large self-weight and long-term behavior deficiency. To overcome these limitations, the application of FRP cables is adopted in long-span cable supported bridges to achieve light weight, longer span and durability (Meier 1987; Wang and Wu 2010). A series of FRP cables have been developed by the authors’ team. Aside from CFRP cables, the authors’ team has addressed issues on developing BFRP as cables owing to their superior fatigue and creep behaviors as well as their high strength. Meanwhile, to overcome the shortcomings of CFRP, such as high cost, brittleness and deficiency in aerodynamic stability, hybrid FRP cables were developed to achieve the balance between cost and performance. The adoption of various FRP cables in cable-stayed bridges not only can achieve higher static performance compared to steel cable bridges, but also benefit lowering the
resonance possibility between stay cables and bridge deck (Wang and Wu 2010; Wang et al. 2013). In addition, the adoption of FRP cable can enhance the damping effect of cable and benefit vibration control, which has been demonstrated by reduced scale experiments of various FRP cables (Wang and Wu 2011a, 2011b; Yang et al. 2014, 2015). In addition, the breakthrough of anchor method of large capacity FRP cable provides more feasibility for FRP cable bridges with the assurance of high performance (Wang et al 2014a, 2015c). Those studies indicate that various FRP cables can enhance bridge behavior and realize long service life. The following introduces the concept of longevity design of bridges with FRP cables and the key compositions supporting the detailed design.

Concept of longevity design

The concept of life-controllable design of long span bridges is proposed based on the consideration of bridge span, service life requirement and economic index as shown in Figure 27. Span requirement of bridge determines the selection of different types of FRP cables, while service life requirement can be obtained by controlling design stress of FRP cable according to their fatigue and creep behavior and also bridge stiffness needs. The economic index is also required by life design due to the maintenance cost minimization, which can be realized by proper cable arrangement. The following section articulates the above three key issues.

Cable selection based on the bridge span

In order to avoid ineffective use of FRP composites in different spans of bridges, different types of FRP cables including hybrid FRP cables were recommended to be used in various spans of bridges according to their sufficient performance in both strength and stiffness. The applicable span for different kinds of cables were evaluated to be 1,200 m, 1,600 m, 1,900 m, 2,100 m, 3,500 m, 6,040 m, and 10,000 m for steel, B/SFRP 30%, B/SFRP 20%, BFRP, B/CFRP 25%, B/CFRP 50%, and CFRP cables, respectively. Based on the applicable span of different FRP cables, the superior performance to ratio selection of cables in bridge can be obtained.

Optimization of cable design stress

The design method for different FRP cables in long-span bridge is a key issue to control bridge life as shown in Figure 29. The design stress of FRP cables not only needs to take into account the structural behavior, especially the nonlinear behavior caused by cable sag effect, but it should also consider the fatigue and creep limit of each type of cable, which usually control service life of the critical areas of bridges. Based on the above considerations, the proper design stress of FRP cable can be determined by the structural analysis of the entire bridge with certain requirements in stiffness.
Determination of cable arrangement

To minimize the maintenance cost of bridges and realize LCC cost, the hybrid cable arrangement is a potential selection. The concept is to adopt different FRP cables in the applicable length so that not only the superior performance can be realized but also LCC cost can be lowered.

CONCLUSIONS

Focusing on the longevity design of major structures strengthened/reinforced with FRPs, this paper evaluated the long-term behaviors of FRP composites and FRP-concrete interface, and proposed several effective methods for their enhancement. Furthermore, by focusing on new construction with FRPs, the design methods to realize high performance and longevity of FRP cable supported bridges were introduced. The main conclusions were drawn as follows:

1. Fatigue and creep behavior of FRP composites are two key factors controlling the service life of structures subjected to the cyclic and sustained load at a high stress level. The newly developed basalt FRP composites show advantageous fatigue and creep behavior, which makes it suitable for realizing the longevity of major structures. Marine environment causes degradations in fatigue and creep life, but the reductions are limited and the structural requirements can still be fulfilled. Furthermore, the long-term behaviors of FRP composites can be effectively enhanced through hybridization, matrix modification and pretension treatment.

2. The long-term behavior of FRP-concrete interface is another key factor controlling the service life of structures strengthened by external FRPs. Through the modelling methods proposed by the authors, the creep and fatigue behavior of the interfaces were simulated accurately. Polymer treatment, which enhances concrete layer, can improve the long-term behavior of FRP-concrete interface.

3. Based on the research studies on fatigue and creep behavior of FRP composites and mechanical and economic behavior of FRP cable-stayed bridge, the concept of life-controllable design of long-span bridges is proposed based on the consideration of bridge span, service life requirement and economic measures. By these three key issues, the longevity of bridges with FRP cables is expected to be well controlled and designed.

FRP SANDWICH STRUCTURES IN BRIDGE AND BUILDING CONSTRUCTION

T. Keller
Swiss Federal Institute of Technology Lausanne, EPFL
Composite Construction Laboratory, CCLab
Email: thomas.keller@epfl.ch

ABSTRACT

Selected applications of fiber-reinforced polymer (FRP) sandwich structural elements in building and bridge construction are discussed. It is shown how in building construction this technology enables the integration of functions such as load-bearing capacity, thermal insulation, daylight entry and energy production, into single, large-scale and lightweight roof or façade panels. In bridge construction, the high resistance against environmental impact enables conceiving much simpler construction details because no sealing layer is required, and lightweight deck panels enable the widening of existing bridges without additionally loading the substructure.

KEYWORDS

Sandwich structures, bridge construction, building construction, function integration.

INTRODUCTION

Fiber-reinforced polymer (FRP) sandwich structures offer high structural efficiency and are lightweight – the reasons why successful applications in aerospace, naval, automotive and rail industries are widespread. Due to their advantageous properties, load-bearing FRP sandwich structures are also arousing increasing interest in civil infrastructure, i.e. bridge and building construction; a growing number of pilot projects have been built in recent years.

In building construction, the potential multifunctionality provided by FRP sandwiches, i.e. the possible integration of structural, architectural, building physics and energy supply functions, is of great interest. The sandwich concept basically allows the integration of structural and building physics functions, i.e. the merging of building envelope (thermal insulation) and load-bearing structure. The flexibility and transparency of optically optimized glass-FRP (GFRP) materials further enables the integration of architectural functions (complex shapes, light, color) and energy supply functions (encapsulation of photovoltaic cells in transparent skins). Function integration results in a significant reduction in the number of building components, which can be prefabricated under controlled conditions, and thus improves quality compared to cumbersome multilayered on-site production using traditional materials such as concrete or steel.

In bridge construction, lightweight FRP sandwich decks are corrosion-free and thus allow construction details to be simplified and maintenance costs reduced. The replacement of heavy concrete decks may also allow the widening of existing bridges without increasing the total load on the substructure. In both building and bridge construction, lightweight components can be large scale but nevertheless easily transported to the construction site and rapidly installed, thus shortening construction time and compensating for higher material cost. Selected projects in Switzerland, already built or in the realization stage, demonstrate these advantages of FRP sandwich structures in civil infrastructure in the following.

FRP SANDWICH STRUCTURES IN BUILDING CONSTRUCTION

Eyecatcher Building, Basel, 1998

The five-story Eyecatcher Building in Basel, still the tallest FRP building in the world, was conceived as a reusable temporary building. After a first year of being used for a building fair at one location in Basel in 1999, it was
dismantled and reinstalled at another location in Basel where it still remains and is used as an office building, see Figure 1. The primary load-bearing structure is composed of three parallel multilayer GFRP frames connected by timber slabs. Translucent sandwich panels are used for the side-facades and were also made of GFRP. They consist of two thin face sheets separated by a sheet with trapezoidal corrugations. A fibre content of approximately 30% results in a translucency of approximately 70%. To provide thermal insulation, the panels are filled with aerogels, which can be either opaque or translucent. With a panel thickness of only 50 mm it was possible to obtain a U-value of 0.27 W/m²K (Keller et al. 2004).

**Novartis Main Gate Building, Basel, 2006**

The lightweight 400-m² GFRP web-core sandwich roof of the Novartis Main Gate Building is supported by only four glass walls, giving the building maximum transparency, see Figure 2. The sandwich construction integrates static functions (vertical load transfer and bracing of the glass walls), building physics functions (thermal insulation and integration of an acoustic ceiling) and architectural functions (double-curved wing shape), which allowed the prefabrication of the entire roof in only four panels that were easily transported to the site and rapidly installed. CNC cutting of 460 PU foam blocks up to 600-mm-thick, each of a different geometry, and adhesive bonding proved to be advantageous procedures for the fabrication of the complex shape, without the use of expensive molds (Keller et al. 2008).

**CLP Building, Montreux (Project)**

The 1000-m² GFRP web-core sandwich roof of the CLP Building, replaces a timber roof over an indoor swimming pool. It provides the inside space with architectural spatial effects thanks to double-curved enclosure shapes that bring daylight through the roof, see Figure 3. The impact of the complex shapes on the manufacturing cost is decreased by the repeated use of one (expensive) double-curved mold. The lightweight GFRP sandwich construction was selected for two main reasons: to allow the use of the existing vertical structural members as supports within their limited load-bearing capacity, and to meet demanding serviceability and durability requirements, particularly concerning performance under high temperature and relative humidity service conditions (up to approximately 34°C and 80%, respectively). The prefabrication of the roof, envisaged in the form of 5-m-wide panels transportable by road to the site, is expected to speed up the installation process (which could be done almost simultaneously with the dismantling of the existing timber roof) and thus reduce the swimming pool closure time.
A/GFRP Thermal Break Element, 2016

A multifunctional highly-insulating aramid/glass-FRP (A/GFRP) thermal break element has been developed for the transfer of moment and shear forces from an outside balcony concrete slab through the thermal insulation layer of a building envelope to the inner concrete slab. The new connector considerably improves the energy savings of buildings due to its low thermal conductivity which is 115 (20) times smaller for AFRP (GFRP) compared to the currently used stainless steel bars in such connectors. The moment-tensile force of the balcony cantilever is transferred by an AFRP loop, the compression force by a short pultruded GFRP element. The latter is connected to a hexagonal AFRP or GFRP sandwich element with polyurethane core, which transfers the shear force through an inclined compression diagonal. This combined compression-shear element is industrially fabricated by filament winding. The 55mm insulation gap, located in the insulation layer, is filled with highly insulating aerogel granulate (Goulouti et al. 2016).

FRP SANDWICH STRUCTURES IN BUILDING CONSTRUCTION

Avançon Road Bridge, Bex, 2012

The GFRP-balsa-steel bridge over the Avançon River is designed for 40 tons truck loads. The new two-lane lightweight bridge replaced a deteriorated one-lane concrete bridge without increasing the total load on the old stone abutments and foundations below the riverbanks, which could thus both be maintained despite the widening and doubling of the traffic loads, see Figure 5. The GFRP-balsa sandwich deck – of 11.45-m length, 7.50-m width, 285-mm thickness, including a skew angle of 65° and longitudinal slope of 8% – was prefabricated by vacuum-infusion in three panels. The deck consists of two 22-mm thick GFRP face sheets and a 241-mm thick balsa core, the latter composed of a laminated veneer lumber with fibers oriented perpendicularly to the face sheets. The deck panels were adhesively bonded onto two steel girders adjacent to the existing bridge. The transverse deck joints were subsequently manufactured using on-site adhesive vacuum infusion. After removal of the concrete bridge, the new bridge was installed in one day and the bridge closure was thus reduced from 50 days (required for a conventional replacement) to 10 days. The semi-integral bridge concept, without expansion joints and separate sealing (required on concrete decks), and thus entailing much simpler construction details, significantly reduces the maintenance required (Keller et al. 2014).
Figure 5 Avançon Road Bridge, Bex – GFRP-balsa sandwich deck: panel composition, panel with skew angle and asphalt adhesion layer, installation with pre-cast concrete end-beams

**TSCB Pedestrian Bridge, Bissone**

The 18-m-span pedestrian bridge is designed as a spatial frame composed of six identical combined modules – of 3-m length, 2.4-m height and up to 4.2-m width each – made of carbon-FRP (CFRP) sandwich sections, see Figure 6. Each combined module comprises two half pieces (basic modules) with the same geometrical shape – except for an additional opening in the roof – and different thicknesses, ranging from 30 to 40 mm, for the roof, wall and deck sandwich elements, which can therefore be fabricated using the same mold. The modules will be assembled at the production site, allowing the manufacturing of the vacuum-infused module-to-module joints, the project’s most challenging construction elements, under controlled conditions. The fully prefabricated, one-piece bridge will be transported to the site ready for installation on the previously built foundations and abutments. The proposed modular system also enables the construction of footbridges of different span lengths using the same mold, thus offsetting the costs associated with their complex geometry by tailoring the sandwich material properties and/or thickness for an optimized design.

Figure 6 TSCB Pedestrian Bridge, Bissone – CFRP sandwich space frame (architect F. Broggini, Bellinzona): architectural model, prototype module, architectural rendering

**FRP SANDWICH STRUCTURES - OUTLOOK**

**Photovoltaic Cell Encapsulation**

GFRP materials may be translucent or transparent if the optical refraction indices of glass fibers and matrix match. The potential transparency allows the encapsulation of photovoltaic cells in load-bearing GFRP sandwich skins and may thus add an energy supply function, see Figure 7. Replacing the traditional polycrystalline silicon cells, which are opaque, with transparent dye solar cells enables the integration of translucent energy production zones (with transparent aerogel insulation) into GFRP sandwich structures in building construction (Keller *et al.* 2010, Agullo 2014).

Figure 7 Encapsulation of photovoltaic cells into translucent GFRP sandwich skins: flexible thin-film silicone cells, sandwich with encapsulated cell under loading, translucent DSC cells encapsulated in GFRP laminate
Multifunctional Fire Resistant Components

Multifunctional components in building construction, as described above, can further include a cellular structure with cells containing slowly circulating water, as in existing underfloor heating or cooling ceiling systems, see Figure 8. The water serves as heat transfer medium for several purposes: fire resistance through storage and removal of heat, interior room heating during winter and cooling during summer, thermal mass, but also as potential absorber for integrated thermal solar systems or cooling of photovoltaic cells. Furthermore, the extension of the water system to capture geothermal energy may extend the above-mentioned energy supply function. Fire performance experiments have confirmed the efficiency of water cooling systems: fire endurances of up to two hours were obtained for cellular GFRP floor systems (Tracy 2005).

Complex Core Assemblies

The load-bearing performance of FRP sandwich structures may be significantly improved by optimizing the core material selection and composition. Combining balsa wood of different densities for example and inserting a thin CFRP arch into a slab of (maximum) 800-mm thickness enables the span of GFRP sandwich slab (road) bridges to be increased by up to 19 m, see Figure 9. Combining further GFRP sandwich decks with steel main girders and adding timber and steel inserts above the (adhesively-bonded) deck-to-girder joints to improve composite action allows the span of such lightweight hybrid GFRP-steel bridges to be increased by up to 30 m, see Figure 10 (Osei-Antwi et al. 2013, 2014).

CONCLUSIONS

Requirements regarding length of the design working life, live load level, construction within the built environment and building physics differentiate GFRP sandwich applications in bridge and building construction from other fields.

In building construction, the integration of structural, building physics and architectural functions into large-scale, prefabricated and lightweight FRP sandwiches, which can be rapidly installed, may lead to efficient and sustainable solutions of high quality.

In particular, the potential transparency of GFRP laminates and free formability may contribute to architecturally attractive freeform structures with integrated energy production through solar cells.

In bridge construction, the use of FRP sandwich decks with complex core assemblies may result in durable and economic solutions which can minimize traffic interruptions and increase the load-carrying capacity or enable the widening of existing bridges without overloading the substructure.

ABSTRACT

Fibre-reinforced polymers (FRP) are increasingly being used in the field of Civil Engineering construction; however, with growing demand, they could pose an environmental concern. Conventional FRP systems are derived from non-renewable sources and require extensive energy to produce. Throughout the past several years, the authors have been conducting a series of investigations into the replacement of common FRP constituents with sustainable alternatives that include resins derived from under-valued agricultural bi-products such as corn cobs and sugar cane as well as natural fibres such as flax. Through these investigations, the short- and long-term performance of multiple FRP-combinations have been characterized. The authors have established bio-based FRP combinations which can replace FRP in common applications, such as confinement of concrete columns and flexural strengthening of beams. In addition, bio-based FRPs can extend to new construction such as the development of structural insulated panels for lightweight rapid construction. Through appropriate selection of material, the authors demonstrate that bio-based composites have a place within construction. At the same time, some challenges exist and have been identified. In these studies, the authors approached this topic from the view angle of mechanical properties characterization that relate to the expertise of a structural engineer, rather than the underlying chemistry and micro-structure analyses. Nonetheless, the latter is equally important but is beyond the scope of these studies and the expertise of the authors.

KEYWORDS

INTRODUCTION

Fibre-reinforced polymers (FRP) systems are increasingly being accepted in new construction and retrofits. Their high strength-to-weight ratio, ease of installation and corrosion-resistance make them ideal for many structural applications. However, conventional FRP components are derived from petroleum and require extensive energy to produce. Therefore, they are considered an unsustainable long-term solution to society’s structural engineering demands. FRP systems are composed of fibres and a resin matrix. Conventional fibres, such as fibreglass and carbon fibre, require extensive energy to produce. For example, carbon fibre has an embodied energy of 355 MJ/kg and fibreglass has an embodied energy of 31.7 MJ/kg, whereas a natural fibre such as flax has an embodied energy of only 2.75 MJ/kg (Cicala et al. 2010).

One potential option to derive a more sustainable alternative to conventional FRP systems is to replace the components of the traditional system with more environmentally friendly alternatives. Plant-based resins may be a suitable alternative to conventional ones. These systems range from partial resin replacement via functionalized vegetable oils, such as epoxidized pine oil, to full resin replacement, such as furfuryl alcohol resin derived from corncobs and sugarcane. However, limited research has been done on these systems for structural engineering.

It is of the utmost importance to determine the short- and long-term performance of new materials and systems. This will enable engineers to provide a sustainable solution to structural demands. As a novel system, there is a large gap in information for FRP derived from natural materials. This paper summarizes the pioneering efforts of the authors in introducing bio-based composites in structural engineering applications in Canada, towards developing natural ‘green’ FRPs. The aim is to address the question of whether bio-based FRPs can meet the demands of current conventional FRP systems.
DEVELOPMENT OF NATURAL FRP SYSTEMS

The development of a natural FRP system should address both components of the FRP system, fibre and resin matrix, while balancing structural, environmental and practical reasons. To meet these demands, the authors studied the replacement of both the fibre and the resin of varying degrees.

Materials

Three resin systems and three unidirectional fibre types were studied. This includes conventionally-used constituents and natural alternatives. The laminate combinations will be denoted by a combined letter system in the order of resin, fibre and manufacturing method. For example, FP-GF-WL FRP represents an FRP system that uses furfuryl alcohol resin cured with p-Toluenesulfonic acid monohydrate (FP) and glass fibres (GF), and is manufactured using the wet lay-up moulding technique.

Resin Systems

_Epoxy (SE):_ Tyfo S, a commercial epoxy resin with a reported post-cured tensile strength and modulus at 60°C for 72 hours of 72.4 MPa and 3.18 GPa, respectively. It exhibits a maximum elongation of 5%.

_Epoxy GR (EP):_ An epoxy blend comprised of epoxidized pine oil and bisphenol A/F with a reported post-cured tensile strength and modulus at 60°C for 72 hours of 58.8 MPa and 2.63 GPa, respectively. It exhibits a maximum elongation of 2.6%.

_Furfuryl alcohol (FA):_ QuaCorr 1001, a commercial furfuryl alcohol resin which is derived from renewable resources such as sugar cane and corn cobs. It has a dark-reddish to brown color, and has the following physical characteristics: a 1.22 specific gravity, viscosity of 300-600 cps and a flash point of 75.6°C. Two catalysts were used to cure the resin: QuaCorr 2001 (FQ), a proprietary catalyst, and p-Toluenesulfonic acid monohydrate 97.5% (FP). A 3% per weight ideal concentration of either catalyst was established (Fam et al. 2013).

Fibres

_Carbon fibres (CF):_ Tyfo SCH-41, a 1.74 kg/m² unidirectional carbon fibre fabric with a reported tensile strength and modulus of 4,000 MPa and 230 GPa, respectively. It exhibits a maximum elongation of 1.7%.

_Glass fibres (GF):_ Tyfo SEH-51A, a 2.55 kg/m³ unidirectional E-glass fibre fabric with a reported tensile strength and modulus of 3,240 MPa and 72.4 GPa, respectively. It exhibits a maximum elongation of 4.5%.

_Flax fibres (FF):_ Biotex Flax UD, a 1.5 kg/m³ unidirectional flax fibre fabric with a reported tensile strength and modulus of 500 MPa and 50 GPa, respectively. It exhibits a maximum elongation of 2%.

Manufacturing Methods

_Wet Lay-up (WL) Moulding_: A manufacturing method in which the fibres are saturated by hand and cured in ambient conditions. No additional equipment or resources were used during this process. This is representative of many retrofitting methods which use dry fibres and an impregnating resin.

_Vacuum Bag (VB) Moulding_: A manufacturing method in which the FRP, after being saturated similar to that of the wet lay-up process, is subjected to a constant pressure to improve impregnation, eliminate voids and increase fibre volume fraction. A rotary vane pump provided a constant pressure of 72±2 kPa of pressure during the initial 24 hours of curing.

Characterization of Natural FRP Materials

Short-term Performance

The tensile performance of FRP composites composed of the above-mentioned resins and fibres was investigated as a preliminary study to assess the viability of natural FRP systems. A summary of the tensile tests is given in Table 1.
Two general trends can be observed from the preliminary coupon tests. Firstly, the replacement of SE with EP, FP and FQ showed minimal reduction in ultimate tensile strength and modulus of up to 10%, except for FP-GF-WL. The variation is typically within standard deviation. Secondly, the replacement of GF with FF showed a reduction of ultimate tensile strength and modulus to a third of the conventional counterpart. These two trends highlight the known fact that the fibre contributes significantly more to the mechanical properties of the composite than the resin. Furthermore, it helps outline the potential fields of application for each of the FRP composite systems based on the impact of using a bio-based replacement.

Table 1: FRP tensile coupon test matrix and results, where all values are based on an average of five repetitions (Fam et al. 2013; Mak et al. 2015a; Mak et al. 2015b; McSwiggan and Fam 2016)

Long-term performance

To gain a better understanding of the long-term environmental performance of the FRP systems, a selection of the FRP composites were conditioned in a 3.0-3.5% salt concentration solution at three temperatures below the wet glass transition temperature, for up to 365 days. In most instances, 23, 40 and 55°C were the set temperatures.

The combination of salt solution and elevated temperatures were reported as the most suitable and efficient method to evaluate the impact of environmental conditioning at an accelerated rate (Al-Zahrani et al. 2002; Cromwell et al. 2011). Furthermore, the Arrhenius equation was used to determine the service life of FRP (Bank et al. 2003). An in-depth description of the procedure is described by Mak et al. (2015b).

The strength retention of the FRP composites are shown in Table 2. The strength retention is shown at 180 days of conditioning for all temperatures and specimens, so that all composites can be compared at the same conditions. This is not the maximum conditioning period. The difference in the maximum conditioning temperature of 50 and 55°C was to ensure that the FP resin did not post-cure in the conditioning tank. SE- and EP-equivalent variations were also conditioned at 50°C to allow for comparison.

The total conditioning period was taken into account to predict the strength retention after 100 years of service at 3°C, 10°C and 20°C. These temperatures correspond to average temperatures in central Canada, southern parts of Canada and southern parts of the United States. Predictions were not made for all FRP composites at this time.

Table 2: Strength retention after 180 days of conditioning and prediction after 100 years of service (Eldridge and Fam 2014b; Fam et al. 2013; Mak et al. 2015a; Mak et al. 2015b; McSwiggan and Fam 2016)

Three major trends can be observed from long-term environmental aging. Firstly, the most prominent difference between the resin systems is that the FA resin exhibited a lower strength retention compared to alternative resin systems. Furthermore, this difference even exists between two FA systems: FP-CF-WL and FQ-GF-WL. Although these are two different fibres, it highlights a necessity to further assess the environmental resistance of the composite. Secondly, composites containing CF have a better strength retention when subjected to elevated temperature conditioning compared to GF and FF. This is likely due to the bond between the fibre and resin. Lastly, FF demonstrated a more immediate drop in strength retention; however, its strength stabilizes sooner. This is likely due to the immediate effect of moisture on the natural fibres.

Due to the different chemical structure of FA resins compared to SE resins and the lower strength retention observed above, Foruzanmehr et al. (2016) studied FQ-GF-WL in further detail in comparison to SE-GF-WL. To simulate a harsh environment condition, the FRP was subjected to an alkaline solution of up to 180 days at 60°C. This is harsher than real-life scenarios. After six months of conditioning, SE-GF-WL showed no signs of hydrolysis degradation, whereas FQ-GF-WL showed signs of hydrolysis degradation leading to the failure of the backbone of the polymer. When assessing the inter-laminar shear stress (ILSS), SE-GF-WL showed a significant decrease in capacity of 22% after six months, which is likely due to interface failure between the fibre and resin. FQ-GF-WL showed a significant decrease in capacity of 30% after six months, which is due to the degradation of the resin. SEM showed that the resin-fibre interface is better for FQ-GF-WL composites than SE-GF-WL composites, which supported the ILSS results. Furthermore, FQ-GF-WL showed a higher water absorption capacity due to its lower hydrophobicity and higher porosity. The study suggested that FA resins may exhibit some deficiencies when subjected to environmental conditioning; however, it performs better than conventional resin systems in other respects.

**Future Work**

To expand on the long-term performance of FA, the authors are in the process of investigating the mechanical performance of FQ-CF-WL and FQ-GF-WL when subjected to tension-tension cyclic/fatigue loads.

To address the challenges associated with the last two trends for FF, the authors are currently studying the effects of moisture on natural fibres, specifically wet-dry cycles and freeze-thaw cycles. In addition to SE-FF and EP-FF, the research will incorporate treatment of FF to improve the resin-fibre interface.

**APPLICATION OF A NATURAL FRP SYSTEMS**

**Resin Replacement – Retrofitting Applications**

The most common application for FRP is retrofitting and rehabilitating current structures. This is due to the high strength-to-weight ratio, ease of application and minimal effect on the member dimensions. Based on the previous section results, it was deemed that the most appropriate resin-fibre combinations for ‘heavy-loading’ structural application such as retrofitting reinforced concrete structure would be bio-based resins and conventional fibres such as glass and carbon. The tensile strength and modulus of natural fibres (flax in this case) were quite low.

**Contact-Critical Applications – Column Confinement**

To determine the feasibility of confinement with natural FRP systems, Eldridge et al. (2014a) studied the short- and long-term durability of concrete cylinders wrapped with GF. SE was used as the control resin, since it is commonly used in practice. The bio-based alternative resin system was FQ.

Prior to the confinement study, it was necessary to establish the required overlap length to develop sufficient anchorage. Fam et al. (2013) established that FQ-GF-WL lap-splices of up to 300mm did not reach the ultimate tensile capacity of the FRP. There is an increase in shear strength as the overlap increases; however, once the overlap reaches 200mm it begins to plateau at approximately 68% of the ultimate tensile capacity. This was used as a design factor for the concrete cylinder confinement study.

The confinement study focused on concrete cylinders of dimensions 152mm-by-305mm. Concrete cylinders were prepared as plain unconfined, SE-GF-WL-confined and FQ-GF-WL FRP-confined concrete cylinders. Two layers of fabric were used for confinement. Performance was based on the concrete cylinder compressive strength. Long-term performance was determined after conditioning similar to that described in the Long-term Performance section. The unconfined concrete strength was 41.9±0.79MPa.
The performance of SE and FQ systems was similar as shown in Figure 1. The short-term performance of confined cylinders was 93.9±0.53MPa with SE and 94.0±1.06 with FQ. Additionally, both systems demonstrated a similar bilinear stress-strain curve (Eldridge et al. 2014a). There was no statistical difference between the two resin systems in this short-term test. The long-term performance showed a similar response. At the highest temperature of 55°C and longest period of 300 days, there was no statistically significant difference between the two resin systems. Both systems demonstrated approximately a 28% reduction in compressive strength. This similarity was also reflected at 40°C; however, SE-GF-WL demonstrated a slightly higher strength retention at 23°C. Therefore, FQ FRP systems may be a viable alternative to conventional SE FRP systems for concrete columns confined with FRP. Figure 2 shows the failure modes based on the two resins (further details are in Eldridge et al. 2014a).

Figure 1 Percentage compressive strength retention after 300 days of conditioning at elevated temperatures

![Figure 2 Failure mode of GF-confined concrete cylinders using a) SE and b) FQ resins](image)

**Bond-Critical Applications – Flexural Retrofitting**

To determine the feasibility of bond-critical applications, McSwiggan et al. (2016) studied the short- and long-term durability of notched-concrete prisms reinforced with CF. SE was used as a control resin, since it is commonly used in practice. The natural alternative resin systems were FP and EP. FA resin cured with p-Toluenesulfonic acid monohydrate was chosen due to the apparent environmental resistance.

A preliminary study demonstrated that FA resin-based systems do not cure or adhere properly to concrete surfaces (McSwiggan et al. 2016). As such, FP-CF-WL laminates were created as separate (prefabricated) plates and then adhered to the prisms, simulating the application of commercially available pultruded CF plates.

The study focused on concrete prisms of dimensions 305mm-by-102mm-by-102mm. Concrete prisms were all notched at mid-span up to mid-depth as shown in Figure 3. Prisms were studied as notched-plain, notched with SE-CF-WL FRP and notched with FP-CF-WL FRP. Performance was quantified based on the normalized shear strength retention, where long-term performance was determined after conditioning similar to that described in the
Long-term Performance section. Normalization was done by dividing the shear strength by the square root of $f_c'$. The design concrete strength was 35MPa; however, it varied from 30 to 44MPa, depending on the exposure conditions.

![Figure 3 Bond test specimens and setups](image)

The performance of SE, EP and FP systems is shown in Figure 4. The short-term normalized shear strength was 0.683 for SE-CF-WL, 0.722 for EP-CF-WL and 0.964 for FP-CF-WL. There was no statistical difference between SE and EP, but there was a statistical difference between SE and FP. After conditioning, the normalized shear strength remained statistically insignificant between SE and EP. The same holds true between SE and FP. At the highest temperature of 50°C, there was no statistical difference between the unconditioned and conditioned specimens; however, at 40°C and 240 days, FP showed a statistical difference when compared to an unconditioned alternative. Variability was observed between degradation strengths, which may be attributed to the combined impact of increasing concrete strength and FRP degradation due to conditioning. Overall, limited degradation was observed with FP- and EP-based FRP systems, therefore the bio-based resin systems may be a viable alternative to SE in prefabricated plates bonded using conventional epoxy paste.

![Figure 4 Normalized shear strength retention after 240 days of conditioning at elevated temperatures](image)

Due to the success of the notched-concrete prism study with regard to prefabricated bio-based laminates, the authors have expanded the study to include nine full-scale reinforced concrete beams. The beams are of dimensions 2,800 mm-by-300mm-by-175mm and simulate a direct bond-critical application, where strips of FRP are adhered on the tension side of the beam as additional flexural reinforcement. FRP sheets made of SE, EP or FP resin types and CF or GF were used to reinforce the beams. Beams were either reinforced with a single or double layer of FRP.
The beams were tested symmetrically in a four-point loading configuration with a constant moment region of 500mm. One beam did not have any FRP and served as a control, with a maximum load of 84.25kN. For one layer of reinforcement, CF-based laminates showed minimal difference between different resins and application methods. EP applied with wet lay-up, FQ applied as a laminate and SE applied as a laminate demonstrated increases in ultimate capacity ranging from 33.5 to 36.6%. There was a significant decrease in capacity gain when GF was used, notably 17.7% with EP applied with wet lay-up. With two layers of reinforcement, SE-CF-WL and EP-CF-WL increased the ultimate capacity by 49 and 54%, respectively, whereas SE-GF-WL and EP-GF-WL increased the ultimate capacity by 43 and 32%, respectively. Minimal difference was observed in the ultimate capacity between the two CF-reinforced beams, whereas there was over 10% difference in ultimate capacity for GF-reinforced beams. All beams showed a primary failure of yielding followed by shear failure, except for SE-GF-WL, which had a secondary failure of concrete crushing. Throughout these tests, it was observed that the primary factor for the performance of the reinforced beams was the type of the fibres. The impact of changing the type of resins has very minimal impact on the performance of the reinforcement.

**Future Work**

The authors are currently extending the full-scale study to incorporate freeze-thaw durability, where full-scale beams will be subjected to 300 freeze-thaw cycles to simulate conditions experienced by bridges in Northern climates. The authors are also exploring other types of partially-bio resins for direct bonding of FRP to concrete.

**Fibre Replacement – Sandwich Panels**

Given the significantly lower tensile strength and modulus of natural fibres (flax in this case), the authors have concluded that they are most suited for systems subjected to ‘light-loading’, particularly those whose failure modes are not governed by tension failure of the FRP. An example is sandwich panels with FRP skins and foam cores. These panels can be used for flooring, roofing, cladding or decking of pedestrian bridges. Their failure modes are typically governed by compression skin wrinkling or crushing or by core shear failure. As such, the authors focused on sandwich panels with flax-FRP skins.

**Flexural Performance**

To determine the feasibility of natural FRP-skinned sandwich panels, Mak et al. (2015a) studied the flexural behaviour of sandwich panels consisting of a FRP-based structural skin and a 64kg/m³ polyisocyanurate (PIR) foam core. SE-GF-WL FRP was the control structural skin due to its common acceptance in industry. FF was studied as a replacement to GF. The number of layers of FF was also studied to determine the impact of more fabric. Sandwich panels were 150mm wide and 75mm thick with a span of 900mm. Panels were tested symmetrically in four-point bending with a constant moment region of 150mm as shown in Figure 5(a).

Figure 6 shows the load-deflection responses of the FF-reinforced sandwich panels with one, three and five skin layers, compared to control GF-reinforced sandwich panel with one layer skin. For SE-FF-WL skinned sandwich panels, it was found that the optimum number of FF layers to provide a comparable response to GF, in terms of stiffness and strength, was three layers. This represents an FF skin with a total thickness that is 80% larger than the GF skin thickness. A minimal improvement in mechanical properties was observed with five layers of FF, whereas a significant reduction in performance was observed with one layer of FF. For manufacturing methods, VB sandwich panels typically yielded a lower structural capacity. Wrinkling of the skin suggests that this may be due to the reduced moment of inertia of the thinner VB skin, thereby resulting in skin instability.

To further develop this application, the authors investigated sandwich panels with varying PIR densities of 32, 64 and 96 kg/m³. A single resin type, SE, and manufacturing method, WL, were used for this study. The same test configuration was used as before, except that the foam width and thickness were 100 mm-by-50 mm. FF-skins were manufactured using three layers.

A general trend was observed where increased core density resulted in increased flexural performance. For SE-FF-WL, increasing the core density from 32 to 64 and 96kg/m³ resulted in an increased flexural capacity of 82 and 213%, respectively. It also corresponded to an increased flexural stiffness of 65 and 150%, respectively. A similar increase was observed for GF, where flexural capacity increased by 90 and 232%, respectively, and flexural stiffness increased by 72 and 164%, respectively. No major difference was observed between the two skin types; however, the foam core density greatly impacted the failure mode, where 32 and 64kg/m³ were governed by inward skin wrinkling in the shear span and 96 kg/m³ was governed by core shear failure.
In an attempt to replace both fibres and resin, Mak et al. (2015a) studied sandwich panels of the same nature as the flexural sandwich panel study with flax fibres; however, SE was replaced with EP. EP-FF-WL sandwich panels showed a decrease in strength and stiffness of up to 23%. The decrease in stiffness is prevalent at higher loads and as such, is not noticeable within the serviceability limits of L/180 and L/360. Thus the use of a bio-based resin system in conjunction with a natural fibre is a viable option for a natural FRP given the appropriate structural system.

**Axial Loading Performance**

The authors investigated the axial performance of SE-FF-WL skinned sandwich panels with slenderness ratios ranging from 25 to 60. SE-GF-WL FRP was the control structural skin due to its common acceptance in industry. FF was studied as a replacement to GF. The number of layers of FF was also studied to determine the impact of more fabric. Sandwich panels were 100mm wide and 50mm thick and of varying heights.

The load-slenderness ratio is shown in Figure 7 for the three different core densities. Slenderness ratio is indicative of the potential for Euler buckling. For low density foams, the axial strength appears somewhat stable and independent from slenderness ratio, whereas at higher densities, a clear reduction in strength appears as slenderness ratio increases. This is attributed to a range of failure modes that was observed. By increasing the core density from 32 to 64 kg/m$^3$, the average peak load increased by 73, 56 and 72% for one, three and five skin layers, respectively. By increasing the core density from 32 to 96 kg/m$^3$, the average peak load increased by 116, 130 and 176%, respectively. Nevertheless, similar to the flexural performance, three layers of FF respond similarly to a single layer of GF for all slenderness ratios.

Failure mode of FF panels is heavily governed by slenderness. Panels with slenderness ratios of 51 and above experience global buckling at peak loads, while those with slenderness ratios below 32 experienced localized failures. The intermediate range saw a combination of global and local failure modes. The most common secondary
failure mode of panels failing primarily by global buckling is skin buckling on the concave side, especially for thicker skins. Thinner skins mostly crushed after global buckling. In some cases, both secondary failures were associated with a core shear failure, especially at high density cores. The primary local failure was outward skin buckling. This was followed by core shear failure associated with convex side skin debonding.

Figure 7 Load-slenderness plot sandwich panels under axial load for three PIR densities, where FFRP represents flax-based FRP with SE resin and GFRP represents glass-based FRP with SE resin.

**Future Work**

The authors are in the process of investigating the fatigue performance of FF-skinned sandwich panels and their performance in different environmental conditions.

**CONCLUSION**

Conventional FRP systems have become an essential part of many forms of construction; however, it poses a significant environmental impact. The authors investigated the application of bio-based resins and natural fibres as a replacement to conventional FRP constituents. Characterization of the mechanical properties of the natural FRP systems have shown both strengths and limitations, both in the natural FRP systems as well as the conventional FRP systems. As a designer, it is important to capitalize on this knowledge and design with the appropriate materials. The authors are of the belief that a combination of conventional fibres and bio-resins is suitable for ‘heavy’ structural applications, including structural retrofitting such as reinforced concrete column wrapping, while natural fibres such as flax are more suited for ‘lighter’ structural applications such as sandwich panels for cladding, roofing and decking. The authors believe that with the growing interest in sustainability and the potential shown in these systems, natural FRPs are a viable alternative to conventional FRPs in specific structural applications.

ABSTRACT

The properties of Carbon Fibre Reinforced Polymers (CFRPs), very high strength, light weight, zero corrosion and no fatigue can fully be exploited for cable structures. The ideal structures for CFRP cables are highly pre-tensioned cable systems that are loaded orthogonally to their cable axes. High performance structures, such as stress-ribbon bridges, long-span roofs and facades made of CFRP can already be built economically today. To prove this point, CFRP prototype structures, a stress-ribbon bridge and a small spoked wheel cable roof built at the Technische Universität Berlin, are presented. First, however, cable structures, CFRP materials and existing CFRP cable structures are introduced in general.

KEYWORDS
Lightweight, bridges, roofs, CFRP and cables.

INTRODUCTION

A cable structure can be defined as structures in which a cable or a system of cables is used as the primary load-bearing structural element (Krishna 1978). The materials for cables have evolved from natural fibres in ancient times to wrought iron and finally to high-strength steel today (Schlaich et al. 2015).

A milestone in the development of cable structures is the Munich Olympic Stadium roof completed in 1972, which shows that the structural ideal of “leicht und weit” can be realised by using cables (Schlaich et al. 2003). Due to their ability of achieving long spans with minimal use of material while expressing lightness and elegance at the same time, cable structures are modern. Their structural forms are many and varied.

Reviewing the history of cable structures, it can be found that the development of cable materials promoted the development of new structural types. The availability of high-strength steel cables allows not only the construction of long-span cable structures, such as modern suspension and cable-stayed bridges, but also the reality of cable structures with new forms, such as cable roofs and facades. Carbon Fibre Reinforced Polymer (CFRP) is a new advanced composite material with advantages of high strength, lightweight, no corrosion and high fatigue resistance, which makes it suitable to be made into cables and potentially replace steel cables (Liu 2015).

CFRP AND CFRP CABLES

Carbon Fibre Reinforced Polymer

Carbon Fibre Reinforced Polymer, abbreviated to CFRP, is a non-mental composite material with outstanding properties. As its name suggests, it is composed of carbon fibres as the reinforcement embedded in a polymer resin as the matrix (Bhargava 2004).

The carbon fibres are very thin filaments (about 5 μm – 10 μm in diameter) containing between 90 and 100 weight % carbon (Donnet 1998). The mechanical properties of three typical carbon fibres are listed in Table 1, compared with two commonly used steel materials (Morgan 2005; Eurocode 3 2005; Eurocode 3 2006).

As shown in Table 1, the tensile strengths of carbon fibres are significantly higher than those of steel materials, while their densities are much lower. The breaking length $L_b$ (defined as the length of material hangs vertically at which it will break through its own weight) is a good parameter to show the high strength and lightweight characteristics of certain materials. It is calculated by $\sigma_u/\rho g$, where $g$ is the standard gravity constant of 9.8 m/s$^2$. As seen from the above table, the breaking lengths of carbon fibres are orders of magnitude larger than those of steel materials (Schlaich et al. 2015).

In addition to high strength and low weight, CFRP has better corrosion and fatigue resistance and lower thermal expansion than steel. Because carbon fibres have excellent creep resistance, the stress relaxation of CFRP is very small, and thus restraining sustained stress is unnecessary for CFRP (Morgan 2005).

The above merits make CFRP an excellent material in structural engineering. The first practical utilisation of CFRPs in construction was in 1991 for strengthening the Ibach Bridge in Lucerne, Switzerland (Meier 1992). From then on, more and more CFRP products have been used not only in strengthening, repairing, reinforcing and pre-stressing but also as cables in cable structures.

**CFRP cables**

Usually, unidirectional CFRP materials are used to manufacture CFRP cables. The mechanical properties along the fibre direction of CFRPs, such as the tensile strength $\sigma_u$ and the elastic modulus $E$, are usually approximately 60% - 70% of those of the carbon fibres because the fibre volume fraction is usually 60% - 70%. It should also be noted that $\sigma_u$ and $E$ of CFRP cables are slightly smaller than those of the corresponding CFRP; this is similar to the fact that $\sigma_u$ and $E$ of steel cables are slightly smaller than those of steel wires (Liu et al. 2015).

According to their cable form and cross section, today’s CFRP cables can be classified as shown in Figure 1 (Schlaich et al. 2012). Figure 1(a) shows a CFRP cable in the form of lamella, which can be fabricated by pultrusion or lamination. Figure 1(b) shows a CFRP cable in the form of rod, which is usually fabricated by pultrusion; such CFRP cable can be made up of a single rod or a rod bundle, and the CFRP rod can be circular or deformed. Figure 1(c) shows a CFRP cable in the form of strip-loop, which is fabricated by winding a continuous CFRP strip on two pins; the strip-loop can be laminated or non-laminated. Figure 1(d) shows a CFRP cable in the form of wire rope, which is fabricated by twisting several CFRP wires into a helix; CFRP wires used are usually produced by pull-winding (Liu et al. 2015).

![Figure 1 Schematic diagrams of four types of CFRP cables](image)

The mechanical properties of four CFRP cables (in different forms and from different producers) are compared with that of a steel full locked coil rope cable in Table 2 (Winistoefer 1999; Schober and Rautenstrauch 2005; Grace et al. 2002; Grace et al. 2003; Pfeifer 2011).

As seen from Table 2, the tensile strengths of CFRP cables are higher than that of the steel cable while their densities are only approximately 1/5 of the steel cable’s density. However, CFRP cables also have some...
disadvantages, such as lower elastic modulus than that of steel cables (see Table 2), difficult anchoring and relatively high cost, which may hinder the application of CFRP cables (Liu et al. 2015).

EXISTING CFRP CABLE STRUCTURES: OVERVIEW

Studies on CFRP cables in cable structures can be dated back to the early 1980s (Meier 2012). As early as in 1987, a CFRP cable-stayed bridge with a main span of 8400 m crossing the Strait of Gibraltar was proposed (Meier 1987). However, the first practical use of CFRP cables in a real cable structure was in 1996 (Karbhari 1998). From then to now, there have been eleven CFRP cable structures over the world, even though all of them were built more or less experimentally. Nine of them are listed in chronological order of completion in Figure 2 (Schlaich et al. 2014), while another two from the Technische Universität Berlin will be introduced in following sections.

![Figure 2 Nine CFRP cable structures](image)

Brief introductions of the CFRP cable structures in Figure 2 are listed as follows.
1: Tsukuba FRP Bridge; pedestrian cable-stayed bridge; all stay cables are made of CFRP; completed in 1996 and located in Tsukuba, Japan (photo credit: I. Sasaki).

2: Stork Bridge; highway cable-stayed bridge; two stay cables are made of CFRP; completed in 1996 and located in Winterthur, Switzerland (photo credit: EMPA).

3: Neigles CFRP Footbridge; pedestrian suspension bridge; two main cables are made of CFRP; completed in 1998 and located in Fribourg, Switzerland (photo credit: Tokyo Rope).

4: Herning CFRP Bridge; pedestrian cable-stayed bridge; all stay cables are made of CFRP; completed in 1999 and located in Herning, Denmark (photo credit: COWI).

5: Laroin CFRP Footbridge; pedestrian cable-stayed bridge; 16 stay cables are made of CFRP; completed in 2002 and located in Laroin, France (photo credit: Freyssinet).

6: Jiangsu University CFRP Footbridge; pedestrian cable-stayed bridge; all stay cables are made of CFRP; completed in 2005 and located in Zhenjiang, China (photo credit: K. Mei).

7: Penobscot Narrows Bridge; highway cable-stayed bridge; six strands are made of CFRP; completed in 2006 and located in Penobscot, Maine, USA (photo credit: MOT).

8: EMPA Bowstring Arch Footbridge; pedestrian bowstring arch bridge; all bowstrings are made of CFRP; completed in 2007 and located in Dübendorf, Switzerland (photo credit: U. Meier).

9: Cuenca Stress-Ribbon Footbridge; pedestrian stress-ribbon bridge; all stress-ribbons are made of CFRP; completed in 2011 and located in Cuenca, Spain (photo credit: J. R. Lopez).

CFRP STRESS-RIBBON BRIDGE

The department of Conceptual and Structural Design, Technische Universität Berlin (TU-Berlin), started research on CFRP cable structure in 2005. In May 2007, the first CFRP stress-ribbon bridge in the world was completed at the laboratory of TU-Berlin. It is still standing. After completion, an active vibration control system was installed in the bridge to reduce pedestrian-induced oscillations (Bleicher et al. 2012). The photo and sketch of this bridge are shown in Figure 3 (Liu et al. 2015). The TU-Berlin CFRP Stress-Ribbon Footbridge is a single span stress-ribbon bridge with the sag-to-span ratio of 1/60. Six CFRP ribbons are used as load bearing components in this bridge, which were provided by Carbo-Link GmbH, Switzerland. In the transverse direction, each ribbon has $2 \times 5$ layers and the total thickness is approximately 1 mm. The load bearing capacity of single ribbon is 105 kN (Schlaich and Bleicher 2007).

![Figure 3 TU-Berlin CFRP Stress-Ribbon Footbridge (a) photo (photo credit: A. Bleicher) (b) sketch](image-url)

The CFRP ribbon used in this bridge is a non-laminated pin-loaded strip-loop (see Figure 3). Such cables are manufactured by winding a very thin (approximately 0.1 mm thick) CFRP strip around two round pins (the pins are made of steel in this case) continuously. After winding, only the part between the strip start and strip end is bonded together through fusion to form a closed loop (thermoplastics matrix is adopted to produce the CFRP strip). Compared with the laminated strip-loop, the shear and radial stresses at the anchorage zone (especially the layer contacting the pin) of the non-laminated strip-loop will distribute more uniformly, because the different layers of the non-laminated one can mutually slide, thus achieving a more uniform strain distribution than the laminated one. This will lead to relatively small stress peak in the CFRP non-laminated pin-loaded strip-loop cables and help increase their ultimate bearing capacity. The cable anchorage is illustrated in Figure 4 (Liu 2015).
The above anchorage system mainly consists of two round pins, a triangular steel box and two steel anchoring bolts to connect to the ground. The anchor pin, with a diameter of 80 mm, is for holding the strip-loop, while the steering pin, with a diameter of 100 mm, is for changing the direction of the loop to facilitate tensioning and anchoring (Liu 2015).

**CFRP CABLE ROOFS AND FACADES**

All the existing CFRP cable structures, introduced in the above sections, are cable bridges. Moreover, the majority of them are cable-stayed bridges. However, cable roofs and facades are ideal structures for CFRP cables, because most of them are orthogonally loaded by external loads.

In orthogonally loaded cable structures, such as stress-ribbon bridges, cable roofs and cable facades, the structural stiffness is mainly comprised of the geometric stiffness which is induced by the pre-tension force in the cables. The elastic stiffness caused by the elastic modulus of cables is less important. For such cable structures, increasing the tensile strength of cables to increase the pre-tension force is a more efficient way to raise the structural stiffness than increasing the elastic modulus of cables. Using CFRP cables, whose tensile strength is considerably greater than that of steel cables (see Table 2), in orthogonally loaded cable structures can improve the economic efficiency, although the elastic modulus of CFRP cables is smaller than that of steel cables (see Table 2) and their unit price is also much higher. Therefore, using CFRP cables in cable roofs and cable facades will be an important component of future buildings (Schlaich et al. 2014; Liu et al. 2015; Schlaich et al. 2015).

To investigate the feasibility of applying CFRP cables to cable roofs and cable facades, a small CFRP spoked wheel cable roof was built at TU Berlin in 2013, as shown in Figure 5 and Figure 6.
In this prototype, the radial cables are loop-shaped CFRP tension members and the tension ring is a closed octagon CFRP loop. The cross section of the radial cable and the tension ring is 30 mm × 1.2 mm, which can bear nearly 80 kN tension force. Both types of CFRP structural elements were manufactured at TU Berlin by hand through laminating a continuous carbon fibre tow coated with epoxy resin on a rotating form and using vacuum technique to harden. The material of the compression ring, pillars and nodes is aluminium. To pre-tension the CFRP cables, each node of the tension ring was separated into two semilunar parts, which are linked together by four bolts. By tightening the bolts and hence shortening the distance between these two parts, the CFRP cable system of the spoked wheel cable roof was pre-tensioned to a sufficient level and a very stiff system was achieved (Liu et al. 2015).

In addition to the CFRP cable roofs, CFRP cable facades also have a bright prospect of application. Perhaps the highly pre-tensioned steel cable net facade like the one shown in Figure 7 can be made of CFRP cables in the future.
CONCLUSION AND PROSPECT

The history of building is also a history of building materials. The emergence of a new material usually leads to new structural types. CFRP could now drive the progress of cable structures.

This paper mainly reviews the existing CFRP cable structures in the world and proposes future application for this promising material. Admittedly, there are still several challenges that may hinder the wide use of CFRP cables, such as difficulty in anchoring, fire safety problems and relatively high cost. However, this should not prevent us from going ahead in this domain (Liu et al. 2015). For example, the anchorage problems could be eased by applying the CFRP Continuous Band Winding System (see Figure 8) (Liu et al. 2015). The structural engineering community can be looking forward to most interesting developments in the field of CFRP cable structures.

REDUCING THE COST OF FRP RC RESEARCH AND DEVELOPMENT

D.J. Oehlers and P. Visintin
School of the Civil, Environmental and Mining Engineering, The University of Adelaide, Australia

ABSTRACT

Over the last few decades, the main thrust of steel reinforced concrete research and development has been based on empirical testing. While material properties may be determined empirically using relatively inexpensive approaches, semi-empirical mechanical models, which are commonly used to develop design rules, require member level testing. Hence any advancement, such as a new approach or new product, has to be accompanied by significant quantities of member level tests, which due to their scale, are both costly and time consuming. Furthermore, being empirically based, the new approach or product can and should only be used within the bounds of the experimental tests from which it was developed, which in itself places significant restriction on application. The advent of FRP reinforcement, FRP confinement, FRP retrofitting and textile reinforced concrete has radically changed the possibilities of design with reinforced concrete. If we keep to the same semi-empirical approach, as we all have through our own member testing, it will be extremely costly and time consuming to develop these advances to the stage of application and refine them further.

An alternative approach is to develop mechanics based solutions to replace the semi-empirical approaches, so that only material properties need to be determined empirically. Hence, in theory, a manufacturer of a new product, for example a new type of fibre, would only need to test for the material properties which can then be used in mechanics models for the behaviour of a member. The manufacturer can then modify the product at little expense as only material properties are required until the required member properties, obtained through the mechanics models, are achieved. In short, the manufacturer only needs to spend money on inexpensive material testing and not on expensive member testing.

This presentation explains the partial interaction material properties and partial interaction local mechanisms that the mechanics model has to incorporate and simulate in order to quantify the total behaviour of a reinforced concrete structure. This is followed by the categorisation of the different levels of research sophistication which explains the huge amount of testing currently required and the need for mechanics models. Examples of partial interaction mechanics approaches are then illustrated for quantifying the flexural rigidity at serviceability allowing for time effects. Finally a brief discussion of how advanced mechanics based design techniques will enhance the use of FRP using moment redistribution and member debonding as examples.

INTRODUCTION

Structural engineers may wish to develop for general use a new FRP product such as an FRP reinforcing bar or fibre concrete or a new type of RC FRP beam or slab or column. Or they may wish to develop a new FRP retrofitting technique for general use or simply expand the use of an existing FRP retrofitting technique or make it more accurate. Or they may simply want to develop a unique one off FRP RC member for a specific use or enhance the strength of an individual member beyond the scope of existing FRP techniques. To do this, the structural engineer has to ensure that the product or member or technique can resist a very wide range of stress resultants for members of virtually any shape and size, notwithstanding the time dependent behaviour at serviceability and the ductility required for members in a frame. Currently this requirement is done through a very large amount of member testing, the cost of which is incredibly prohibitive (Oehlers 2010; Oehlers et al 2011a; Oehlers et al 2016b; Oehlers et al 2012; Oehlers et al 2014b; Oehlers et al 2016b). However, if the structural engineer had a numerical mechanics model that can directly simulate behaviours that occur in RC members (Oehlers et al at 2016a; Oehlers et al 2016c; Oehlers et al 2014a; Zhang et al 2016a), then this would obviate the
need for member testing which would considerably reduce the cost of development. That is the engineer requires an approach which simulates the slip or partial interaction which occurs across interfaces. Even better, if the structural engineer had a mechanics analytical equation that allowed for these PI localised mechanisms (Lucas et al 2011; Visintin et al 2013a; Visintin et al 2013b; Visintin et al 2016a; Visintin and Oehlers 2016b; Zhang et al 2016b) then this would directly provide design rules for new products or members further reducing the cost of development. In this case all that is needed through testing are the material properties which once obtained do not have to be repeated.

This paper first briefly clarifies the partial interaction (PI) material properties that lead to the PI localised mechanisms that have to be simulated if a model is to directly simulate what is seen and measured in practice. Then explains why currently a large amount of member testing is required through a discussion of the different approaches to research and also shows how a mechanics based approach can save considerable costs. This is then illustrated for the serviceability behaviour of FRP RC beams and for the moment redistribution at ultimate. Furthermore, these examples will be used to show how mechanics based models that incorporate the PI localised RC mechanisms can be used to help empiricalists in: planning tests to extricate the material properties required for the design equations for the new products; and used in the inverse mode to speed up the development of new products.

RC PARTIAL INTERACTION

Figures 1 to 3 show the apparently myriad characteristics associated with RC members at all stages of loading and of which structural engineers are familiar with. All of these characteristics have to be simulated if a model is to truly represent what actually occurs in practice and, thereby, quantify strengths and deformations for all stress resultants. The task may appear daunting but these myriad behaviours can be categorized into just a few PI localised mechanisms which themselves can be simulated with even fewer PI material properties. Partial interaction (PI) being the behaviour associated with slip across an interface.

Figure 1 Characteristics of an RC beam predominant under flexure

Figure 2 Characteristics of an RC beam under shear

Figure 3 Encased column

Figure 4 illustrates a portion of an RC beam predominantly in flexure which could be prestressed or not and in which the reinforcement could be FRP or steel or a combination. The observer may see on loading the formation of near vertical flexural cracks. Their formation is governed by the PI local mechanism of tension stiffening which controls the crack spacing and crack width and consequently the flexural rigidity of the member. The observer may also see plate separation which is governed by the local PI mechanism of intermediate crack (IC) debonding which controls member debonding and consequently the effectiveness of the retrofitting technique. The observer may then see the formation of a double sliding wedge which is governed by the PI mechanism of shear sliding which controls concrete softening and consequently the ductility of the member.

For RC beams predominantly in shear as in Figure 5, the above flexural mechanisms still exist but the observer may also see the formation of a diagonal crack which forms a single sliding wedge. The force in the reinforcement, such as the inclined externally bonded plates or internal stirrups, crossing the diagonal crack is still governed by tension stiffening. However this tensile force in the reinforcement is balanced by compression in the concrete across the interface which is confinement. Hence this PI shear sliding mechanism controls the beneficial effect of confinement as well as the shear capacity of the member.
Depending on the magnitude of the stress resultants, RC columns may exhibit the localised mechanisms described above in Figures 4 and 5. Those columns with large axial loads as in Figure 6 may form a single diagonal crack. In this case the outer tube and inner stirrups provide beneficial confinement to the concrete through the PI shear sliding mechanism.

It has been shown in Figures 4 to 6, that the many characteristics associated with the behaviours of RC members in Figures 1 to 3 are governed by only three PI local mechanisms that is: (1) tension stiffening; (2) shear sliding, and (3) IC debonding. These three PI local mechanisms are due to just two PI material properties that is: (1) the PI shear friction material properties across a potential sliding plane as in Figure 7 that are often presented in the form shown in Figure 8; and (2) the PI bond-slip material properties as illustrated in Figure 9.

Hence, Figures 8 and 9 represent the only additional material testing required to simulate the PI local mechanisms shown in Figures 4 to 6 in order to form the apparently myriad characteristics shown in Figures 1 to 3. For a new product, this additional material testing is relatively inexpensive, compared with member testing, which should
mean that the development of new products should be inexpensive. Why this is not the case is explained in the following section.

![Figure 9 PI bond-slip material properties](image)

**LEVELS OF RC RESEARCH SOPHISTICATION**

The different levels of research sophistication are listed in Column 1 in Table 1 with a brief description in Column 2 (Oehlers et al 2016b). The costs are listed in Columns 3 to 5. As the cost of determining the material properties from tests applies to all levels of research this cost has not been included in the table. Where the research approach requires member testing this is a cost in Column 3. Where the research approach requires further effort in developing design rules this is a further cost in Column 4. The range of application has been included as a cost in Column 5 as those research levels with finite ranges incur an additional cost should the designer wish to go beyond the range.

</tr>
<tr>
<td>Level 1: Empirical</td>
<td>All parameters determined experimentally</td>
<td>Member testing: Yes, Design rule development: Yes, Range of application: Limited</td>
</tr>
</tbody>
</table>

The lowest level of research sophistication in Table 1 is Level 1: Empirical. All parameters are determined experimentally. Hence there is a cost for member testing, a cost for the development of design rules and the application is limited to within the range of the specimen properties in the member testing. This is a very useful approach at the start of the development of a new product that is to get the product on the market. The manufacturer may wish to expand the use of the product so then uses the semi-empirical approach of Level 2 where a mechanics model is used but at least one parameter of the model requires to be determined experimentally. An example is the use of full-interaction (FI) flexural rigidities that are then calibrated through tests to allow for PI. Hence there is a cost for member testing and design rule development and a limit from the range of tests to calibrate the mode. Level 3: Simplified Numerical could for example be a strain-based finite element analysis in an attempt to eliminate member testing. Being strain based it cannot cope directly with PI that is with interface slip so PI such as for tension stiffening is allowed for by adjusting the strain based material properties which is often done through calibration with test results. Hence this approach is also limited by the range of tests used in calibration. Generally speaking, Levels 1 to 3 do not attempt to simulate the PI localised mechanisms directly.

Level 4: Numerical Mechanical model in Table 1 is a numerical model that can simulate all the PI localised mechanisms in Figs. 4 to 6. As the numerical model can simulate all the behaviours and characteristics of RC members for any size and shape of member there is no need for member testing. All that is required are the material
properties for the numerical model. This model can be used to replace member testing in Levels 1 to 3 with the advantage that numerical modelling is much less expensive than member testing. Furthermore, whereas experimental testing is limited by the capacities of the laboratory there is no limit in numerical modelling to the size of the specimen being modelled. The Numerical Mechanics model can be used to provide data for a parametric study leading to Level 5: Semi-Mechanical approaches for design.

Numerical modelling, as with experimental testing, does not give the mechanics directly and as such provides the structural engineer with a shallow understanding of the behaviour to make decisions. Hence the next level of sophistication that is Levels 6 and 7 in Table 1 are closed form solutions that provide the mechanics equation that incorporates all the relevant PI localised mechanisms. When the solution provides an equation that can be used directly in design then this is a Level 7: Closed Form. If this is available then the structural engineer can use this directly in the design of a new product or member and all that is needed are the material properties. Hence the costs are minimal their being no member testing, no design development and no limit to its application. Should the mechanics be too complex to provide a direct solution, then the mechanics can be simplified to produce a Level 6: Simplified Closed Form solution such that the application should be limited to within the bounds of the simplification should there be any. The use of Levels 4 to 7 models in the development of design rules for new products that is without the need for member testing is illustrated in the following section for serviceability. This is followed by a discussing of how Levels 6 and 7 models will allow structural engineers to design for specific conditions that fall outside the scope of codes.

**TIME DEPENDENT SERVICEABILITY BEHAVIOUR OF RC BEAMS**

Consider the time dependent serviceability behaviour of RC (Sturm et al 2016; Visintin et al 2016c).

**Levels 4 and 5 Models**

A segmental analysis of a segment of a beam between two adjacent cracks in Figure 1 is shown in Figure 10(b). After flexural cracking, the tension reinforcement is simulated with a tension stiffening prism as in Figure 10(a). The segment is subjected to a shrinkage strain \( \varepsilon_{sh} \) such that if the concrete was unrestrained the concrete segment end would move from A-A to B-B in Figure 10(c). An Euler-Bernoulli deformation C-C is applied. The force in the compression reinforcement \( P_{rc} \) is given by the reinforcement deformation relative to A-A shown shaded. In contrast, the force in the concrete in compression \( P_{cc} \) is given by the concrete deformation relative to C-C shown shaded. Similarly for \( P_{ct} \). The force in the tensile reinforcement \( P_{rt} \) depends on the half crack width \( \Delta \). This depends on the crack opening stiffness \( K \) that depends on the bond-slip stiffness \( k \) which can be obtained from a numerical analysis of the tension stiffening prism (Visintin et al 2013c) and for which closed form solutions are also available (Sturm et al 2016). For a given rotation \( \theta \), it is a question of varying \( d_{NA} \) until there is equilibrium.

![Figure 10 Level 4 Segmental analysis of beam at serviceability](image)

The material properties required for the analysis as listed in Figure 10(e) where: \( E_r \) is the reinforcement modulus; \( E_c \) the concrete modulus allowing for creep if necessary; \( \varepsilon_{sh} \) the shrinkage strain which can be assumed constant but the analysis can cope with non-linearity if necessary as shown; and the PI material bond-slip stiffness \( k \) which can be assumed to be constant at serviceability although it is very easy to allow for non-linearity if required. The segmental analysis in Figure 10 is a Level 4: Numerical Mechanical model which can be used in a one off analysis or in a parametric study to develop Level 5: Semi-Mechanical models for design.
Level 7 Model

First consider the case without shrinkage as in the segment in Figure 11(b). An Euler-Bernoulli deformation \( C - C \) is applied. The concrete in tension immediately below the neutral axis \( d_{NA} \) will be ignored as is common practice.

Above the neutral axis in Figure 11(a) there is full interaction (FI) that is there is no interface slip. Hence the resistance to deformation above the neutral axis can be determined by the commonly used transformed section as shown above the neutral axis in Figure 11(c) where the FI modular ratio is given by

\[
n_{FI} = \frac{E_r}{E_c}
\]

Below the neutral axis there is partial interaction so the full interaction modular ratio \( n_{FI} \) cannot be used. The force in the tension reinforcement \( P_{rt} \) in Figure 11(b) is equal to \( K\Delta \) where \( K \) is the crack opening stiffness and \( \Delta \) the extension as shown. From this PI mechanics can be derived the following PI modular ratio (Sturm et al 2016).

\[
n_{PI} = n_{FI} \sqrt{\frac{\beta k S_{cr}}{2}}
\]

in which \( \beta \) is the following prism axial rigidity factor

\[
\beta = \frac{S_{cr}}{2} \left( \frac{1}{E_r A_{rt}} + \frac{1}{E_c A_{ct}} \right)
\]

It can be seen in Eq 2 that the second factor on the right hand side allows for the beneficial effect of tension stiffening that is the increase in the full interaction modular ratio due to tension stiffening.

From the elementary analysis of transformed sections, the curvature at an applied moment \( M \) is given by

\[
\chi_{trans-3} = \frac{M}{E_c I_{trans-cr}}
\]

where the moment of inertia is

\[
I_{trans-3} = n_{PI} A_{rt} d (d - d_{NA}) - n_{FI} A_{rc} c_c (d_{NA} - c_c) - \frac{1}{b} d_{NA}^3
\]

in which

\[
d_{NA} = \sqrt{\left(\frac{n_{PI} A_{rt} + n_{FI} A_{rc}}{b}\right)^2 - \frac{2 n_{PI} A_{rt} d + n_{FI} A_{rc} c_c}{b} - \frac{n_{PI} A_{rt} + n_{FI} A_{rc}}{b}}
\]

The above PI transformed section analysis is mechanically exact and is, therefore, a Level 7 model. There are already closed form solutions for the crack spacing \( S_{cr} \) that depends on \( k \) (Sturm et al 2016) and, hence, the above procedure could be used directly in design should a suitable value of \( k \) be available for the new product. Alternatively, it could be used as a development tool to extract the material bond property \( k \) from member tests.

Level 6 Model

The transformed section analysis in Figure 11 can be applied when there is a single linear strain profile which does not occur when there are shrinkage strains such as in Figure 10. To determine a closed form solution for the effects of shrinkage, the compression zone in Figure 10 or 11 can be simplified to a full interaction prism as in Figure 12(a).

When the applied moment \( M \) in Figure 12(b) is zero, shrinkage causes the deformation \( D_{FI} \) that can be obtained from FI mechanics and the deformation \( D_{PI} \) that can be obtained from PI mechanics; this is shown as the Euler-
Bernoulli deformation $C_1-C_1$. From these deformations can be obtained the following curvature due to shrinkage alone (Visintin et al 2016)

$$\chi_{sh-1} = \frac{\varepsilon_{sh}}{d_r} \left[ \frac{E_{cc}A_{cc}}{E_{cc}A_{cc} + E_{rc}A_{rc}} - 1 + \frac{2}{\sqrt{\beta k}} \tanh \left( \frac{\sqrt{\beta k} S_{cr} / 2}{d_r} \right) \right]$$

in which $d_r$ is the distance between the tension and compression reinforcement. Now applying a moment which causes an increase in rotation $\theta_{sh-2}$ such that the deformation $D_{FI}$ now equals $\varepsilon_{sh}E_{rc}S_{cr}/2$ as shown in C2-C2 causes the following increase in curvature

$$\chi_{sh-2} = \frac{\varepsilon_{sh}}{d_r} \left[ \frac{2E_{rc}A_{rc} \tanh \left( \frac{\sqrt{\beta k} S_{cr} / 2}{d_r} \right)}{\sqrt{\beta k}E_{rc}A_{rc}S_{cr}} - \frac{1-E_{cc}A_{cc}}{E_{cc}A_{cc} + E_{rc}A_{rc}} \right]$$

which occurs when the applied moment $M$ is

$$M_{sh-2} = \varepsilon_{sh}E_{rc}A_{rc}d_r$$

which also depends on the shrinkage strain.

At the Euler-Bernoulli deformation $C_2-C_2$ in Figure 12(b), the strain in the compression reinforcement is simply the concrete shrinkage strain $\varepsilon_{sh}$ such that the force in the compression reinforcement is given by

$$P_{cc-sh} = \varepsilon_{sh}E_{rc}A_{rc}$$

which represents a constant residual force of whose affect is catered for by Eqs 7 and 8. As the effect of shrinkage has now been catered for, any further increase in rotation $\theta_{trans-3}$ in Figure 12(b) due to the component of the applied moment $M$-$M_{sh-2}$ is given directly by Eq 4 that is from a transformed section analysis that is independent of the shrinkage strain.

**Level 6 Model including $S_{cr}$ simplification**

A further simplification to the mechanics models is to assume that an approximation to the primary crack spacing is

$$S_p = \frac{2}{\sqrt{\beta k}}$$

Substituting Eq 11 into Eqs 2 gives the following simplified modular ratio

$$n_{FI-simp} = 1.31n_{FI}$$

which on substituting into Eq. 5 gives the following moment of inertia

$$I_{trans-cr-simp} = 1.31n_{FI}A_{rt}d(d - d_{NA}) - n_{FI}A_{rc}c_c(d_{NA} - c_c) - \frac{1}{6}\pi d_{NA}^3$$

Furthermore substituting Eq 11 into Eqs 7 and 8 gives

$$\chi_{sh-1-simp} = \frac{\varepsilon_{sh}}{d_r} \left[ \frac{E_{cc}A_{cc}}{E_{cc}A_{cc} + E_{rc}A_{rc}} - 0.238 \right]$$

$$\chi_{sh-2-simp} = \frac{0.762E_{rc}A_{rc}}{E_{rc}A_{rc}S_{cr}} - \frac{1-E_{cc}A_{cc}}{E_{cc}A_{cc} + E_{rc}A_{rc}} \frac{\varepsilon_{sh}}{d_r}$$
It can be seen that the curvatures from Eqs 13-15 are now in a form that are very easy to apply and can be used directly in design. In conclusion, the total curvature is given by

\[ \chi_{\text{total}} = \chi_{\text{sh-1}} + \chi_{\text{sh-2}} + \chi_{\text{trans-3}} \] (16)

where the first two terms depend on the shrinkage strain and the third component is independent of shrinkage and all the components depend on the bond-slip stiffness \( k \). These equations could be used directly in a one off design or used to develop design rules. Furthermore, as they separate the effects of bond stiffness, shrinkage and creep they will be very useful in research to study the time effect properties of concrete.

ADVANCED DESIGN

In the simplified approach above, the curvatures are independent of the bond-slip stiffness \( k \) leading to incredibly simple design rules. However the crack width \( w_{cr} \) is given by

\[ w_{cr\text{-simp}} = \frac{1}{\sqrt{2k}} [0.762\varepsilon_{sh} \left(1 + \frac{A_{rc}}{A_{ct}}\right) + \frac{(M - M_{sh-2})(d - d_{NA})}{k_{\text{trans-3}}}] \] (17)

where it can be seen that the crack width does depend on the bond-slip stiffness \( k \). This could be used by FRP reinforcement manufacturers to ensure that the bond is adequate.

Consider moment-redistribution in a continuous beam (Oehlers et al 2016b) in which moment is being redistributed from the hogging region to the sagging region and in which the moment redistribution factor \( K_{MR} \) is \( \Delta M_{\text{hog}}/M_{\text{hog}} \) and which is often given as a percentage in codes. Purely from mechanics, the moment redistribution factor is given by

\[ K_{MR} = \frac{1}{1 + \frac{\theta_{\text{max}}}{\theta_{\text{max}L}}} \] (18)

where \( \theta_{\text{max}} \) is the rotation capacity at a moment \( M_{\text{max}} \) that is close to the maximum moment capacity, \( L \) is the span and \( EI \) is the flexural rigidity of the beam between hinges. There are mechanics closed form solutions available for all of these parameters. This can be used to develop design rules for FRP reinforced members. Importantly the main parameter that controls \( \theta_{\text{max}} \) is not the ability of the reinforcement to yield but the softening branch of the concrete which could if required be enhanced with the addition of fibres. There is no reason to restrict moment redistribution in FRP reinforced section to any greater degree than for steel reinforced sections.

Finally consider IC debonding in Fig. 4. Level 7 models are now available to predict the occurrence of IC debonding and should it occur whether it is stable or catastrophic (Oehlers et al 2016a and 2016b). Hence the structural designer now has the tools to optimise the retrofitting technique. Furthermore should it be found through mechanics that catastrophic IC debonding cannot be avoided by for example changing the FRP plating system then mechanical analytical solutions are available for quantifying the effects of adding mechanical connectors to the adhesively bonded plated area to assist when IC debonding occurs. Another words the structural engineer now has the tools for an advanced FRP retrofitting design.

CONCLUSIONS

1. The main aim of this research is to provide structural engineers with Levels 4 to 7 models that incorporate all the relevant partial interaction local mechanisms that control the behaviour of RC members. This will eliminate the huge cost of member testing and also much of the substantial costs of the development of design rules.
2. Consultants can use these partial interaction models to design one-off FRP members and one off FRP retrofitting techniques for a specific need. Or they can be used in national standards to provide wide ranging mechanics design rules.
3. Manufacturers can use these models to develop new FRP products at considerable reductions in costs as the only testing required are the material properties. Once these properties are determined by tests they can be used in the PI models to determine the RC behaviour and consequently optimise the product.
4. Researchers will benefit from these models as they provide a deep understanding of the interaction between material properties such as concrete creep and shrinkage and bond-slip which will allow a better extraction of these material properties.
5. Much of this mechanics work has already been done. By substantially reducing costs and providing a mechanics in depth understanding, we believe that this approach will encourage, expand and speed up the use of FRP.

ABSTRACT

Fibre-reinforced polymer (FRP) composites in general and pultruded glass-fibre-reinforced polymer (GFRP) profiles in particular are finding increasing applications in civil engineering, due to the several advantages they offer over conventional construction materials. However, for some applications, widespread use is being hindered due to concerns about their behaviour when subjected to elevated temperature and, especially, under fire exposure. These well-founded concerns are particularly acute for building applications, where relatively strict requirements need to be fulfilled in terms of fire reaction and fire resistance performance. With respect to bridges, fire is generally not a concern; yet, in some (special) cases, owners may also set fire behaviour requirements in tender specifications.

This paper presents a state-of-the-art review about the fire performance of pultruded GFRP structures, including the main research contributions from the author in the past 12 years. First, the effects of elevated temperatures on the thermo-physical and mechanical properties of the GFRP material are addressed. Subsequently, the fire reaction behaviour of the GFRP material (Figure 1) and the effects of using different types of fire protection on such behaviour are discussed. Next, the available fire resistance tests on pultruded GFRP elements, including slabs, beams (Figure 2) and columns, are reviewed and discussed, as well as the available modelling studies that aimed at predicting their thermal (Figure 3) and mechanical responses at elevated temperatures. Finally, international guidance for the fire design of pultruded FRP structures is summarized, and the most relevant research needs in this field are identified.

Figure 1 – Fire reaction test on a pultruded GFRP laminate.
Figure 2 – Different stages of a fire resistance test on a pultruded GFRP beam.
Figure 3 – Thermal (CFD) model of a GFRP profile exposed to fire.

ABSTRACT

A proper traction-separation law based on the physical behaviors of epoxy/concrete interface is needed to simulate the debonding behavior of fiber reinforced polymers (FRP)-strengthened concrete structures. This study proposes a novel method using a wedge splitting specimen to directly measure the traction-separation law of the concrete/epoxy interface. This method requires a very simple testing set-up to produce stable crack propagation in the specimen. By adopting a rigid body moment assumption, the traction in the concrete/epoxy interface can be expressed as a function of the applied load and the crack opening displacement. In this way, the relationship between the traction and the separation of the concrete/epoxy interface can be directly measured through recording the crack opening displacement and the applied load during the test. Experimental results show that the traction-separation law of the concrete/epoxy concrete under mode-I loading can be approximated by a tri-linear law. This new method is also used to evaluate the long-term durability of concrete/epoxy interface subjected to moisture attack.

KEYWORDS

Debonding, environmental deterioration, fracture toughness, interface, traction-separation law.

INTRODUCTION

The traction-separation law of the concrete/epoxy under mode-II loading has been studied extensively. However, very few methods can be used to produce the traction-separation law of the concrete/epoxy interface under mode-I loading. To address this gap in the literature, this study presents a simple method to directly measure the traction-separation law of the concrete/epoxy interface under mode-I loading using a wedge splitting test (WST).

The long-term behaviors of the concrete/epoxy interface subjected to aggressive environments threats have become the focus of recent studies. Experimental studies show that exposure to moisture for a long time is the foremost factor that can degrade the interface. Substantial loss of fracture toughness of the interface induced by moisture was observed. In this study, the proposed new testing method will be used to evaluate the effect of water invasion on the concrete/epoxy interface. Organofunctional silane coupling agents (SiH4) have been proved to be useful to enhance the bond between an organic material such as epoxy and an inorganic material such as metal for long time. A few studies (Amidi and Wang 2016; Ye et al. 1998) also suggest that silane can be used to enhance the bonding between concrete and epoxy. Therefore, this role of silane will be examined by the proposed method.

MATERIALS AND METHOD

Wedge Splitting Test

The wedge splitting test is chosen because of its advantages over other popular fracture testing methods. WST requires very simple testing set up. The specimen is easy to fabricate and therefore, even can be done on-site or drilled from the structure. More importantly, the crack propagation in this specimen is stable, which eliminates the difficult task to control the crack growth in the other existing methods such as three-point bending test (Qiao and Xu 2004). The WST specimen consists of three parts: two identical concrete blocks, and a thin layer of cured epoxy bonding these two concrete blocks together, as shown in Figure 1. Since debonding is unlikely to occur
along the interface between the FRP and the adhesive layer, no FRP sheet was used in the specimen shown in Figure 1.

A commercially available silane coupling agent based on γ-glycidoxypropyltrimethoxysilane (γ-GPS) was used in this study to enhance the durability between the adhesive and the concrete. 1% silane solution (aqueous) was prepared. After hydrolysis for 1 hour in room temperature, the silane solution was continuously brushed onto the bonding surface of the concrete block for 10 minutes. The treated concrete blocks were then immediately dried in a preheated oven at 93 °C for one hour. Then the dried blocks were removed from the oven and cooled down to ambient temperature in the laboratory.

The testing set-up for the WST is shown in Figure 2a. The specimen is placed on a roller support mounted on a MTS machine. A steel wedge with two identical parallel plates is fixed at the top of the specimen to transfer the vertical force \( P_v \) applied by the MTS machine to two parallel roller supports at the top of the pre-crack region (Figure 2b). A splitting force \( P_s \) which is the horizontal component of the forces acting on the specimen \( P_N \) and friction force \( \mu P_N \) can be generated to drive two rollers apart (Figure 2b), leading to a mode-I fracture in the specimen. Digital Imagine Correlation (DIC) method is used to directly measure the crack opening of the specimen.

The testing set-up for the WST was first conditioned in a water tank at room temperature (23°C) for 4, 8 and 16 weeks before testing. In addition to the untreated specimens, specimens treated with silane coupling agent were also conditioned in water and then tested to evaluate the role of covalent bonds provided by silane in improving the resistance to water invasion of the concrete/epoxy interface. As a reference, a control group of specimens were conditioned in the ambient environment (with temperature (23°C) and relative humidity level of 50%). Four duplicated specimens were used for each test. The data reported in this study are average of these duplicated specimens.

**Testing Plan**

Inspired by the rigid double cantilever beam technique used for adhesive by Dastjerdi et al. (2013), a new direct measurement method of the traction-separation law of the concrete/epoxy interface using WST is proposed. Since concrete block is much stiffer than the adhesive layer, we can assume that the major deformation of the specimen is within the adhesive layer and the interface. Then the movement of the left and right concrete blocks of the specimen can be approximated as rotating about the symmetric axis like rigid bodies during testing, as shown in Figure 3. In such a case, we can assume that crack opening \( w(y) \) at position \( y \) (Figure 3) can be expressed by a linear function as

\[
w(y) = \frac{\delta}{h}y.
\]
where $\delta$ is the crack opening displacement (COD) at the crack mouth, and $h$ is the crack length. Dastjerdi et al. (2013) have confirmed through theoretical analysis that such a rigid body assumption is reasonable for short and stiff beams, which is the case of the WST specimen used here.

Since each half of the specimen can rotate about the vertical symmetric axis as a rigid body, its free-body diagram can be presented as shown in Figure 3. In this figure, the peel stress within the interface $\sigma(w(y))$, is a function of the separation of $w(y)$ of the interface. The equilibrium condition of the wedge in the vertical direction shown in Figure 2b gives

$$\eta P_N \cos \theta + P_N \sin \Phi = \frac{P_v}{2},$$

(2)

where $\eta$ is the friction constant between the roller and the wedge, $P_N$ is the reaction force from the roller to the wedge. Considering the equilibrium condition of the roller shown in Figure 2b in the horizontal direction, we can obtain the splitting force $P_{sp}$ applied by the wedge to the specimen as

$$P_{sp} = P_N \cos \Phi - \eta P_N \sin \Phi.$$  

(3)

Therefore,

$$P_{sp} = \frac{1 - \eta \tan \Phi}{2(\eta + \tan \Phi)} P_v,$$

(4)

where $\eta$ ( = 0.2) is the friction constant between the roller and the steel wedge; $\phi$ is a the angle of the steel wedge shown in Figure 2b.

**Figure 3 Free-body diagram of the half specimen**

Considering the moment equilibrium of the specimen about the right bottom corner of the half-specimen shown in Figure 3, we have

$$t \int_0^h \sigma(w(y))wdy = P_{sp}d_2 + \frac{1}{2} P_v d_1 + \frac{1}{2} mg e,$$

(5)

where $d_1$ and $d_2$ are the lever arms of force $P_v$ and $P_{sp}$ as shown in Figure 3, respectively; $mg$ is the self-weight of the concrete block; and $e$ is the distance of the center of the half specimen to the symmetric axis, as shown Figure 3.

Considering Eq. (1), Eq. (5) can be rewritten as

$$\int_0^\delta \sigma(w)wdw = \frac{1}{t} \left( \frac{h}{2} \right)^2 \left( P_{sp} d_2 + \frac{1}{2} P_v d_1 + \frac{1}{2} mg e \right).$$

(6)

Taking derivatives on both sides of Eq. (6) with respect to $\delta$ yields

$$\sigma(\delta) = \frac{2}{h^2 t} \left( P_{sp} d_2 + \frac{1}{2} P_v d_1 + \frac{1}{2} mg e \right) + \frac{\delta}{h^2 t} \left( \frac{dP_{sp}}{d\delta} \frac{d_2}{d\delta} + \frac{dP_v}{d\delta} \frac{d_1}{d\delta} \right).$$

(7)

Equation (7) directly gives the relationship between the separation $\delta$ and the traction (stress) $\sigma$ of the epoxy-concrete interface. It requires neither a pre-assumed shape for the traction-separation curve, nor any complicated inverse analysis. By measuring the COD and the applied load, the traction-separation law for epoxy-concrete interface under mode-I can be directly calculated using Eq. (7). The total fracture energy of the epoxy-concrete interface under mode-I loading can then be calculated from the traction- separation law as

$$G_I = \int_0^\delta \sigma(\delta) d\delta.$$  

(8)
TESTING RESULTS AND DISCUSSION

WST was conducted with a MTS machine under displacement control at the rate of 0.13 mm/min. A digital image correlation (DIC) system was used to take pictures of the specimens every 15 seconds. Images captured during the test were used to derive $\delta$ by simply reading the difference between displacements of two predetermined points at each half-specimen adjacent to the tip of the pre-crack. Figure 4 shows a typical result of the measured splitting force $P_{sp}$ versus COD $\delta$ for a WST specimen conditioned in water for 16 weeks. In order to extract the traction-separation law, the measured $P_{sp}$-COD curve was first smoothened to make it possible to calculate the derivative of $P_{sp}$ with respect to COD in Eq. (7), as shown by the red line in Figure 4. A typical result of such traction-separation law is shown in Figure 5 for a specimen conditioned in water for 8 weeks. It can be seen that the traction within the interface appears to increase with the separation initially. After reaching its maximum, the traction starts to drop with the separation, as shown in Figure 5. This traction-separation law can be approximated by a tri-linear traction-separation law shown in Figures 5 and 6.

![Figure 4](image1.png)

Figure 4 Splitting load versus COD measured at the crack mouth ($\delta$) for a specimen conditioned in water for 16 weeks.

![Figure 5](image2.png)

Figure 5 Measured traction-separation law of the epoxy-concrete interface under mode-I for a specimen conditioned in water for 8 weeks.

The resulted tri-linear traction-separation laws are shown in Figure 6. The control specimen exhibits much higher maximum tensile traction than the conditioned specimens. Silane coupling agent can improve the bond quality by forming a covalent bond of Si-O-Si between the epoxy and the concrete. A comparison at the beginning segment of the traction-separation law shows that conditioning in water can significantly reduce the initial stiffness of the bond, making it remarkably softer in comparison with the control specimens, as shown in Figure 6c. This is exacerbated when longer conditioning duration is used. Silane coupling agent treatment can slightly improve the stiffness of the interface after short-term conditioning in water, as shown in Figure 6b.
Figure 6 Tri-linear traction-separation laws measured for concrete/epoxy interface after conditioning in water: a) effect of conditioning in water on the traction-separation law; b) effect of silane on the traction-separation law of the interface after conditioning in water; c) effect of water conditioning on the stiffness of the concrete/epoxy interface

Using Eq. (8), the mode-I fracture toughness for each group can be obtained and presented in Figure 7. After conditioning in water for 4 weeks, the mode-I fracture toughness of all untreated specimens have been decreased remarkably compared to the control ones.
Figure 7 Effect of duration of water conditioning on the fracture energy of the concrete/epoxy interface with and without silane coupling agent

CONCLUSIONS

In this study, a novel testing method using WST specimen is proposed to directly measure the traction-separation law of the concrete/epoxy interface under mode-I loading. This new method is then used to evaluate the long-term durability of the concrete/epoxy interface subjected to moisture attack. Experimental study suggests that the traction-separation law of the concrete/epoxy interface under mode-I loading can be conveniently obtained using this new method. The traction-separation law of the concrete/epoxy interface under mode-I loading can be approximated by tri-linear laws. Conditioning the specimens in water can significantly reduce the tensile strength and the fracture toughness of the interface. By applying saline coupling agent, the residual strength and fracture toughness of the concrete/epoxy interface after conditioning in water are higher than that of the specimens without silane treatment, suggesting that the silane coupling agent is effective to improve the long-term durability of the concrete/epoxy interface subjected to moisture attack.

ABSTRACT

The on-site evaluation of the bond quality between externally bonded Fiber-Reinforced Polymer (FRP) composites and concrete structures is crucial to assess the performance and predict the durability of the reinforcement system. In this study, it is proposed to determine the bond properties of the adhesive layer by using a nondestructive testing (NDT) method derived from the standard pull-off test. This method consists in analyzing the linear load vs displacement behavior of the adhesive joint subjected to a mixed-mode loading, in order to determine a bond stiffness which could be related to the bond quality. This paper gives some insight into the proposed test method applied to concrete slabs reinforced with Carbon-FRP (CFRP) plates bonded with three different epoxy adhesives. The experimental implementation and the first results are shown and discussed.

FRP composites, concrete, bond quality, non-destructive evaluation, pull-off test.

INTRODUCTION

Over the last 30 years, structural reinforcement and retrofitting with externally bonded composite materials has proven to be an efficient and cost-effective solution to increase both the safety and lifespan of civil engineering structures (ISIS Canada Research Network, 2007). In the composite – adhesive – concrete assembly, the stress is transferred from the structure to the composite material through the shear deformation of the adhesive layer. Therefore, for the sake of performance and durability, the level of adhesion between the FRP material and concrete substrate must be of good quality (Ferrier et al, 2010).

A common way to assess the bond quality in the field is to use the standardized direct tension pull-off test (ASTM D7522 / D7522M, 2015; EN 1542, 1999), pictured on Figure 1.a. It consists in bonding a steel fixture called dolly at the FRP surface and drilling a partial core around it. The dolly is then loaded perpendicularly to the FRP surface, until failure occurs at the so-called pull-off strength. A sound assembly shows a cohesive failure in the concrete substrate with a pull-off strength higher than a minimal value (usually 1.5 or 2 MPa, depending on the guidelines). However this destructive method has many drawbacks, as there is a large scattering on test results and the pull-off strength is highly influenced by the concrete properties and the geometrical characteristics of the partial core.

The present study intends to develop an alternative nondestructive (ND) test method which is able to evaluate the level of adhesion, and is suitable for use in the field. The proposed method is derived from the standard pull-off test, but an additional equipment provides measurements of the dolly displacements with a high accuracy, and the test is only carried out in the linear elastic domain. It is thus possible to plot the load vs displacement curve, whose slope relates to the assembly stiffness. The scope of this first paper is to show the feasibility of this method for providing quantitative and discriminating data on the stiffness of the concrete/CFRP bonded assembly that can be further interpreted in terms of bond quality.

DESCRIPTION OF THE NONDESTRUCTIVE TEST METHOD

This feasibility study is restricted to the case of composite plate systems for simplicity reasons. Further researches should be conducted on other systems like fiber sheets bonded to the structure by wet lay-up. The proposed ND method is depicted on Figure 1.b. As mentioned before, it is based on the standard pull-off test, but there are three main differences: (1) no core is drilled around the dolly, (2) a displacement measurement is performed in addition
to the load measurement, and (3) the test is carried out in the linear elastic domain. From both measurements, a load vs displacement curve can be plotted, whose slope will be called the bond or assembly stiffness.

The displacement should be measured at a well-chosen location of the concrete/FRP bonded assembly, so that it provides relevant information on the bond behavior. A differential displacement is also an interesting way to focus on the most interesting contributions. In the present study, a differential displacement between the dolly and the concrete surface is considered (Figures 1.b and 2.a). In addition to the E-modulus of the adhesive, several parameters influencing this displacement and the bond stiffness have been identified, namely the thickness of the adhesive, the elastic properties of the concrete substrate, the E-modulus and the thickness of the bonding agent between the dolly and the composite plate. This issue will be addressed in the developments. Differently, the deformation of the steel dolly is considered negligible and the contribution of the pultruded composite plate is supposed well-known. It should be pointed out that micron-level displacements are expected.

As no core is drilled around the dolly, the adhesive joint is not subjected to pure tensile stress but to a mixed-loading mode similar to a peel test. This type of loading is actually experienced by the FRP systems in flexural strengthening applications (Buyukozturk et al., 2004), and by FRP systems bonded to curved substrates like arches or cooling towers (De Lorenzis and Zavarise, 2009). This mixed-loading mode is thus relevant for assessing the bond quality.

In order to investigate the feasibility of the ND pull-off test, an experimental campaign was conducted, which is described in the following sections.

EXPERIMENTAL PROGRAM

The aim of this experimental campaign is to check whether the ND pull-off test is able to distinguish between adhesive materials showing various Young’s moduli and simulating different levels of adhesion.

Experimental setup

In order to have precise control of the experimental setup at the metrological level, it was decided to carry out the tests on laboratory equipment instead of using a commercial pull-off tester. The ND pull-off test is conducted on a universal testing machine equipped with a load cell of capacity 50 kN. In order to firmly hold the concrete specimens, a clamping device, presented Figure 2.b, was designed using a commercial computed aided design (CAD) software, and then machined in a precision manufacture. This device consists of two overlapping steel plates and vises and allows two translational degrees of freedom for more flexibility in specimens’ geometry. A finite elements model of the apparatus was computed to understand its behavior during the loading phase and estimate, for all bolts, the torques needed to ensure that the different parts remain in contact, so that undesirable motions are minimized. The whole device was consequently assembled and installed on the universal testing machine using a torque wrench and following a specific procedure aiming to insure horizontality as much as possible.

As for the standard pull-off test, the load is applied to the dolly through a ball-joint fixture. For the present experimental campaign, the ball-joint system (a spherical headed bolt and a mechanical coupling) was supplied as spare parts of a commercial pull-off tester. Special care is given to the centering of the spherical headed bolt into the coupling, in order to minimize possible flexion loading.

Special steel loading fixtures were produced, whose geometry was based on standard dollies. On top of a 50 mm diameter cylinder was added a 110 mm diameter and 5 mm thick plateau, with total height of 25 mm (Figure 2.a). This plateau allows performing displacement measurements, which would not have been possible otherwise,
because of the bulk of the ball-joint coupling. Dollies are glued to the specimens using a contact cyanacrylate adhesive, which is rubber toughened and exhibits increased flexibility and peel strength. Its low viscosity ensures a contact bond, which minimizes the tensile deformation of the bond line and its contribution to the measured displacement, which was earlier identified as a parameter influencing the bond stiffness. The fixture time for a steel – CFRP interface is about 2 – 3 minutes, which gives enough time for positioning the dolly properly.

The displacement measurement between the dolly and the concrete surface is performed using high accuracy optical digital sensors, which provides consistent submicron measurement over a 12 mm displacement range. Two sensors are installed on each side of the system’s plane of symmetry, in order to get average values based on two displacement measurements (see Figure 2.a). The two sensors were calibrated prior the tests and presented expanded uncertainties of 0.9 µm and 0.6 µm respectively (coverage factor of 2). They were attached to the sides of the dolly’s plateau by means steel rings glued with a 2-component fast curing methacrylate adhesive.

Load measurement is provided by the load cell of the universal testing machine. However, it was necessary to retrieve the load data with the acquisition system of the displacement sensors in order to synchronize both measurements. This was carried out by means of a specific input / output board and an analog-to-digital converter. This load acquisition system was also calibrated prior to the tests and present an expanded uncertainty of 120 N. All experiments are performed at a controlled room temperature of 21°C ± 2°C.

Specimens

Different levels of adhesion were simulated using three commercially available epoxy adhesives, with Young’s moduli of 11,200, 4,950 and 965 MPa respectively. It is worth noting that Adhesives 1 and 2 are commercial systems intended for bonding CFRP plates on concrete structures, while Adhesive 3 is a low modulus system that simulates an environmentally aged epoxy adhesive, as a significant decrease in the elastic properties is usually observed after accelerated ageing in humid environments, due to a plasticization of the polymer network (Benzarti et al, 2011). The properties of the unidirectional CFRP laminate are listed in Table 1.

The experimental program consists of eighteen concrete slabs strengthened with CFRP-laminates bonded using the three different adhesives (six specimens for each adhesive). Among each series of six specimens, three specimens (labelled “D” for destructive) were tested until failure. A limit load, lower than the recorded ultimate failure loads was then chosen. The load applied to the three others specimens (labelled “ND” for nondestructive) did not exceed this limit load, insuring the nondestructive nature of the tests. It is to note that displacement data acquired for four out of the eighteen specimens were not exploitable. The overall experimental program is summarized in Table 2.

300 × 300 × 70 mm³ concrete slabs of type MC 0.45 were casted according to (EN 1766, 2000). The maximum aggregate size is 10 mm. Three concrete batches were mixed for a total of thirty-six blocks (the rest of the blocks will be used in a durability study). The 28 days compressive strength of concrete was evaluated on cubic specimens with 150 mm long edges, giving an average value of 63.5 MPa, which corresponds to a C45/55 strength class and an indicative compressive modulus of 36 GPa (EN 1992-1-1:2004). Due to the bad condition of the concrete surface, an extensive grinding treatment was achieved, until the surface was completely planar. The different steps of the specimen preparation are presented in Figure 3. For each specimen, a 300 mm long strip of composite plate is bonded at the center of the concrete slab. However, the edges of the concrete blocks were covered with a rubber tape of width 2 cm, in order to prevent edge effects. The total bonded length for the CFRP plate is therefore 260 mm.

Figure 3 Specimen preparation

As mentioned earlier, the thickness of the adhesive layer is expected to influence the overall bond stiffness. Special care was given to control the thickness as much as possible during specimen preparation. A steel mass with legs 3 mm high was used to press the composite plate and the adhesive layer in order to obtain a desired thickness of the adhesive joint. The final thickness in the central area was also measured with a caliper prior to the bonding of the dolly, as shown in Figure 3.g. Thickness values of the adhesive layer are given in Table 3 for specimen on which the displacement measurement could be performed. A value is the average of 9 point-like measurements in the central area of the composite plate. The associated uncertainty is calculated by summing the square experimental error (valued at 0.1 mm) and the standard deviation of the different measurements.

Loading procedure

A specific loading procedure was followed during the tests. The loading is displacement-controlled, the crosshead of the testing machine moving at a speed of 0.3 mm/min. A cyclic protocol is applied, with a baseline at 200 N and the maximal load increasing every three cycles. No limit load was set for the “D” specimens, unlike “ND” specimens.
RESULTS AND DISCUSSION

Determination of the limit load

The failure loads for the nine “D” specimens tested until failure are given in Table 4. It should be noted that all specimens exhibited a brittle fracture, except for specimens 2.1 and 3.3. For these specimens, a loss in the slope of the load vs displacement curve, i.e. in the bond stiffness, could be observed. The failure load is defined as the load corresponding to the first brittle event associated with damage or to a loss in the bond stiffness. The nature of this event (type of damage) is also reported.

Table 4 Failure load and associated event for the “D” specimens, and limit load chosen for the different adhesives.

</tr>
</tbody>
</table>

* The failure load of specimen 1.3 could not be recorded since the specimen was accidently damaged during installation.

As regard failures accompanied with a dull noise, a small bulge of the composite plate could also be observed in the area surrounding the dolly. This dull noise is due to the tensile failure of the concrete substrate underneath the dolly, which could be verified after the composite plate was completely pulled off.

Taking the previous results into account, the following limit loads were chosen for the “ND” specimens (also reported in Table 4): 10 kN for Adhesive 1, 8 kN for Adhesive 2 and 8 kN for Adhesive 3.

Load vs displacement curve and bond stiffness

The load vs displacement curves of all fourteen exploitable specimens (see Table 2) are presented in Figure 4. Only the last load cycle is displayed. In the present results, the average displacement of the two sensors is used.

![Figure 4 Load vs displacement behavior acquired during the ND pull-off tests.](image)

Values of the bond stiffness, corresponding to the slope of the load vs displacement curves, are also calculated through linear regression. Only the data until the limit load associated with each adhesive are considered, even for “D” specimens which provide further data. Calculated values of the bond stiffness are given in Table 5, together with a first estimation of the expanded uncertainty (coverage factor of 2). It is evaluated from the uncertainty on the displacement measurement using linear least-square formulae. The uncertainty on the load measurement is
neglected as it is relatively small compared to the uncertainty on the displacement. Repeatability and reproducibility uncertainties will also be taken into account in the future.

From the previous results, the following observations can be made:
- It is possible to distinguish specimens according to the type of adhesive used for bonding CFRP plates, although there is an ambiguity for specimens 2.4 and 2.5 one the one hand, specimens 3.3 and 3.5 on the other hand, which show close bond stiffness values. Thus, the ND pull-off test can discriminate several levels of adhesion.
- Different slopes, i.e. different values of bond stiffness, are found for specimens produced with one given adhesive. However, this is unlikely due to statistical dispersion as several specimens can have very close bond stiffness values (specimens 2.1, 2.2 and 2.6 for instance).
- The adhesive thickness seems not to influence significantly the bond stiffness. For instance, specimens 1.4, 1.5 and 1.6 have thicknesses of the adhesive layer equal to 1.5 ± 0.1 mm, 1.6 ± 0.2 mm and 1.9 ± 0.1 mm respectively, but they exhibit very close values of the bond stiffness.
- Damaging of specimen 2.4 started just below 8 kN, which could be detected by a loss in the bond stiffness. However, voids in the adhesive layer located near the dolly area were detected by infrared thermography prior to the test. It is believed that the early failure of this specimen is due to the voids. Only the data collected before this loss of bond stiffness (under 6 kN) are presented in Figure 4 and are used to calculate the slope.

It is believed that differences in the apparent bond stiffness observed for a given type of epoxy adhesive are not related to statistical dispersion, but may result from variations in other influential parameters of the bonded assembly, and most likely the properties of the concrete substrate. As a reminder, three batches of concrete were used to cast all the slabs, which is consistent with the maximum of three different slopes observed in the case of specimens prepared with Adhesive 2. To confirm this hypothesis, further research will consist in conducting the ND pull-off test on the bare concrete surface in order to measure a reference stiffness for each batch of concrete.

**CONCLUSION AND PERSPECTIVES**

In this paper, a nondestructive test is proposed for assessing the bond quality in a concrete-to-FRP bonded assembly. It is based on the popular standard pull-off test, but shows three main differences: (1) no partial core is drilled around the dolly, (2) a displacement measurement is performed in addition to the load measurement, and (3) the test is carried out in the linear elastic domain. The bond quality criterion depends on the bond stiffness deduced of the load – displacement curve. The first results presented in this paper suggest the ability of the ND pull-off test to distinguish between different levels of adhesion. These are experimentally simulated by using different epoxy resin systems showing distinct Young’s moduli. Nonetheless, different values of bond stiffness are found for a given adhesive, and it is believed that a change in the concrete’s properties is responsible for this difference. It is therefore suggested to complete our experimental methodology by conducting the same ND pull-off test on the bare concrete surface, in order to measure a reference stiffness related to the concrete’s behavior. A finite element modeling will also be completed to help analyzing the behavior of the system and the test results.

This test method could be a promising tool to assess the bond quality of composite strengthening systems in the field. It could be carried out using a commercial pull-off tester, provided it is equipped with a sufficiently precise load cell and a displacement measurement system, and a synchronization is ensured between both measurements.

DEFECT CRITICALITY IN FRP/CONCRETE BOND JOINT – A FINITE ELEMENT STUDY

C. Tuakta and C. Yoopom
Department of Civil Engineering, Kasetsart University,
Thailand, Email: fengcptu@ku.ac.th

ABSTRACT
Defects, such as debonded region at FRP/concrete interface, can occur over time in fiber-reinforced polymer (FRP) strengthening system in concrete structures. Limited numbers of researches have showed that the overall performance of reinforced concrete members strengthened with FRP can deteriorate due to the presence of defects. This can result in reduction of load capacity, stiffness, and durability, potentially causing premature failure, if not treated properly. This study investigated the effects of defect (or defect criticality) at bond level, using finite element analysis of specimens used in single-lap shear test. The defect was in the form of debonded region at FRP/concrete interface. The parameters included bond width and bond length, size and location of defect, and the compressive strength of concrete ($f'_c$). The results have showed that, in most cases, the distribution of interfacial shear stress and bond strength were affected by the presence of defects. Bond strength reduction was more pronounced in FRP/concrete bond joint with bond length smaller than the effective value or with higher FRP stiffness.

KEYWORDS
Defect criticality, bond strength, bond-slip relationship, FRP/concrete interface.

INTRODUCTION
Fiber reinforced polymer (FRP) composites have been increasingly used to enhance load capacity and improve serviceability of existing reinforced concrete (RC) members and structures in the last two decades. This is due to their advantages over other conventional strengthening materials, such as higher strength-to-weight ratio, corrosion resistance, and ease of installation. For flexural strengthening of RC beams, FRP material is externally bonded to the tension face of the RC member using adhesive, or embedded in concrete in case of near-surface mounted FRP rods. In spite of ample research on short-term mechanical behavior, this strengthening technique still cannot realize its full potential due to limited knowledge on its long-term durability and criticality of potential defect. Due to its composite nature, the effectiveness of the FRP strengthening system for flexure and shear depends on the performance of the FRP/concrete interface. However, defect in the form of debonded regions can exist at the FRP/concrete interface in flexurally and shear strengthened members as a result of poor construction, or subsequent physical damage and environmental degradation during its intended service life after rehabilitation. Limited numbers of studies have showed that the presence of defects can have detrimental effects on FRP-concrete systems (Seim et al. 2001, Karbhari and Navada 2008, Kalayci et al. 2009, Guo et al. 2012). This paper is aimed at gaining more understanding on the effect of defect on the FRP/concrete system at bond joint level using finite element analysis (FEA). The parameters included bond width and bond length, size and location of defect, and the compressive strength of concrete ($f'_c$).

METHODOLOGY

Bond-Slip Relationship for FRP/Concrete Interface
In simulating debonding failure of FRP/concrete bond joint in FEA, the relationship between shear stress ($\tau$) and slip ($\delta$) in the FRP/Concrete interface can be described by a bond-slip model. Several forms of bond-slip model have been proposed in the past 10 years based on analysis of experimental results from fracture tests (Nakaba et al. 2001, Lu et al. 2005). The simplest form is a bi-linear bond-slip curve consisting of linear ascending and descending branches, which can be described by three parameters: maximum interfacial shear stress ($\tau_m$), slip at maximum interfacial shear stress ($\delta_0$), and maximum slip ($\delta_f$) (Figure 1a). The linear ascending branch describes...
the stress-slip relationship in elastic regime when \(0 \leq s \leq s_0\), which is expressed by Eq. 1. In this regime, the bond joint will behave elastically until the interfacial shear stress and slip reach \(\tau_m\) and \(s_0\), respectively. The linear descending branch or softening branch describes the behavior of damaged interface (due to micro-cracking and crazing in the adhesive) after shear slip exceeds \(s_0\). As the value of slip increases beyond \(s_0\), the interfacial shear stress decreases linearly according to Eq. 2. Debonding of the FRP/concrete bond joint takes place when \(s > s_f\), after which the interfacial stress becomes zero, signifying the inability of the interface in the debonded region to transfer load between FRP and concrete.

\[
\tau = \tau_m \left( \frac{s}{s_0} \right) \quad \text{for} \quad 0 \leq s \leq s_0
\]

(1)

\[
\tau = \tau_m - \frac{\tau_m (s - s_0)}{s_f - s_0} \quad \text{for} \quad s_0 \leq s \leq s_f
\]

(2)

Figure 1 A typical bi-linear bond-slip relationship (a) and single-lap shear specimen (b)

Ko et al. (2014) have recently developed a bond-slip relationship for practical design purpose by calibrating the afore-mentioned model parameters using database of various single-lap shear and double-lap shear test results. According to Ko et al. (2014), the parameters for the bi-linear bond-slip model may be calculated from Eqs 3 through 5.

\[
\tau_m = 0.165f'_c
\]

(3)

\[
s_0 = -0.001f'_c + 0.122
\]

(4)

\[
s_f = -0.002f'_c + 0.302
\]

(5)

where \(f'_c\) is the compressive strength of concrete (MPa). The maximum interfacial shear stress and slip parameters are given in MPa and mm units. This study used the bond-slip relationship proposed by Ko et al. (2014) to simulate the debonding behavior of the CFRP/concrete interface.

Figure 2 FE models without defect (a) and with defect of size 10 mm at midpoint in bond (b)

Finite Element Model of Single-lap Shear Test Specimen

In this study, 2-dimensional FE models of FRP/concrete bond joint were constructed based on the specimens in single-lap shear test conducted by Yao et al. (2005). Figure 1b shows the schematic representation of single-lap shear test, and Figure 2 shows the FE models with and without defect. The models consisted of 4-node plane-stress elements (CPS4) for concrete block and FRP plate, and 4-node cohesive elements for interface layer (COH2D4). Note that various tests have shown that failure in FRP/concrete bond joint is mainly in the form of separation at concrete/adhesive interface with thin concrete layer remaining on adhesive surface. Therefore, the interface layer in the FE models with bond behavior governed by the specified bond-slip relationship will represent this failure zone in real specimens. The 4-node cohesive elements used in this study are capable of describing both normal (mode I) and shear (mode II) deformations as shown in Figure 3. The relationship between normal deformation (\(n\)) and normal stress (\(\sigma\)) can be specified by bi-linear relationship similar to the bond-slip relationship for shear behavior in Figure 1a (Eqs 1 and 2). However, since the interface in single-lap shear test mainly deforms
in shear, debonding by mode I fracture was prevented in the FE models by specifying a value of maximum normal stress $\sigma_m$ significantly higher than the maximum interfacial shear strength $\tau_m$ (e.g. 2 orders of magnitude higher).

Both concrete and FRP used linear elastic material behavior, with compressive strengths of concrete equal to 23 and 27.1 MPa, and Young’s modulus of FRP equal to 256 GPa. The Young’s moduli of concrete ($E_c$) at the two strength levels were calculated according to the ACI Guideline (2008) to be 22.68 and 24.62 GPa, respectively. According to Eqs 3 and 4, the initial stiffness of the interface layer are 38.33 and 47.12 MPa/mm, and the maximum interfacial shear stress ($\tau_m$) are 3.80 and 4.47 MPa, for the two concrete strength levels. Figure 4 compares bond strengths obtained from FEA (without defect) and from the experiment reported in Yao et al. (2005). It suggests that the proposed FE model could adequately simulate the strength and behavior of FRP/concrete interface in single-lap shear test.

In order to investigate the effect of defect, debonded region was inserted into the interface by omitting cohesive elements in the corresponding region for a specified length. Without cohesive elements, there is no shear transfer between FRP and concrete in defect area. Figure 5 shows the characteristics of defect, including length ($L_d$) and
location along the bond line. The size of concrete block, free concrete height ($h_c$), bond length ($L_d$), and FRP thickness were based on the single-lap shear specimens without defect in the study by Yao et al. (2005). Table 1 shows model groups with corresponding geometries. $L_a$ and $a$ in the model codes are defect size and location, respectively, with $L_a = 0$ and $a = 0$ meaning no defect in the interface. Locations of defect are denoted by $LE$ for defect located close to the loaded end, $L/4$ for defect located at quarter length closer to the loaded end, $L_f$ for defect located at the center of bond joint, $3L/4$ for defect located at quarter length closer to the free end, and $FE$ for defect located close to the free end. The sizes of defect $L_a$ in this study were 10, 20, 40 mm.

**RESULTS AND DISCUSSION**

**Behavior of FRP/concrete Bond Joint with and without Defect**

In both models with and without defect, the interfacial shear stress ($\tau$) distribution can be categorized into three regimes – Elastic, Elastic-softening, and Elastic-Softening-Debonding. These three behaviors depend on the magnitude of the applied load. At low load level, behavior of the interface is Elastic. Elastic-softening behavior starts just after the applied load exceeds the softening load ($P_s$). As the load increases beyond $P_s$, local debonding will take place (slip $> s_0$) and the behavior becomes Elastic-Softening-Debonding. The ultimate load or bond strength $P_c$ corresponds to when shear stress in the entire interface becomes zero. Figure 6 shows samples of interfacial shear stress distributions from models E-0-0 and E-10-C. Note that by examining the stress distribution in perfect models of various bond lengths, the effective bond length for this particular FRP/concrete system was approximately 190 mm. When comparing stress distribution between bond joints with and without defect, it has been observed that defect can cause slightly increase in stress magnitude, depending on size and location. Figure 7 shows the effect of defect of various locations and sizes on the shear stress distribution for the models based on D-0-0. The increase in shear stress is more pronounced in the vicinity of defect (see Figure 7). This can be attributed to the reduction in the true bond length. Larger defects ($L_d = 40$ mm) resulted in generally higher increase in overall shear stress. In addition, defects at locations of high stress normally in perfect bond (e.g. $L/4$ and $C$) resulted in higher increase in shear stress. This may be because there is high shear transfer between FRP and concrete in these locations. Therefore, removing a portion of the interface in this zone will result in higher shear transfer in the proximity.

![](image)

Figure 6 Sample of interfacial shear stress distribution under varying applied load: (a) Model without defect (Model E-0-0 with with $f'_c = 23$ MPa, $b_i = 150$ mm, $b_f = 25$ mm, $L_d = 190$ mm, and $h_c = 5$ mm) and (b) Model with defect (Model E-10-C with $L_d = 10$ mm and defect at the center of bond line)
Figure 7 Sample of interfacial shear stress distribution as affected by: (a) Defect sizes (Models D-0-0, D-10-C, D-20-C, and D-40-C) and (b) Defect locations (Models D-0-0, D-10-LE, D-10- Lf/4, D-10-C, D-10-3Lf/4 and D-10-FE)

**Effect of Defect on Bond Strength**

Figure 8 shows the bond strength as affected by defect size and location in the FRP/concrete bond joint with varying $L_f$. Larger defect resulted in higher reduction in bond strength, which is consistent with the increase in interfacial shear stress. For the defect of the same size, defects at the center and at $L_f/4$ seemed to reduce bond strength the most. The effect of defect was also more pronounced when the bond length ($L_f$) was much smaller than the effective bond length. In addition, for defects of the same size at location LE and FE, the bond strength reductions were not much different in most cases because the resulting bond areas were still similar.

Figure 8 Effect of defect on bond strength in models with varying $L_f$ (models with $f'_c = 23$ MPa, $b_c = 150$ mm, $b_f = 25$ mm, and $h_c = 5$ mm)

Figure 9 Effect of defect on bond strength in models with varying $b_f$ (models with $f'_c = 27.1$ MPa, $L_f = 100$ mm, $b_c = 150$ mm, and $h_c = 120$ mm)
Figure 9 shows the bond strength as affected by defect when the FRP width was varied, and the bond length was kept constant at 100 mm. Similar trends were observed, in which larger defects and defects at the center of bond joint resulted in higher bond strength reduction. In addition, higher percentage of bond strength reduction was observed in the models with wider FRP. This implied that the influence of defect was more pronounced in FRP/concrete bond joint with higher FRP stiffness.

CONCLUSIONS

This paper presents the derivation of stress distribution and bond strength in FRP/concrete bond joint with a defect by using finite element analysis. The FEA results have showed that characteristics of the defect, namely the location and size, influenced the interfacial shear stress distribution, the debonding behavior, and the bond strength. The effects of defect may be concluded as follows:

- Behavior of FRP/concrete bond joints with and without defect are similar in that they both consisted of three stages – elastic, elastic-softening, and elastic-softening-debonding, which depend on load level.
- Interfacial shear stress in FRP/concrete bond joint with defect was higher than that in FRP/concrete bond joint without defect under the same load due to lower true bond length.
- Larger defects resulted in higher interfacial shear stress, while defects in the zone of high shear stress (i.e. locations closer to the loaded end) could increase shear stress further.
- Bond strength of FRP/concrete bond joint was affected by the presence of defect. Larger defects resulted in higher reduction in bond strength, while defects in the zone of high shear stress (i.e. locations closer to the loaded end) can reduce bond strength further. The reduction in bond strength was more pronounced when the original bond length is much smaller than the effective bond length ($L_e$).
- FRP/concrete bond joint with higher FRP stiffness seemed to be affected more by the presence of defect.

ABSTRACT

Bond performance of RC strengthened with polyurea resin and strand sheet depends on the concrete strength and the amount of polyurea resin. The present experimental study was undertaken in order to confirm the effect of above factors in the bond behaviour of concrete - strand sheet with a layer of polyurea resin by means of one side pull-out bond test method. Consequently, the specimen of the low strength concrete showed lower ultimate bond strength than that of the normal strength concrete at the same amount of polyurea resin regardless of presence or absence of the polyurea resin. However, the specimens with polyurea resin showed far higher ultimate strength than that of the specimens without polyurea resin regardless of the concrete strength. Furthermore, the bond strength was almost the same in the range of polyurea resin coating amount of 0.5-3kg/m².

KEYWORDS

Strand sheet, polyurea resin, concrete strength, bond, amount of polyurea resin.

INTRODUCTION

The effectiveness of flexural strengthening using the strand sheet is equivalent or greater compared to the one that uses the conventional fiber sheet, which has been shown experimentally (Akira et al. 2008). However, when peeling between the strand sheet and the concrete surface due to opening of flexure and shear cracks in concrete member occurs, the tensile strength of the strand sheet may not be provided properly. Improvement for this problem has been shown experimentally by inserting a layer of polyurea resin between the concrete and the strand sheet (Masaki et al. 2012). One of the reasons that polyurea resin was adopted is that the material properties of polyurea resin is more stable than those of other resins such as epoxy resin at a low temperature level of -20°C and at a high temperature level of 50°C. The bond tests under different temperature were conducted in order to confirm that polyurea resin is more stable at temperature. As a result, it was found that the certain effect was able to be obtained by using polyurea resin (Masaki and Akira et al. 2014, Masaki and Takahiro et al. 2014). However, how the concrete strength and the amount of polyurea resin may influence the bond behaviour had not yet been confirmed. Therefore, bond tests were carried out in order to confirm the impact of the factor, and the results have been reported.

BOND TEST PROGRAMS

Method of bond tests

The experimental report that the effective bond length of the specimens with polyurea is longer had been presented (Masaki et al. 2012). Therefore, one side pull-out bond test method was adapted due to constraints of the test equipment. Geometry of specimens is shown in Figure 1. Concrete blocks of size 150x300x600 mm were prepared. Specimens were 25mm in bond width and 520mm in bond length of the strand sheet and concrete. The release film was inserted at the upper tip of the concrete brock. During the loading tests, besides the load and the stroke...
of the test equipment (displacement), the strain of strand sheet was measured. Strain gauges were put in 40mm pitch from the end of the release film to measure the strain distribution.

![Diagram of Geometry of specimens](image)

**Figure 1 Geometry of specimens**

**Parameters of the bond tests**

As shown in Table 1, bond tests were carried out on different types of specimens in 9 cases, which include the case1 and the case5 without polyurea resin. Two or four specimens were prepared in each case. The experimental parameters were concrete strength and the amount of polyurea resin. Bond tests were selected at two different compressive strength of concrete (14.5N/mm² and 35.2N/mm² at the time of the experiment), in consideration of that some structures to apply this method have low strength concrete. Further, the coating amount of polyurea resin of the specimens was varied between 0-3kg/m², in consideration of that the concrete surface of the structure is not necessarily smooth although the standard application of the amount of polyurea resin on this method is 1.0kg/m². The outline of the construction process of the specimen is shown below. In Case1 and case5, strand sheet was attached using epoxy putty resin after grinding the concrete surface. In other specimens, urethane primer was coated at 0.2 kg/m² after grinding concrete surface. After polyurea resin was coated, the strand sheet was attached with epoxy putty resin. Properties of strand sheet and resin are shown in Table 2(a), 2(b).

RESULTS AND DISCUSSIONS

Maximum load and failure modes

Relationships of maximum load and amount of polyurea resin are shown in Figure 2. Maximum load and interfacial fracture energy are shown in Table 3. Interfacial fracture energy was calculated by using equation 1.

\[
G_f = \frac{P_{\text{max}}^2}{2 \cdot b^2 \cdot E_f \cdot t}
\]

where \(G_f\) is interfacial fracture energy [N/m], \(P_{\text{max}}\) is maximum load [N], \(b\) is strand sheet width [mm], \(E_f\) is elastic modulus of strand sheet [N/mm\(^2\)] and \(t\) is thickness of strand sheet [mm].

At the same amount of polyurea resin regardless of presence or absence of the polyurea resin, specimens of low concrete strength (14.5N/mm\(^2\)) showed approximately 0.75 times lower ultimate strength than that of the normal concrete strength (35.2N/mm\(^2\)). However, the specimens with polyurea resin regardless of amount of coating showed approximately 2.7 times higher ultimate strength than that of the specimens without polyurea resin also at the low-strength concrete. Interfacial fracture energy of the specimens with polyurea resin were approximately 7.0 times higher than that of the specimens without polyurea resin. Furthermore, the bond strength was almost the same in the range of polyurea coating amount of 0.5-3kg/m\(^2\). To stretch it a little, the specimens of 3kg/m\(^2\) showed slightly higher bond strength than that of the specimens of 0.5-2kg/m\(^2\).

Load - displacement curves and failure modes

Load - displacement curves are shown in Figure 3. It shows that the leaning of the load and displacement becomes moderate or load drops temporarily when strand sheet has partly peeled. Initial stiffness of the load displacement without polyurea resin is higher than that of the specimens with polyurea resin regardless of concrete strength. Initial stiffness of load and displacement was almost the same in the range of polyurea coating amount of 0.5-3kg/m\(^2\). To stretch it a little, the specimens of 3kg/m\(^2\) showed slightly lower initial stiffness of load and displacement than that of the specimens of 0.5-2kg/m\(^2\).

Typical failure modes of specimens are shown in Figure 4. The failure mode of all specimens was peeling failure of strand sheet. All specimens without polyurea resin showed the failure modes that concrete was thinly adhered to the strand sheet side such as in case1-1. Some specimens with polyurea resin showed the failure modes that concrete was thickly adhered to the strand sheet side such as in case3-2 in comparison with specimens without polyurea resin. Others showed partly cohesive failure of polyurea resin such as in case2-2.

Figure 3 Load - displacement curves

Figure 4 Typical failure modes of specimens
Strain distribution

Strain distributions at the maximum load are shown in Figure 5. In Case1-1 and case5-1 without polyurea resin, FRP strains have locally changed at certain locations regardless of concrete strength. For example, FRP strain of Case1-1 varied from 40 mm to 160 mm of location. Thus, it was found that bond stress was shared in almost 100 mm length. FRP strains of other specimens with polyurea resin have gradually changed in comparison with the specimens without polyurea resin. Therefore, it was found that bond stress was shared for longer length because polyurea resin has low Young’s modulus and high elongation. Because of this characteristic, the specimens with polyurea resin are able to have higher ultimate strength than the specimens without polyurea resin. In addition, the more the amount of the polyurea resin coat, the more the range of bond stress spread regardless of concrete strength.

(a) concrete strength 35.2N/mm²
(b) concrete strength 14.5N/mm²

Figure 5 Strain distributions at the maximum load

Bond stress and effective bond length

Relationships between bond stress or effective bond length and amount of resin at the maximum load are shown in Figure 6. Bond stress and effective bond length were calculated by using equation 2, 3 (JCI publication).

\[
\tau_y = \frac{\Delta \varepsilon_f E_F A_F}{s_i b} \quad \text{(2)}
\]

\[
l_e = \frac{P}{\tau_y b} \quad \text{(3)}
\]

where \(\tau_y\) is bond stress [N/mm²], \(\Delta \varepsilon_f\) is the difference of the value of the strain in the strain increase section, \(E_F\) is elastic modulus of strand sheet [N/mm²], \(A_F\) is cross-sectional area of strand sheet [mm²], \(s_i\) is distance of the strain increase section [mm], \(b =\) strand sheet width [mm] and \(P\) is load [kN].

Regardless of the concrete strength, bond stress of specimens with polyurea resin was smaller than that of the specimens without polyurea resin. However, effective bond length of specimens with polyurea resin was about 5 times longer than that of the specimens without polyurea resin. By this long effective bond length, the specimens
with polyurea resin are able to have higher ultimate strength than that of the specimens without polyurea resin. On the specimens with polyurea resin, the more amount of the polyurea resin coat, the shorter the bond stress is. In the case of the same amount of polyurea resin, the specimens of the low strength concrete showed slightly lower bond stress and shorter effective bond length than that of the normal strength concrete. By low bond stress and this short effective bond length, the specimens of low strength concrete with polyurea resin have lower ultimate strength than the specimens of normal strength concrete with polyurea resin.

CONCLUSIONS

1. The specimens of low concrete strength showed lower ultimate strength than that of the normal concrete strength at the same amount of polyurea resin regardless of presence or absence of the polyurea resin. However, the specimens with polyurea resin regardless of amount of coating showed approximately 2.7 times higher ultimate strength than that of the specimens without polyurea resin also at the low strength concrete. Interfacial fracture energy of the specimens with polyurea resin were approximately 7.0 times higher than that of the specimens without polyurea. Furthermore, the bond strength was almost the same in the range of polyurea coating amount of 0.5-3kg/m².

2. The failure mode of all specimens was peeling failure of strand sheet. All specimens without polyurea resin showed the failure modes that concrete was thinly adhered to the strand sheet side. Some specimens with polyurea resin showed the failure modes that concrete was thickly adhered to the strand sheet side in comparison with the specimens without polyurea resin. Others were partly cohesive failure of polyurea resin.

3. Regardless of concrete strength, bond stress of specimens with polyurea resin was smaller than that of the specimens without polyurea resin. However, effective bond length of specimens with polyurea resin was about 5 times longer than that of the specimens without polyurea resin. By this long effective bond length, the specimens with polyurea resin have higher ultimate strength than that of the specimens without polyurea resin.

As a result, it was proved that the polyurea resin was effective for improving bond ability between the strand sheet and concrete surface at low strength concrete as well as normal strength concrete and in the range of polyurea resin coating amount of 0.5-3kg/m².

ABSTRACT

In the construction field composite materials as a strengthening are widely used to face the problem of ageing and overloading of old infrastructure. The material performances are often deteriorated or inadequate for the current loads and could be compared to nowadays low resistance materials. The here presented research aims at analysing the debonding process on concrete weak resistance classes reinforced with externally glued CFRP strips. The joint behaviour is investigated with single-shear tests technique varying concrete performances and gluing techniques. The debonding growth are compared considering a dimensionless parameter dependent on the fracture energy. The results point out different behaviours among the concrete classes. The characterization of the cracking patterns is analysed with specific roughness measurements offering a clear link to the fracture energy of the debonding process. This finding is opening new possibilities to bond models development.

INTRODUCTION

For several decades carbon fibres have been used to retrofit ancient building or to extend the service life of infrastructures. In the past years the research focused on the study of the interface law between fibres and substrate, the maximal force and the durability of the joint. Bond failure is a brittle phenomenon caused by stress accumulation on the joint interface and occurs without any warning (Täljsten 1995; Triantafillou, Plevris 1992). One of the main purposes of this study is to predict bond resistance as the conditions of the material change. The research aims at finding the parameters that influence the behaviour of the joint and therefore the bond failure. Different aspects can affect the behaviour of the joint; among others we can mention geometrical characteristics (width of the strips related to the width of reinforced elements), peculiarity of material and treatments like surface preparation (Iovinella et al. 2013; Mazzotti et al. 2009).

The paper presents an experimental investigation on the behaviour of the bond varying gluing techniques and mechanical properties of the substrate. The debonding phenomenon was analysed in a continuous displacements field using the digital image correlation technology.

The study considers the single shear test results, as well as the behaviour of fracture propagation in different test configurations. A characterisation of the fracture plane is conducted analysing the roughness of surfaces for the two materials after the tests. In order to compare the different fracture patterns, we took into account several roughness parameters, measured with different instruments and methods.

OBJECTIVES

The goal of this paper is investigating how the substrate performance and the gluing techniques affect the fracture pattern. The carbon fibre-concrete bond was proved with a single-shear test setup. The experimental campaign involved concrete specimen with different mixture (several aggregate dimensions) and reinforcing gluing techniques. Particular importance took the roughness study of the surfaces of strips and concrete after reinforcing comparing different methods and parameter. The calculated roughness values seem to present correlation with the energy release of the debonding.

EXPERIMENTAL SET UP
The test program was divided in two series, where the concrete mixture and gluing techniques were varied. In the first series a parameter study on the concrete mixtures and gluing techniques was conducted. Two different concrete mixtures (8 and 16mm maximal aggregate dimension) were prepared in order to obtain performances comparable to strength class C16/20 and C20/25 according to Eurocode 2 (EN 1992-1-1). Moreover, two different gluing techniques were used: a strip set was glued using only epoxy resin; for the other one a primer film was spread on the surface before gluing.

Furthermore, to analyse the effect of the primer for lower strength concrete classes, another specimen series (C12/15) was casted using the same two gluing techniques applied in the previous series. For ease of reference in the further tables the test groups are mentioned with their own resistance class. If the word “Primer” displays it means that the CFRP is glued in combination with the primer. As concrete support, prisms with 50 cm height and 15 cm square section similar to (Bizindavyi, Neale 1999) were used. All the specimens were unmoulded 24 hours after casting, submerged in water for 7 days and stored under norm climate 20º C and 65% r.h. for the next 21 days.

The compression and traction values for the three mixtures are presented in the Tables 1 and 2.

Before gluing the CFRP strips, the surface of all the concrete prisms were treated with a grinding machine and then cleaned with pressured air in order to remove the superficial layer (2-3 mm). Considering different norms and guidelines recommendation (CNR-DT 200), (ACI 440.2R-08) a 35 cm bond length was adopted. The glued length was taken 10 cm away from the loaded edge to avoid effects like wedge cracking. The pre-impregnated carbon strips present a constant section dimensions with 50 mm width and 1.4 mm thickness.

To evaluate the bond behaviour the near-end supported single-shear test setup (Yao et al. 2005) was adopted. The slip evolution during the test was represented with a digital image correlation system “Aramis” (DIC) furnished by GOM and composed of two 5 Megapixel cameras (Optical measurement system). The two cameras take pictures following a trigger set synchronized with the displacement increments of the proof machine. Beside the digital image correlation measurements, two strain gauges were placed respectively at 5 cm and 13 cm to the upper edge of the concrete specimen, i.e. on the unglued and on the glued strip portion.

The tests were carried out following a monotonic slip increase till the failure; the slip constant rate was 0.01 mm/s. The restrain system was made of a screw anchored on a bottom steel plate passing in to the concrete hollow and a piston located on the top of the specimen. To avoid peeling stresses, the concrete specimens were prestressed before applying the force at the strip. To distribute the force on the concrete specimen a 2 cm thick steel plate was placed between the piston and the concrete. The test set up is represented in Figure 1.

**EXPERIMENTAL RESULT**

The test results in terms of maximal force registered with the testing machine are represented in Table 3. For every specimen we calculated the fracture energy related to the square root of concrete tensile and compressive strength Table 3. The values of the fracture energy coefficient increases for the low resistance classes; this trend seems to lead to another failure mechanism that could be influenced with a primer film before gluing.

The fracture coefficient was afterwards represented in a diagram with the roughness parameters in order to find a correlation between the values.

In order to obtain the values of the shear stress and slip we adopted the bi-linear slip-stress law (Holzenkämpfer, 1994). The strains were obtained comparing the slip values from the DIC measurements and the strain gauges. The slip from DIC were calculated on the incipient debonding zone, in order to avoid the scattering of values caused of singularities we considered the average value on three sections.
All the debonding failures occurred on the concrete substrate. Looking at the slip-force diagrams no significant effect of the primer in the bond displays; the behaviour was similar also between different concrete mixtures. In the second series (C12/15) a greater difference arises. The primer influence seems to have a considerable effect on lower concrete mixture. The maximal registered force for the two groups have a minimum range value of circa 4 kN. The effect of the primer seems to be related to the peculiarity of the primer to percolate deeper in the concrete substrate.

Table 3 Maximal bonding force for the two test series with the relative fracture energy dependent parameter in the right column

**ROUGHNESS MEASUREMENTS**

An important part of this experimental investigation is the study of the fracture patterns on the carbon fibres strip and on the concrete substrate, i.e. after debonding. In order to compare the different fracture patterns, the roughness of the strips and the concrete substrate were measured with different methods and parameter. The roughness parameters considered are available on norms and scientific publications (Santos, Júlio 2013), the data were collected with an Optical Measurements System (previously used with as DIC for the shear test) and an Optical Microscope.

Thanks to flexibility of the Optical Measurement system “Aramis” both fracture surfaces, on the CFRP strip and also at the concrete substrate, where digitized. The measurement provides a point mesh with a mean distance between two point of circa 0.08 mm.
The Keyence VHX-2000 Microscope provides a tridimensional mesh point description of the analysed surfaces with a resolution of circa 1 µm between two point. For physical reasons it was only possible to collect the data for the CFRP strip surface. The measurements were focused on the incipient debonding area, i.e. the area where the strips are pulled out tearing off a substrate of the concrete.

To better compare all the parameters collected during the research the parameters based on 2D profiles were considered. This choice is due to the fact that the available parameters are most of the times defined for two dimensional profiles.

ROUGHNESS PARAMETERS

The most important roughness parameters in the analysis are four: two from European norms and two from scientific publications. Referring to the European Norms ISO 4287 the following parameters are considered: the average roughness \( R_a \), which represents the absolute mean value of the deviation between the real surface and the mean value, and the root mean square \( R_q \) of the profile, which is the mean square value between the real value and the mean line. The two parameters are here presented:

\[
R_a = \frac{1}{l} \int_0^l |Z(x)| \, dx \approx \frac{1}{n} \sum_{i=1}^n |Z_i|; \quad R_q = \sqrt{\frac{1}{l} \int_0^l |Z(x)|^2 \, dx} \approx \sqrt{\frac{1}{n} \sum_{i=1}^n |Z_i|^2}
\]  

(1)

Where \( n \) is the measurements number and \( Z_i \) is the data of the point magnitude.

Another important parameter was for the first time introduced from (Iovinella et al., 2013) and has the following expression:

\[
I_R = R \cdot i_A
\]

(2)

It considers the product of two terms, \( R \) that is the amplitude of the profile valleys and \( i_A \) that is the inclination between the points (angularity).

Already mentioned in other researches is the Wenzel coefficient to characterize the concrete surfaces describing the ratio between the profile’s and its effective length:

\[
W = \frac{1}{l} \sum_{i=1}^n \sqrt{(\Delta x_i)^2 + (\Delta y_i)^2}
\]

(3)

where \( l \) is the profile length and \( \Delta x \) and \( \Delta y \) are respectively the increment in vertical and horizontal length between two points of the profile.

All the data collected were elaborated with the same procedure in a Matlab code. For every surface significant profiles were selected, the inevitable inclination of the measurement obtained from optical and microscope measurement was corrected and all the previously mentioned roughness parameter were calculated. To have a brighter profile parameter distribution, the roughness parameters were calculated from several profiles and the average of the values was assumed.

The values obtained for all the concrete and CFRP surfaces observed are presented respectively in Table 4 and 5.

The parameters values are not significantly influenced on the measuring techniques. The difference in the fracture surface roughness as an effect of primer preparation increases for the low performance concrete specimens on the CFRP strip and on the concrete substrate as well. For the higher concrete strength classes, the primer preparation has no effect on the fracture roughness. The results obtained are presented in the histograms for the strip surfaces in terms of \( R_a \) for the data collected with the optical measurement in Figure 5. For every roughness parameter the respective dimensionless values were plotted. In Figure 6 a diagram with the roughness parameter correlated with the related fracture energy is shown. A good correlation between these two parameters seems to be confirmed by the coefficient of determination values although the small number of tests conducted (Table 6).

CONCLUSIONS

The paper presents an experimental investigation of the bond for the carbon fibres glued on concrete support. The analysis aims at representing the fracture pattern after the single-shear test in different gluing and concrete mixture configuration to proof different debonding evolution. To represent the propagation of the debonding on the
concrete substrate several roughness parameters, determined with different measurement instruments, were considered. A linear relation shows a good correlation between the dimensionless fracture energy coefficient and the roughness parameters. It arises that a surface preparation with a primer can have the same effect as an intensive mechanical surface preparation.

The influence of the gluing techniques, especially for low performances concrete support, seems to be significant. This effect put in evidence a different debonding behaviour for this kind of concrete. The study of weak concrete performance assumes a great importance because they can be compared to the aged structures the carbon fibre-reinforcements are applied on. The results obtained in this experimental investigation reveal a different fracture behaviour for the low performances concrete and open the possibility of further experimental campaigns to better understand the debonding for these configurations.

ABSTRACT

The FRP debonding due to the shear stress distinguished around flexural cracks on the RC or PC structure strengthened with externally bonded FRP sheets has been of recent concern. In a previous study, the FRP debonding progresses rapidly under continuous loading. In this study, a tension test of an FRP-concrete double lap shear adhesive joint under sustained loading has been performed. A basalt fibre reinforced polymer (BFRP) sheet was used as the FRP reinforcement. An increase of the pre-crack width and distributed BFRP strain under sustained loading with time have been identified. The load was set at approximately 60% of the debonding load under static loading. From the results, it was observed that the shear stress can be distinguished at the area from the pre-crack to the effective bond length, the stress was greater than the concrete shear strength, and a slip into the concrete surface layer occurred. It was also found that the BFRP debonding slightly propagated until approximately 100 hours from the load being applied, with no significant debonding from 100 to 1000 hours.

Basalt FRP (BFRP) sheets, externally bond, concrete, double-lap shear test, distributed strain, sustained load.

INTRODUCTION

RC or PC structures in service have an increased dead load that results from structural changes in consideration of the performance requirements or from the damage of concrete reinforcements due to corrosion from a long service life. As a result, a shear stress distributed into the FRP sheets around the flexural cracks has increased, and a premature debonding of the FRP sheet is of concern. In a previous study, it was found that premature debonding occurred due to a continuous load (Iwashita et al. 2007). On the other hand, the maximum upper limit load, 2 millions of cyclic loading reachable, was half of the static maximum load (lower limit load is 10% of the static maximum load). The sustained load has a significant influence on the lifetime of the FRP-concrete bonding joints. From this circumstance, investigating the behaviour of the BFRP-concrete interface under sustained loading is important. On the other hand, basalt fibre reinforced polymer (BFRP) sheets have the excellent properties of ductility, strength and modulus of elasticity. It has been attempted to utilize BFRPs in practical situation as a seismic reinforcement for old type or determined RC and PC structures. In this study, BFRP was used as an FRP reinforcement.

TEST SET-UP

Specimen of BFRP-concrete Double-lap Joints

The dimensions of the specimens are shown in Fig. 1. In accordance with the experimental method of the JSCE Recommendations for Upgrading of Concrete Structures with Use of Continuous Fibre Sheets (JSCE, 2000), the specimen was manufactured with two concrete prisms of a 100 mm width, 100 mm height and 300 mm length and was externally bonded to two BFRP sheets with a thickness of 0.254 mm and a width of 50 mm. A summary of the properties of the BFRP sheets, epoxy resin and concrete are shown in Table 1. On the double-lap shear joints, the effects from a flexural moment can be eliminated, unlike the single-lap shear joints. The specimen has a slit (pre-crack) simulating a flexural crack in the concrete at the mid-span. First, the concrete surfaces were treated with a diamond sander, wiped with an acetone soaked cloth and painted with a room temperature setting epoxy
primer adding a total mass of 0.5 kg/m². The sample was cured at room temperature for twelve hours later. After curing, a single BFRP sheet was impregnated and bonded to the concrete surface on both sides along the axial direction with a room temperature setting epoxy resin with a total mass of 0.5 kg/m² for each. The sample was cured at room temperature for seven days, and the tensile sustained test was started.

**Experimental Programme and Measurement**

A tensile load was applied from the connected steel bolts at both ends of the steel frame test device by pulling in both directions with a 350kN load cell and a 200kN hydraulic jack and pump as shown in Fig. 2. The 25 mm displacement sensor was set to the side of the specimen near the pre-crack to measure the expansion of pre-crack width and 5 mm strain gauges were set to the BFRP surface at 25 mm distances from the pre-crack to measure the BFRP strain distribution. The arrangements are shown in Fig. 1.

The established creep load was 25kN and the interfacial fracture energy ($G_f$) signifying the bond capacity, was calculated from Eq. 1;

$$G_f = \frac{P_{\text{max}}^2}{8b_fE_f t_f}$$

where $P_{\text{max}}$ is the maximum load and $E_f$, $b_f$ and $t_f$ are the modulus of elasticity, width and thickness of the BFRP sheets respectively. The calculated $G_f$ is 1.37 N/mm, which is equivalent to the maximum value in the static tests.
from a previous study (Iwashita et al. 2014). The loading rate was 5kN/min until a maximum of 25 kN was reached. The test temperature was approximately 12-16°C.

TEST RESULTS AND DISCUSSION

Debonding Propagation

The average BFRP strain at the pre-crack under a sustained load was 10,936 μ. The strain is significant and equal to the debonding strain. The external appearance of the BFRP surface after 15 hours is shown in Fig. 3. In the area from the pre-crack to 75 mm, several cracks appeared on the FRP surface, and the premature debonding was confirmed to the area with hammering test. It is considered that these cracks and premature debonding occurred due to the shear stress concentration at the pre-crack. The evaluation Eq. 2a to Eq. 2c of an effective bond length ($L_e$) were suggested (ACI Committee 440 2008, Sato et al. 2000, Wu et al. 2007).

$$L_e = n \cdot \frac{E_f \cdot t_f}{f_c'}$$  \hspace{1cm} (2a)

$$L_e = 1.89(t_f \cdot E_f)^{0.4}$$ \hspace{1cm} (2b)

$$L_e = \frac{1.3}{f_c' \cdot 0.095}$$ \hspace{1cm} (2c)

where $n$ is the number of the BFRP layers and $f'_c$ is the compressive strength of the concrete. Calculation values are 61 mm (by Eq. 2a), 105 mm (by Eq. 2b) and 139 mm (by Eq. 2c). It is observed that the shear stress was distinguished in the $L_e$, the stress exceeded the concrete shear strength and a slip into the concrete surface layer occurred.

Applied Load Accuracy

The applied load degradation with time are shown in Figs. 4 (a) – (d) for each time span. From 0 - 500 hours from the load being applied, the load larger than the setting one of 25 kN. The sustained load was variable in the range of ± 5 kN.
Pre-crack Width Expanding with Time

The expansion of the pre-crack has a function of time are shown in Figs. 5 (a) - (d) for each time span. From 0 - 250 hours from the load being applied, the width increased logarithmically. The rate of increase became increasingly smaller after 250 hours and even smaller after 500 hours. The BFRP strain distribution degradation with time are shown in Figs. 6 (a) - (d) for each time span. The strain was distinguished at 125 mm from the pre-crack from 0.01 - 0.1 hours, and it was found that the BFRP debonding propagated 125 mm. From 0.01 - 100 hours from the load being applied, the distributed BFRP strain increased gradually with time. However, after 100 hours, the strain had a negligible increase.
CONCLUSIONS

This paper has experimentally investigated the change of the distributed strain of the externally bonded BFRP sheets to concrete and pre-crack under sustained loading. Based on the results of this study, the following conclusions are drawn:

1) The shear stress was distinguished in the effective shear transfer region and exceeded the concrete shear strength. The premature debonding of the BFRP sheets occurred in the area, but the incremental strain was relatively small under sustained loading.

2) The incremental pre-crack width did not significantly change under the sustained loading.

ABSTRACT

Strengthening of structurally deficient reinforced concrete elements by means of adhesively bonding fibre-reinforced polymers (FRP) is now common practice. Given the uncertainty of the long-term durability of these strengthening systems, the critical bond between the FRP and concrete has seen widespread testing of samples conditioned under accelerated aggressive environments. In order to develop a set of bond deterioration factors, a database of test results containing full range load-displacement relations of FRP-to-concrete joints under various environmental conditions has been collected and a mechanics based approach has been shown to be able to extract bond properties across the various test set-ups, material properties and environmental exposures. Through a statistical analysis, conservative deterioration factors are determined that allow for the design of future durability bond tests that can ensure that the full range load-displacement behaviour is captured.

KEYWORDS

FRP, concrete, bond, durability, effective bond length.

INTRODUCTION

The structural strengthening of reinforced concrete (RC) members by means of adhesively bonding fibre-reinforced polymers (FRP) is now common practice. However, there is uncertainty surrounding the long-term durability of the strengthened system. Current guidelines are only able to demonstrate reservations for environmental effects through a reduction factor of the rupture elongation of FRP in the order of 0.85-0.95 (ACI Committee 440 2008) or imposing a maximum design life (Concrete Society Working Party 2012). Moreover, and unlike conventional RC members that fail by yielding of the steel reinforcement followed by concrete crushing, FRP-strengthened beams are susceptible to premature debonding failures that can severely limit performance. These have been attributed to stress concentrations at the plate end, widening of flexure-shear cracks and through the IC debonding mechanism associated with the widening of flexural cracks (Oehlers and Moran 1990). Design guidelines reflect this by assuming a perfect bond exists between the FRP and concrete and limiting the strain in the FRP. However, the ability of the joint to the transfer stresses between FRP and concrete has not only implications for flexural strength, but also ductility (Oehlers et al. 2016). Shear bond tests isolate the conditions at flexural cracks that cause IC debonding and investigate bond behavior to not only aid in the design of strengthened members, but allow researchers to model the full structural response.

Concerns over the durability of the bond between FRP and concrete has prompted widespread shear bond testing of joints conditioned under various accelerated aggressive environments. A previous study by the authors (Aydin et al. 2016) identified 1,169 individual samples form 48 separate studies to assess environmental impacts on shear bond strength. Despite widespread laboratory testing, reporting of the load-displacement, P-δ relationship, necessary for modelling the full range structural response and deriving full range bond stress-slip, τ-δ relationships are found to be limited to the studies summarised in Table 1 amounting to 165 individual tests. Using these P-δ responses from the published literature, a well-established numerical method (Haskett et al. 2008) is used to extract τ-δ relationships. The results are analyzed to determine bond deterioration factors for a range of conditions (Gravina et al. 2016).

Note:
^aTest conditions: Exposure type, temperature range, concentration of solution, test duration or cycles tested.
^bTest type: SLS = single lap shear; DLS = double lap shear.
^cType of FRP: CFRP = carbon FRP; GFRP = glass FRP; BFRP = basalt FRP; Plate = refers to bonding of pultruded or prefabricated laminates; Sheet = refers to bonding by the wet lay-up technique.
^dFailure modes. Refers to conditioned samples only, since control samples typically fail within a thin layer of concrete. C = thin layer concrete failure; A = failure at the adhesive/concrete interface with little or no concrete remaining attached; P = failure at primer interface; NR = not reported; AF = failure at adhesive/FRP interface.

Failure modes listed in Table 1 are consistent with previous work which has found that the failure planes shift from a thin layer within the concrete substrate to the adhesive/concrete interface with little or no concrete left bonded (Shrestha et al. 2015). As concrete strength increases over time, especially under moisture conditions (Wood 1991), and the adhesive deteriorates, the failure plane generally moves away from the concrete substrate.

ELONGATION OF THE EFFECTIVE BOND LENGTH

Characterizing the interfacial bond mechanism as accurate τ-δ relationships has been of much interest to researchers studying the bond behavior of FRP-to-concrete joints, as they provide more insight into the bond than strength alone. It is well known that bonded lengths, \( L \) should be sufficiently long so as to be greater than the effective bond length, \( L_{\text{crit}} \) which ensures that the full range strain development that occurs during testing is captured (Chen and Teng 2001). The concept of the effective bond length is also critical to deteriorated samples since \( L_{\text{crit}} \) generally increases (Mukhopadhyaya et al. 1998; Kabir et al. 2012). Consider the idealized τ-δ relationship in Figure 1b for a control sample, shown as the Undeteriorated curve, which corresponds to the P-δ relationship in Figure 1a. With environmental loading, shown as the Deteriorated curve, the effective bond length, \( L_{\text{crit}} \) increases such that the strength of the bond drops in Figure 1(a) and the peak bond stress, \( \tau_{\text{max}} \) drops in Figure 1(b). In this scenario only a portion of \( P_{\text{IC}} \) will be recorded and \( \delta_{\text{max}} \) cannot be quantified.

![Figure 1 Elongation of the effective bond length with deterioration](image-url)
EXTRACTION OF BOND PROPERTIES

Limitations to Test Data

In order to extract bond properties from individual samples across numerous studies, certain criteria are required:
1. Tests must simulate mode II (in-plane shear) sliding fracture in IC debonding failures;
2. Specimens must have FRP bonded prior to conditioning;
3. The undeteriorated control sample must be free from sustained loading;
4. It is crucial that that the bonded length, \( L \) be greater than \( L_{\text{crit}} \). Effective bond lengths of test specimens in the ambient condition are checked, where possible, against the well-recognised bond strength models and experimental strain readings. Where \( L_{\text{crit}} > L \) the result will be omitted;
5. Double shear tests are simplified to an equivalent single shear tests by considering half of the load and one bonded side (Lu et al. 2005; Wu et al. 2009).

Mechanics Based Approach

A mechanics based approach is used to extract \( \tau - \delta \) characteristics from the available test data (Haskett et al. 2008). Consider an axially loaded FRP laminate externally bonded to a concrete substrate prism in Figure 2. A force in bonded FRP plate \( P_p \), is chosen such that at length \( L \), \( P_p = 0 \) thus a boundary value problem is produced. To solve this boundary value problem an iterative shooting technique is utilized where the value of \( P_p \) is searched so as to satisfy the boundary conditions of \( \delta_1 = \delta_1' = 0 \). The FRP-to-concrete interface bonded length is sliced into \( n \) segments of equal and very short length \( L_s \). A constant axial displacement, force and stress are assumed over each individual segment. Consider segment 1: the plate slips \( \delta \), the strain the plate is then \( \varepsilon_p \), rigidity characteristics of the plate provide \( P_p \), the strain in the concrete prism opposing the plate is \( \varepsilon_c \). A bond force, \( B_1 \) of magnitude \( \tau_1 L \) per \( L_s \) opposes and reduces the plate force \( P_p \), \( \tau_1 \) is a function of the \( \tau - \delta \) relationship, so the plate force at the end of segment becomes \( P_p - B_1 \). The slip strain \( \delta_1' \) is \( \varepsilon_p - \varepsilon_c \), and multiplying \( \delta_1' \) by the segment length, \( L_s \) gives the change in slip over the segment \( \Delta \delta_1' \), thus the slip at the next segment is \( \delta - \Delta \delta_1 \) and the process is repeated through all segments. The slip is then incremented until it is equal to the slip at unloading in \( P - \delta \) relationship. Where the effective bond length has been attained \( L_{\text{crit}} < L \), full interaction boundary conditions are \( \delta = \delta' = 0 \). For laminates where \( L_{\text{crit}} > L \), the boundary conditions is \( \varepsilon_p = 0 \). Material properties are assumed to remain constant, and deterioration is restricted to changes in bond characteristics.

The rigidity characteristics of FRP laminates are found using the rule of mixtures, shown by Seracino et al. (2007) to be highly correlated with experimentally measured plate moduli. Thus, the role of the structural adhesive in determining the equivalent stiffness of the FRP bonded system is accommodated by

\[
E_p = f E_a + (1 - f) E_f
\]

(1)

where \( E_f \) is young’s modulus of the FRP, \( E_a \) is the tensile modulus of the adhesive, \( f \) in Eq. 2 is the thickness fraction, \( t_f \) is the thickness of the FRP and \( t_a \) is the thickness of the adhesive. To apply the rule of mixtures to sheet bonded specimens, a gross laminate thickness of 1.0 mm is assumed. The numerical procedure may then be applied by first idealizing the form of the \( \tau - \delta \) relationship as seen in Figure 3. This is a modified from of the widely accepted CEB-FIB Model Code (CEB 1993) for steel bars embedded in concrete and is chosen for its fit with experimentally the observed \( P - \delta \) relationships.
The function defining the form is

\[
\tau(\delta) = \begin{cases} 
\tau_{\text{max}} \left( \frac{\delta}{\delta_{1}} \right)^{0.4} & \text{for } 0 \leq \delta \leq \delta_{1} \\
\tau_{\text{max}} - \left( \frac{\tau_{\text{max}} - \tau_{f}}{\delta_{\text{max}} - \delta_{1}} \right) (\delta - \delta_{1}) & \text{for } \delta_{1} \leq \delta \leq \delta_{\text{max}} \\
\tau_{f} & \text{for } \delta > \delta_{\text{max}}
\end{cases}
\]

where \(\tau_{\text{max}}\) in Eq. 3 is the maximum bond stress, \(\delta_{1}\) is the slip at \(\tau_{\text{max}}\), \(\delta_{\text{max}}\) is the slip at the initiation of debonding, and \(\tau_{f}\) is the frictional component of bond stress. Then using the numerical procedure, bond properties are varied to generate a \(P-\delta\) relationship corresponding to a particular sample. In Figure 4(a), a \(P-\delta\) curve, specific to a control sample is generated, which allows for the extraction of bond properties in Figure 4(b). Here \(\tau_{\text{max}}\) is found to be 10.0 MPa, \(\delta_{1}\) to be 0.0500, \(\delta_{\text{max}}\) to be 0.120 and \(\tau_{f}\) to be 2.80 MPa. The process is repeated for all 165 samples collected for this study of which 90 tests satisfy the criteria of \(L > L_{\text{crit}}\).

Existing predictive models have been found to be largely inapplicable to the results collected in this study as test variables are outside their bounds. Most commonly, the elastic moduli of the bonding adhesive is exceeded (Chen and Teng 2001), the elastic moduli of the FRP is under (Lu et al. 2005) or over (Wu and Jiang 2013) the bounds of the model, the FRP layer is too thick (Wu and Jiang 2013), it is not applicable to basalt FRP (Chen and Teng 2001; Lu et al. 2005; Seracino et al. 2007; Wu et al. 2009; Wu and Jiang 2013) the model is specific to only cylinder compressive strengths (Seracino et al. 2007; Wu et al. 2009; Wu and Jiang 2013) or the model is not formulated for application to double shear tests (Seracino et al. 2007; Wu and Jiang 2013).

BOND CHARACTERISTIC DETERIORATION FACTORS

A high degree of scatter exists amongst the available test data due to differences in test set-ups, details of environmental conditioning regimes, material properties and geometries. Thus, an accurate model describing the change in bond properties with a certain type of exposure over time or number of cycles is not possible. Rather conservative deterioration factors may be determined through statistical analysis. First extracted bond properties \(\tau_{\text{max}}\), \(\delta_{1}\), \(\delta_{\text{max}}\) and \(L_{\text{crit}}\) are normalized with their corresponding control samples. Then the extent of deterioration between various types of environmental exposure is compared by means of a two sample t-test. It is found that exposure to water, saltwater and acid solutions exhibit similar deterioration and may be combined. Failure at the adhesive/concrete interface with little or no concrete remaining attached is reported in all three conditions. This may indicate that the deterioration is caused by the presence of water irrespective of the solution, or that the concentrations of salt and acid considered may be too low or too high to amount significant changes.
In contrast, all other exposure types provide highly dissimilar levels of deteriorations and must be treated separately. Six potential outliers of 240 data points (considering all values of $\tau_{\text{max}}$, $\delta_1$, $\delta_{\text{max}}$ and $L_{\text{crit}}$) are identified by the Extreme Studentised Deviate (ESD) test (Rosner 1983) and removed. The remaining data is then analyzed to reveal the 5th and 95th percentiles of bond deterioration as summarized in Table 2 along with the bounds to which they apply. A 5th percentile is assigned to $\tau_{\text{max}}$ as it is expected to decrease with exposure, while a 95th percentile is assigned to $\delta_1$, $\delta_{\text{max}}$ and $L_{\text{crit}}$ as these generally increase. Since the proposed factors are derived from a limited number of tests, they are not recommended for use in design, rather to gauge the expected level of deterioration and aid in the design of future shear bond tests.

A graphical indication of the influence of the various test conditions is possible by superimposing degraded $\tau$-$\delta$ relationships using the deterioration factors in Table 2, as illustrated in Figure 5.

![Figure 5 Influence of various environmental conditions on the $\tau$-$\delta$ relationship](image)

The ascending branch is shaped by the chemical adhesion between the FRP, adhesive and concrete, however as micro-cracks develop along the concrete substrate surface, softening is initiated at slip, $\delta_1$ corresponding to the point the maximum shear bond stress, $\tau_{\text{max}}$ is reached, and descends until the initiation of debonding at slip, $\delta_{\text{max}}$ (Yuan et al. 2004). Consider the normalized changes to the $\tau$-$\delta$ relation in Figure 5, the introduction of environmental effects significantly decreases the stiffness of the ascending branch of the $\tau$-$\delta$ relationship. This corresponds to the breakdown of the chemical adhesion provided by the adhesive, damage via micro-cracking of the concrete substrate bonded surface or a combination of both. Post-peak behavior becomes increasingly ductile with exposure to freeze-thaw cycling and aqueous conditions. Post-peak behaviors under varying temperatures remain largely unchanged indicating that material characteristics may remain unchanged.
CONCLUSIONS

A mechanics based approach is used to quantify the change in bond characteristics for degraded FRP-to-concrete joints under a range of environmental conditions. Given the limited reporting of the $P$-$\delta$ relationship and implications of elongating effective bond lengths, an accurate predictive model cannot be formulated from the extracted bond properties. A statistical analysis of the extracted bond properties revealed that exposure to water, saltwater and acid solutions provide similar levels of deterioration and may be combined. Conservative bond characteristic deterioration factors are proposed which allow for the design of future bond tests such that the extension of the effective bond length may be accommodated and the full-range $P$-$\delta$ behaviour be captured.

ABSTRACT

Flexural strengthening of reinforced concrete (RC) structures by adhesively bonded fibre reinforced polymer (FRP) laminates has become an increasingly popular retrofitting method for RC structures. The effectiveness of such externally bonded FRP strengthening methods depends on the interfacial shear stress transfer mechanism of the bonded interface (Smith and Teng 2002a, b). Therefore, understanding the behaviour of FRP-to-concrete bonded interfaces is of critical importance in determining when the failure will occur and how effectively the FRP is utilized. Many studies have been carried out on understanding and modelling of the FRP-to-concrete bonded interfaces under interfacial shear stresses (Yao et al. 2005; Yuan et al. 2004; Lu et al. 2005).

A bond-slip model, which depicts the relationship between the local interfacial shear stress and the relative slip between the two adherents, is of fundamental importance to understand and model the behaviour of FRP strengthened steel structures. Different bond-slip models with different levels of sophistications have been proposed (Lu et al. 2005). Among which, the bi-linear bond-slip models with a linear ascending branch followed by a linear descending branch are the most widely used owing to its simplicity. Bi-linear bond-slip models are often used to predict the mode-II behaviour in mixed mode cohesive zone models in predicting debonding failures of bonded joints (Teng et al. 2015). In such models, damage evolution is defined using a scalar damage variable which varies from a value of 0 at the initiation of damage to a value of 1 at the full interfacial damage. This damage scalar variable is defined assuming interfacial behaviour is characterized by damaged elasticity and any plastic deformations of the interface are ignored. However, experimentally obtained bond-slip behaviour of FRP-to-concrete bonded joints under cyclic loading showed non-zero residual slip (i.e. slip at zero interfacial shear stress) when local interfacial shear stress is unloaded to zero (Ko and Sato 2007; Mazzotti and Savoia 2009). In addition,
bond-slip behaviour under cyclic loading showed remarkable hysteresis loops, indicating inelastic deformations
occurred during the cyclic loading.

Based on these experimental observations, several analytical bond-slip models have been proposed for FRP-to-
concrete bonded joints under cyclic loading (Ko and Sato 2007; Martinelli and Caggiano 2014; Carrara and De
Lorenzis 2015). Except Ko and Sato (2007) model, the other existing models assumed bi-linear bond-slip
behaviour, as commonly assumed in FRP-to-concrete bond-slip models under quasi-static monotonic loading. The
essential difference between the different bond-slip models proposed for cyclic loading is in the approach used to
define the damage parameter under cyclic loading. In the most advanced of these models (Martinelli and Caggiano
2014; Carrara and De Lorenzis 2015), damaged parameter is either related to the ratio between inelastic and total
fracture energy (Martinelli and Caggiano 2014) or negative slip increments (i.e. reversal of the residual slip at zero
shear stress) (Carrara and De Lorenzis 2015). With the definition of damage parameter in Martinelli and Caggiano
(2014), a negative slip may occur at zero interfacial stress during unloading at higher damage values, thus
resulting in increase of the total energy during the loading unloading process. This is essentially caused by taking
the energy dissipated during degradation of the stiffness (i.e. energy dissipated due to cracking) into account twice
when defining the damage parameter. Carrara and De Lorenzis (2015) model assumed negative shear stresses are
not possible under the assumption that friction and interlocking are negligible. With this assumption, Carrara and
De Lorenzis (2015) assumed that once the interfacial shear stress becomes zero during the unloading process, slip
value will start to reduce while maintaining interfacial shear stress at zero value. However, this assumption does
not agree with the existing experimental results of FRP-to-concrete bonded joints under cyclic loading, where clear
negative values of the shear stresses were observed.

This paper presents the results from a series of simple pull-off test of FRP-to-concrete bonded joints aimed at
investigating the behaviour of FRP-to-concrete bonded joints under cyclic loading. Presented results are a part of
an ongoing study at the University of Queensland (UQ) aimed at understanding and modelling the behaviour of
FRP-to-concrete bonded joints under cyclic loading. Experimental results from six specimens are presented and
discussed against the assumptions made in existing theoretical models for modelling FRP-to-concrete behaviour
under cyclic loading.

MATERIALS AND TESTING METHOD
Specimen Details and Material Characteristics

In total six single lap shear pull off specimens were prepared and tested as a part of an ongoing research work at
UQ structures laboratory. Nominal dimensions of the specimens are given in Figure 1a. The 28-day compressive
strength of concrete, determined by standard concrete cylinder test, was 49.7MPa. The mean value of the concrete
compressive strength tested from cylinders at the time when the pull-off tests were carried out was 64.4 MPa.

Normal modulus CFRP pultruded plates (Sika Carbodur S512) with 50mm width and 1.2mm thickness was
employed in this test. The elastic modulus of the CFRP pultruded pates in the fibre direction was determined from
the test to be 165GPa. A 1.3m long CFRP plate was employed to minimize any effects due to misalignment of the FRP plate and the centre of the actuator.

Sikadur-30 adhesive was used to bond CFRP plate to the concrete substrate. The ultimate tensile strength of the adhesive was determined to be 25.3MPa through adhesive coupon tests. A 50mm gap was provided between the concrete edge at the loaded end and the start of the bond joint, as recommended by Yao et al. (2005) to avoid the edge effects. This gap was prefilled with silicon to better control the gap dimensions. The bonding area (50×300 mm) on the surface of the concrete block was roughened by a needle gun to expose the coarse aggregates (except M1, which was grinded with a hand grinder). Then the dust on the surface was removed using compressed air. The overall test set-up and specimen detail can be seen in Figure 1a. Out of the six identical samples tested, three were tested under quasi-static monotonic loading (named M1, M2 and M3) and three were tested under quasi-static cyclic loading (C1, C2, C3). Before bonding the CFRP plate to the concrete block, voids within the roughened area were filled with the adhesive from the same batch used to bond the CFRP plate. The thickness of the adhesive layer was controlled to be 1mm by placing 1mm thickness aluminium tabs beside the bond area while using a roller to squeeze the excessive adhesive. The bonded specimens were left to cure for at least two weeks before testing.

Testing Procedures and Measurements

The test rig used for single shear pull tests is shown in Figure 1a. In all the specimens, axial strains at the top of the CFRP plate were measure using a digital image correlation (DIC) system. Two LVDTs were employed at the loaded end and the far end to measure any slip between the FRP plate and the concrete. For all samples, two strain gauges were attached to the top and bottom of the CFRP plate within the un-bonded length, 100mm from the loaded end to measure the CFRP plate elastic modulus.

The axial strain of the CFRP plate at any point within the bond length was taken as the mean strain value obtained from five points on the CFRP plate along the transverse direction (width direction). Meanwhile, the interfacial slip and shear stress at different locations were calculated from the strain values using the equations given in Pham and Al-Mahaidi (2007).

For all tests, load was applied using a 100kN capacity MTS servo-hydraulic actuator. Both the quasi-static monotonic tests and the quasi-static cyclic tests were carried out at a displacement rate of 0.05mm/min. In the quasi-static monotonic tests, the samples were loaded till full debonding of the plate. While in the quasi-static cyclic tests, the samples were unloaded to zero force and re-loaded at predefined displacement intervals. Unloading displacement intervals were determined based on the test results from quasi-static monotonic tests to ensure several loading-unloading cycles are achieved within the ascending and descending branches of the local bond-slip curves at different locations along the bond length. The test setup during the test is illustrated in Figure 1b.

![Figure 2 Failure modes of the tested samples](image)

**TEST RESULTS**

**Failure Mode**

The previous study showed that the failure of such kind of bonded joints typically occur within concrete few millimetres away from the bond-line (Yao et al. 2005). Figure 2 shows the failure mode of all the samples. It can be seen that except sample M1, in all other specimens there were a large amount of concrete debris attached to the
debonded plate, indicating these samples failed within the concrete substrate. The main reason for the combined cohesion and adhesion failure occurred in M1 is believed to be the improper surface preparation. It can be seen that with use of needle gun to roughen the surface, combined cohesion adhesion failure could be avoided and failure occurred due to cohesion failure within concrete.

**Load vs Displacement**

Load-displacement curves of the quasi-static monotonic and cyclic tests are shown in Figures 3a and b respectively. In these graphs, load values were taken from the actuator while displacements were taken as the slip at the loaded end calculated from the strain values. The load-carrying capacity of the specimens M1, M2 and M3 were 25.5kN, 28.1kN and 26.6kN respectively. In specimen M1, once the ultimate load is reached, debonding propagation was quite rapid resulting in only few readings within the post ultimate load-displacement curve before the full failure is reached. Specimen M2 showed a short plateau in the load-displacement curve before complete debonding of the interface. However, specimen M3 showed much more gradual failure with a relatively long plateau in the load-displacement curve once the ultimate load is reached.

Compared to the M1-M3 specimens, C1-C3 specimens showed more scatter in the ultimate load readings (Figure 3b). Specimens C1, C2 and C3 resulted in ultimate loads of 26.4kN, 29.9kN and 32.2kN respectively. All C1 to C3 specimens showed a reasonable plateau in the envelope load-displacement curves before complete failure. During the unloading and reloading curves, significant stiffness reduction could be observed due to propagation of debonding. While the curves showed significant scatter, M2 and M3 load-displacement curves agreed well with the envelope load-displacement curves of specimens C2 and C1 respectively (Figures 3c and d).

**Bond Behaviour**

Due to relatively brittle failure of sample M2, data from that specimen didn’t show much debonding propagation, thus omitted in the discussions related to bond behaviour. Strain distributions along the bond length at different displacement values on the load-displacement curves of specimens M1 and M3 (Figure 3a) are shown in Figure 4a. At low displacement values (i.e. displacement I in Figure 3a), strain distribution along the bond length closely matched between the two specimens M1 and M3. This is no surprise considering the close matching of the load-displacement behaviour of the two specimens at lower loads (Figure 3a). As the displacement increased, small differences could be observed in the strain distributions of the two specimens with specimen M3 showing slightly higher strain values for majority of the bond length. At displacement III (i.e. 0.461mm), a relatively constant strain
values could be seen closer to the loaded end indicating debonding (Figure 4a). Considering specimen M3 showed a slightly higher load than M1, strain readings of the debonded region of M3 can be expected to be higher than the strain readings of M1 within the debonded region.

Strain distributions along the bond length of the specimens M3 and C1 at different load levels (Figure 3d) are compared in Figure 4b. While the load is only 20kN (point A), strain distributions of both specimens agreed well. As the load increased to 23.5kN (point B), strain values of C1 closer to the loaded end found to be lower than those of M3. At load 25.7 (point C), strain distributions of the two specimens showed more pronounced differences. From the strain values at the loaded end of C1 and M3 its clear that the debonding of C1 initiated at a lower strain value than in M3. At load 25.7kN (point C), strain values of C1 closer to the loaded end found to be constant, thus indicating debonding within this region. However, strain values of M3 closer to the loaded end still showed some variations, thus showing interfacial shear stress transfer. Nevertheless, about 50mm away from the loaded end, strain values of specimen M3 becomes relatively constant, thus indicating debonding.

![Figure 4 The strain distribution along the bonding length a) Strain distribution of monotonically loaded samples at different stages; b) Comparison between sample M3 and C1 at different load levels.](image)

The interfacial shear stress distributions along the bonding length at different loading points are illustrated in Figure 5 for specimens C1, C2 and C3. Corresponding unloading and reloading points are indicated in Figure 3b for each specimen. In specimens, C1 and C2, with the increase in displacement, peak shear stress moves away from the loaded end. This indicates damage propagation along the bond length. In specimen C3, drop of the shear stresses to zero at the loaded end with the increase in load can be observed, which indicates the initiation of damage.

![Figure 5 Bond shear stress distributions of specimens C1, C2 and C3 at different loading points](image)

The bond-slip curves at different locations along the bond length of specimens M1, M2 and M3 are shown in Figures 6a, b and c respectively. Due to the brittle failure of the specimen M2, complete bond-slip curves could not be obtained for this specimen. Nevertheless, peak shear stress at several locations along the bond length could be observed, thus the curves are shown in Figure 6b. In all the specimens, peak bond shear stress showed higher values closer to the loaded end (approx. 10MPa in specimens M1 and M3 and 7MPa in specimen M2), and gradually reduced along the bond length. In specimens M1 and M3, peak bond shear stress converged to a value of approximately 5MPa after about 45mm length away from the loaded end.

The bond-slip curves of the Specimen C1 at different locations are shown in Figures 6d-f, while those for specimens C2 and C3 are shown in Figures 6g-i and 6j-l respectively. Similar to specimens M1-M3, peak bond shear stress of specimens C1-C3 also showed higher values on locations closer to the loaded end compared
those from locations away from the loaded end. Within the softening region of the curves, unloading showed a residual slip at zero bond shear stress. This residual slip tends to increase with the slip at the unloading point. In addition, bond shear stresses tend to be negative with further unloading beyond zero shear stress point. This is different to the assumption made in Carra and De Lorenzis (2015).

Figure 6 Bond-slip relations for different samples: a) M1; b) M2; c) M3; d) C1 at 13mm from the loaded end; e) C1 at 28mm from the loaded end; f) C1 at 43mm from the loaded end; g) C2 at 13mm from the loaded end; h) C2 at 28mm from the loaded end; i) C2 at 43mm from the loaded end; j) C3 at 13mm from the loaded end; k) C3 at 28mm from the loaded end; l) C3 at 43mm from the loaded end; m-o) Comparison of the bond slip relation between M2 and C1 at m) approx. 39mm, n) approx. 48mm, o) approx. 59mm.
A comparison of the bond-slip curves from specimens M3 and C1 are given in Figures 6m-o. It can be seen that closer to the loaded end, envelope bond-slip curve of the C1 specimen matched closely with the bond-slip curve of M3 at the same location (Figure 6m). However, further away from the loaded end bond-slip curves from the two specimens showed some discrepancy towards latter part of the softening branch of the curves (Figures 6n and o). Towards the latter part of the softening branch of the bond-slip curves, bond-stress of the curves from specimen C1 was higher than the bond-stress observed from specimen M3. This indicates that within this region of the bond length, interfacial stress transfer still occurs in specimen C1 while complete debonding has occurred in specimen M3. The reason behind this higher stress transfer observed in specimen C1 could be due to mechanisms such as friction and interlocking. These mechanisms vary from one location to another and between specimens, which is observed in the differences of bond-slip curves at different locations, especially within the latter part of the softening branch of the bond-slip curves.

CONCLUSIONS

This paper presents the results from a series of simple pull-off tests of FRP-to-concrete bonded joints under quasi-static monotonic and cyclic loading. The results of these tests are expected to provide a better understanding of the behaviour of FRP-to-concrete bonded joints subjected to cyclic loading. Load-displacement behaviour, strain distribution along the bond length at different loads, stress-distributions along the bond length at different loads, and bond-slip curves at different locations along the bond length are presented and discussed. Load-displacement curves showed obvious stiffness degradation as the curve becomes nonlinear. Stiffness degradation was also seen in the bond-slip curves when unloaded-reloaded within the softening region of the bond-slip curve. During the unloading from softening region of the bond-slip curves, a clear residual slip was seen at zero bond shear stress. Therefore, the damaged elasticity assumption made in some of the existing theoretical models for bond-slip behaviour under cyclic loading found to be inaccurate. Bond-shear stress became negative with further unloading. This indicates that reduction of the slip at constant zero shear stress assumption made in some of the existing theoretical models is inaccurate. Bond shear stress values towards the latter portion of the softening part of the bond-slip curves tends to vary from one location to another within the same specimen, and between the specimens indicating possible effects due to friction and interlocking mechanisms within the cracked regions.

ABSTRACT

Fiber-Reinforced Polymers (FRPs) are getting more and more common in structural strengthening of Reinforced Concrete (RC) members, also in seismic areas. However, the current knowledge about their mechanical behaviour and interaction with the existing materials is based on the big deal of research carried out in the last twenty years with almost exclusive reference to the case of monotonic loads. Therefore, in the last years both experimental tests and theoretical studies have been presented in the scientific literature for scrutinising the response under cyclic actions of FRP strips glued to concrete. Based on a model recently proposed by the Authors, this paper aims at unveiling the relationship between fracture-mechanics-related parameters and the resulting fatigue response of FRP-to-concrete adhesive joints. Moreover, it shows the influence of physical quantities and mechanical properties on the resulting fatigue curves.

KEYWORDS

FRP, concrete, strengthening, cyclic actions.

INTRODUCTION

Although, nowadays, the use of Fiber-Reinforced Polymer (FRP) materials is fairly common as a technical solution for strengthening and retrofitting existing constructions (Teng et al. 2001), the current codes and guidelines (ACI 2008; CNR 2013) do not provide practitioners with specific rules for the design under cyclic actions, which is obviously of relevance in seismic areas. As a matter of fact, plenty of experimental (Chajes et al. 1996) and theoretical (Cornetti and Carpinteri 2011) studies have been carried out for investigating the cracking processes leading to debonding of FRP strips Externally Bonded (EB). Conversely, the researches addressing the behaviour of FRP and, specifically, the possible debonding failure, under cyclic loads are much more recent (Carloni et al. 2012) and are mainly experimental in nature.

As for modelling, an empirical bond-slip model intended to simulating the behaviour observed in a series of monotonic and cyclic tests, carried out on Aramid (A), Carbon (C) and Polyacetal (P) FRP strips glued on concrete blocks, can be found in the literature (Ko and Sato 2007). The model is based on assuming a Popovics-like bond-slip law and seven mechanical parameters need to be calibrated experimentally, as a result of the aforementioned empirical nature of the model under consideration.

More recently, Carrara and De Lorenzis (2014) proposed a coupled damage-plasticity model intended at simulating the cyclic behaviour of FRP-to-concrete interfaces under cyclic loads, based on a classical bilinear elastic-softening bond-slip law.

In the same period, the Authors followed an alternative approach, based on Fracture Mechanics concepts, for formulating a model capable to simulating the cyclic behaviour of FRP strips externally bonded to concrete (Martinelli and Caggiano 2014). Two alternative bond-slip laws (namely, linear-exponential and doubly exponential, along with the aforementioned bi-linear one) were originally considered: one of the most attractive features of the proposed model is that the main physical quantities of relevance in Fracture Mechanics, such as the work spent in the fracture process, are derived in closed-form.

This paper is intended as a further contribution to modelling FRP-to-concrete adhesive joints under cyclic actions. Based on a model recently proposed by the Authors, this paper aims at unveiling the relationship between fracture-mechanics-related parameters and the resulting fatigue response of FRP-to-concrete adhesive joints. Moreover, it
shows the influence of physical quantities (such as the bond length) and mechanical properties (such as fracture energy) on the resulting fatigue curves.

Section 2 outlines the key theoretical assumptions of the aforementioned model, whereas Section 3 proposes a parametric analysis and shows the fatigue curves. Finally, the main findings of this study are highlighted in Section 4, along with the future developments of this research.

OVERVIEW OF THE ANALYSIS METHOD

The Authors have recently formulated a numerical model capable of simulating the cyclic response of FRP-to-concrete joints (Martinelli and Caggiano 2014). It is based on the following fundamental assumptions:

− the cracking process develops at the FRP-to-concrete interface in pure “mode II”;
− the softening branch of the bond-slip law is assumed “a priori” and takes an exponential expression;
− stiffness degradation and damage evolution in the unloading stages depend upon the current value of the “fracture work” spent at each point of the FRP-to-concrete interface;
− “small” displacements are assumed at the interface and the concrete substrate is assumed to be rigid.

Although, in its original formulation, the model features two alternative expressions for the bond-slip law, the present study is based upon assuming the following linear-exponential relationship:

\[
\begin{align*}
\tau(z) &= -k_E s(z) & \text{if } s(z) \leq s_e \\
\tau(z) &= -\tau_0 e^{-\beta [s(z) - s_e]} & \text{if } s(z) > s_e
\end{align*}
\]

(1)

where \( s(z) \) and \( \tau(z) \) are, respectively, interface slip and shear-bond stress at the considered \( z \) abscissa, \( k_E \) is the tangential bond stiffness defining the pre-peak branch bond-slip law, \( s_e = \tau_0/k_E \) represents the elastic slip value, \( \tau_0 \) is the corresponding shear strength, while \( \beta \) is a parameter of the post-peak softening branch of the \( \tau \)-s law. Figure 2 depicts the shape of this interface bond-slip law and highlights its relevant mechanical parameters.

Under the aforementioned assumptions, the fracture energy \( G_f^II \) (hereafter expressed by \( G_F \), for the sake of simplicity) can be easily expressed as a function of the three independent parameters \( k_E \), \( s_e \) and \( \beta \).
Therefore, the damage parameter \( d \) can be defined in each point of the adhesive interface as follows:

\[
d = \xi^\alpha_d, \quad \text{with} \quad \xi = \frac{\sigma_s}{G^H_f},
\]

where \( \alpha_d \) controls the loading/unloading stiffness \( k \) (Figure 2).

**ANALYSIS**

Martinelli and Caggiano (2014) validated their model by comparing some of the experimental results obtained by Ko and Sato (2007) on both monotonic and cyclic pull-out tests. The present study moves from the parameters employed in that validation (namely, \( L=300 \text{ mm} \), \( E_p=10.4 \text{ kN/mm} \), \( b_p=50 \text{ mm} \), \( k_s=52.22 \text{ MPa/mm} \), \( \tau_0=2.256 \text{ MPa} \) and \( G_f=G_{F,ref}=0.958 \text{ N/mm} \)). The following analyses aim at investigating the influence of cyclic loading protocol, interface properties (Figure 2) and geometry (Figure 1) on the resulting cyclic response. As for the protocol, it is described by a uniform amplitude \( 2\Delta F \) around a mean value \( F_m \) equal to one half of the maximum load \( F_{mon} \), obtained in the monotonic loading process and determined as follows:

\[
F_m = F_{mon}/2 = \sqrt{2G_F E_p p_p b_p}/2.
\]

Since low-cycle fatigue is mainly considered, in this study \( \Delta F \) ranges between \( 0.30 F_{mon} \) and \( 0.45 F_{mon} \). Figure 3 shows the applied-force-maximum-slip response obtained under the four values considered as the load amplitude \( \Delta F \).

Figure 3c shows that, for \( \Delta F = 0.40 F_{mon} \), structural damage develops slowly, as a significant number of cycles is
needed for the FRP strips to be completely debonded from the concrete substrate. Conversely, debonding develops in a much faster way as the cycle amplitude grows up, and few cycle reversals are sufficient for failure to occur. Moreover, although a linear unloading/reloading process is assumed at the local level (Figure 2), a hysteretic response emerges for sufficiently wide force oscillations: it is already apparent under $\Delta F = 0.35 F_{\text{mon}}$ (Figure 3b) and it gets more and more pronounced for $\Delta F = 0.40 F_{\text{mon}}$ (Figure 3c) and $\Delta F = 0.45 F_{\text{mon}}$ (Figure 3d). The relationship between force amplitude $\Delta F$ and the corresponding number of cycle reversals, after which the system fails in debonding, may be regarded in the light of the Fatigue Theory (Suresh 1998). More specifically, the well-known Wöhler curve (also known as S-N curve) can be drawn by relating these two quantities. Particularly, Figure 4 shows the S-N curve obtained for the system under consideration, along with those determined for shorter bond lengths (namely, equal to 100 mm and 200 mm).

![Figure 4 Fatigue curves S-N: the influence of bond length L.](image)

Figure 4 shows the difference in terms of cyclic response for the three considered bond lengths under a load amplitude $\Delta F = 0.40 F_{\text{mon}}$. More specifically, the two graphs highlight that the system is capable of only two cycle reversals for $L = 100 \text{ mm}$ (Figure 5a) and twelve for $L = 200 \text{ mm}$ (Figure 5b), whereas the number of reversals were twenty for $L = 300 \text{ mm}$.

![Figure 5 Cyclic load-slip curves ($\Delta F = 0.40 F_{\text{mon}}$): the influence of bond length L.](image)

Therefore, two remarkable observations have to be drawn out of Figure 4 and Figure 5:

- as was not obvious in principle, the three curves are represented by a straight segment in a log-log plane, and, hence, they can be represented by the following exponential relationship (Suresh, 1998):

$$\frac{2\Delta F}{F_{\text{mon}}} = a \cdot (2N)^b,$$

where the constants $a$ and $b$ depend on both the interface bond-slip law and the bond length; moreover, in principle, they are also influenced by the average stress/force assumed in the cyclic load protocol;

114
- as expected, for a given amplitude $\Delta F$, debonding occurs earlier in FRP strips with shorter bond lengths. Furthermore, a series of analyses are carried out by considering a variable value of $G_F$, ranging from the aforementioned $G_F = G_{F,ref}=0.958 \text{ N/mm}$ down to $0.70 \ G_{F,ref}=0.671 \text{ N/mm}$.

Figure 6 reports the cyclic response obtained for the lowest value of $G_F$ considered in this parametric analysis: the four graphs correspond to the ones reported in Figure 3 for the case of FRP-to-concrete joint with $G_F = G_{F,ref}$. More specifically, the graphs in Figure 6 compare the cyclic responses obtained in the two cases of $G_F=0.958 \text{ N/mm}$ and $G_F=0.671 \text{ N/mm}$.

![Figure 6 Cyclic load-slip curves ($G_F=0.70G_{F,ref}=0.671 \text{ N/mm}$).](image)

Besides the two extreme cases reported in Figure 6, Figure 7 shows the S-N curves corresponding to the four values of $G_F$ included between $G_{F,ref}$ and $0.70 \ G_{F,ref}$.

![Figure 7 Fatigue curves S-N: the influence of fracture energy $G_F$ (for a given bond length, $L=300 \text{ mm}$).](image)

It is worth highlighting that, for each $G_F$, the corresponding value of $F_m$ was determined afresh according to eq.(4)
and, hence, the variable values of $F_{mon}$ (and $\Delta F$) have been updated for each $G_F$ (Figure 6). Conversely, the bond length $L$ is kept unchanged; hence, the cases analysed by assuming lower values of $G_F$ result in being characterised by a higher ratio between the actual bond length $L$ and the effective transfer length (Teng et al. 2001). This is the reason why, as shown in Figure 7, the S-N curves determined for lowest $G_F$ is above the ones with higher values of fracture energy.

Moreover, a progressive transition is observed in terms of S-N curves (Figure 7) from the highest to the lowest values of $G_F$, and, however, all points belonging to each series line up on a straight segment, confirming the general validity of a linear relationship in the log-log plane described by eq. (5).

CONCLUSIONS

This paper aims at understanding the debonding of FRP strips glued to concrete and subjected to cyclic loads. Based on the results achieved in this study, the following aspects can be remarked:

- as expected, force amplitude significantly affects the resulting cyclic response of the analysed systems;
- low-amplitude cycles result in high number of reversals, whereas a progressive reduction in reversals (with significant hysteresis of cycles) is observed for wider cycle amplitudes;
- it is unveiled that the number of cycle reversals can be correlated to the corresponding amplitude by means of a linear curve in the log-log plane, as commonly occurs in the Theory of Fatigue;
- more specifically, the results reported in this paper deals with the so-called low-cycle fatigue and shows that the bond length significantly influences position and slope of the resulting curve;
- on the one hand, if the fracture energy is kept constant (and, hence, both $F_{mon}$ and the effective transfer length of the system keeps unchanged), reducing the bond length results in a significant reduction of the number of cycles leading to a complete debonding (namely, a reduction in fatigue life) of the FRP-to-concrete joint;
- on the other hand, if $G_F$ varies without changing the bond length $L$, reducing $G_F$ reverberates on both $F_{mon}$ and the effective transfer length and, hence, the fatigue life obtained in cases of lower fracture energy is higher than the ones with higher $G_F$.

In the Authors’ best knowledge, these results have not been highlighted so far in the international scientific literature. However, this work is intended as a first step towards connecting fracture mechanics and fatigue theory for predicting the cyclic response of FRP-to-concrete joints subjected to cyclic actions.

ACKNOWLEDGMENTS

The study is part of the SUPERCONCRETE Project (H2020-MSCA-RISE-2014, n. 645704): the Authors wish to acknowledge the financial contribution of the EU-funded Horizon 2020 Programme. More specifically, it was mainly developed in February/March 2016, during the period spent by the first author and the home institution of the second one.

ABSTRACT

For a fiber reinforced polymer (FRP) strengthened concrete structure, minor defects and flaws, such as interfacial debonding, can lead to catastrophic failure. Electromechanical impedance (EMI) technique is proved to be efficient to identify structural damage by using piezoceramic transducers (PZT) bonded on the structure as actuator-sensor. Therefore, with the purpose of SHM, this study presents a simplified spectral model to obtain the impedance signatures of PZT which is bonded on a FRP laminated concrete beam. One of the advantages of the proposed model, which is established in frequency domain, is its efficiency to capture dynamic response in high frequency range. Furthermore, in order to validate the accuracy of proposed model, experimental test was carried out to measure impedance signatures and the results show the capability of presented spectral approach and EMI technique for monitoring debonding damage in FRP-strengthened structures.

INTRODUCTION

Although FRP has attracted great attentions in civil engineering field as an effective way of retrofitting and strengthening due to its high strength to weight ratio and corrosion resistance, structural damage often appears due to the various kinds of loading, temperature changing and severe environment exposure. The premature interfacial debonding is an important structural damage which always leads to a brittle and sudden failure, and it undoubtedly limits the extension of this technique (Teng et al. 2002; Bank 2006). This kind of failure is always initiated at a major flexural crack and then propagates towards the end of composite plate (Pesic et al. 2003), thus, the bond health condition of FRP-strengthened structures should be paid more attentions. However, debonding damage appears as minor defect in its early stage which is very difficult to be detected by using traditional methodologies such as dynamic analysis, for that reason, reliable SHM approach that can identify incipient debonding damage is required.

More recently, piezoelectric sensor is very popular in SHM which can evaluate structural damage based on the measured electromechanical impedance. By bonding PZT patch on the structure as both actuator and sensor, the measurement of impedance is directly related to the mechanical impedance of host structure, and the changes in structural properties can be reflected by the alternation of measurement results in high frequency domain. Up to now, the EMI method has been implemented in numerous applications to identify structural damage. Experimental test were carried out (Park et al. 2005; Min et al. 2012) to monitor the healthy condition of alloy beam, pipe system and spot-welded joints, and the interfacial debonding of FRP-strengthened concrete beam were evaluated (Xu et al. 2010; Park et al. 2011) by using EMI analysis. The results show the capability of PZT sensors for monitoring structural damages, especially minor damages.

Furthermore, numerical simulation has also drawn researchers’ attention in this field. Taking into account that the mesh size of finite element model should be comparable to the wavelength of highest frequency sweep range, it results in huge number of elements and high computational cost (Hamzeloo et al. 2012). In this work, a one-dimensional spectral model is employed to calculate the impedance signatures for bonded PZT-FRP beam, and very limited elements are implemented in the proposed model. Experimental test were carried out to validate the proposed model, it’s clear that this approach might be a potential tool for the identification of FRP debonding damage.
SPECTRAL ELEMENT METHOD

For FRP reinforced concrete segment, spectral model (Doyle 1997; Gopalakrishnan et al. 2008) was established to investigate the mechanical behavior. To this end, Hamilton’s principle was applied to obtain the governing equations, considering the kinematic motions of a two-nodes element with four degree of freedom $u_0$, $w$, $\phi$ and $s$ are shown in Fig 1, which denote the axial displacement, the transverse displacement, the rotation of the beam about y-axis, and the interfacial slip between FRP and concrete, respectively.

![Figure 1 Kinematic motions of FRP-RC beam with PZT patch](image)

The governing equations of the reinforced beam are given as

\[ \delta u_0 = I_0 \ddot{u}_0 - I_1 \dot{\phi} + I_{0\text{FRP}} \ddot{s} - A_1 u_{0xx} + B_1 \dot{s}_{xx} - A_{\text{FRP-xx}} s_{xx} = 0 \]  \hspace{1cm} (1)

\[ \delta w = I_0 \ddot{w} - A_{22} w_{xx} + A_{22} \phi_s = 0 \]  \hspace{1cm} (2)

\[ \delta \phi = I_2 \ddot{\phi} - I_1 \dot{u}_0 - I_{1\text{FRP}} \ddot{s} + B_1 \dot{u}_{0xx} - A_{22} \phi_{xx} - A_{22} \phi + B_{\text{FRP}} s_{xx} = 0 \]  \hspace{1cm} (3)

\[ \delta s = I_{0\text{FRP}} \ddot{s} + I_{0\text{FRP}} \dot{u}_0 - I_{1\text{FRP}} \ddot{s} - A_{\text{FRP-xx}} s_{xx} = 0 \]  \hspace{1cm} (4)

where $\dot{}$ represents temporal derivative and $(\ )_{xx}$ denotes double differentiation with respect to x. The coefficients $A_1$, $B_1$, $D_1$, $A_{22}$, $A_{\text{FRP}}$, $B_{\text{FRP}}$ are related to materials properties and $I_0$, $I_1$, $I_2$, $I_{0\text{FRP}}$, $I_{1\text{FRP}}$ are associated with inertial terms.

Applying Discrete Fourier Transform (DFT), the displacement field introduced previously $\{u\} = \{u_0(x,t), w(x,t), \phi(x,t), s(x,t)\}$ takes the following formulation in frequency domain

\[ \{u\} = \sum_{n=1}^{N} \{ \hat{u}(x, \omega_n) \} e^{-j \omega_n t} = \sum_{m=1}^{M} \left( \sum_{n=1}^{N} \{ \hat{u}^*(n) \} e^{-j \omega_n x} \right) e^{-j \omega_n t} \]  \hspace{1cm} (5)

where $\omega_n$ denotes the n-th circular frequency, N is the number of frequency points and $\hat{u}(x, \omega_n)$ represents the spectral amplitude vector corresponding to the generic displacement vector as a function of $(x, \omega_n)$. A Fourier expansion of $\hat{u}(x, \omega_n)$ has been also carried out in the longitudinal direction where $\{ \hat{u}^*(n) \} \omega_n = \{ \hat{u}_0, \hat{w}, \hat{\phi}, \hat{s} \}$ represents the wave coefficient vector associated with the m-th mode of wave and for each frequency and $k_{mn}$ denotes the m-th wave number related to n-th frequency $\omega_n$. Therefore, the governing formations can be represented as the following polynomial eigenvalue problem:

\[ [W(k)] \{ \hat{u}^* \} = 0 \]  \hspace{1cm} (6)

where $W(k)$ is the matrix polynomial depending on the wavenumbers $k_{mn}$ for each frequency $\omega_n$. In this case, the order of the matrix polynomial is 8. Thus, there are eight eigenvalues ($k_{mn}$ where $m = 1, \ldots, 8$) and eigenvectors ($\{ \hat{u}^* \}$). After solving the eigenvalue problem and combing boundary force conditions, the expression of spectral element model is obtained as follows

\[ \begin{bmatrix} f_1 \\ f_2 \end{bmatrix} = [T_2][A][T_2]^{-1} \begin{bmatrix} \{ \hat{u}_1 \} \\ \{ \hat{u}_2 \} \end{bmatrix} \begin{bmatrix} \{ \hat{u}_1 \} \\ \{ \hat{u}_2 \} \end{bmatrix} \]  \hspace{1cm} (7)
where \([T_1]\) and \([T_2]\) are obtained from governing equations and boundary forces respectively, and finally the dynamic stiffness matrix \([K]\) for the spectral PZT-bonded FRP strengthened concrete element is formed. From the expressions of proposed spectral element, it can be noted that only one element is needed as long as the structure remains uniform in material and geometrical properties which is able to reduce computational cost significantly.

Based on the presented spectral model, the impedance signature of PZT sensor can be evaluated by using formula as follows (Liang et al. 1994)

\[
Y(\omega) = j\omega b_{PZT} \frac{e_{PZT}}{e_{PZT}} (\varepsilon_3^T Y_{31} - \frac{Z_s(\omega)}{Z_s(\omega) + Z_a(\omega)} d_{33}^T Y_{11})
\]

where \(Y(\omega)\) is the admittance (inverse of impedance), \(\omega\) is the angular frequency of the driving voltage, \(d_{33}\) is the piezoelectric strain constant between \(z\) and \(x\) directions at zero stress, \(j\) is the imaginary unit. Furthermore, \(Z_s(\omega)\) and \(Z_a(\omega)\) are the mechanical impedances of the PZT and the host structure, they are able to be evaluated easily as long as the displacement field are obtained in frequency domain by applying proposed spectral approach.

RESULTS

With the purpose of validating the feasibility of the presented model, experimental tests were performed on a concrete block strengthened with FRP plate. The dimensions of the specimen are \(31.3 \times 9.5 \times 7.5 \text{cm}^3\) and the dimensions of the FRP reinforcement are \(29 \times 5 \times 0.12 \text{cm}^3\). As shown in Fig 2, PZT sensors were bonded to the external face of the FRP reinforcement using an epoxy adhesive distributed along the surface of the FRP plate. The three sensors were individually connected to three different channels of a multiplexor, which was used to make a multiple connection between the impedance analyzer and the sensors. The Impedance Analyzer excited the PZT sensors and simultaneously recorded the impedance signatures received by the PZT sensors.

![Figure 2 Experimental set-up](image)

In this work, the output impedance of PZT2 in the middle is selected to compare with numerical results. As presented previously, only one spectral element is enough as long as no discontinuity happens in the structure, thus, as shown in Fig 3 the specimen is represented by 5 spectral elements (E1-E5) along the whole beam with the length of 0.01, 0.14, 0.01, 0.14 and 0.013 respectively. It’s clear that the number of elements is very limited leading to low computational costs compared with conventional finite element model.

![Figure 3 Spectral element mesh distribution](image)
Fig 4 illustrate the comparison of EMI spectra obtained by experimental test and numerical simulation in the frequency range of 10-100kHz. It can be observed that the proposed model is able to predict output impedance with satisfied accuracy considering only five elements were applied.

Figure 4 Comparison of experimental and numerical impedance signatures

To perform the proposed model for damage detection, the interfacial shear modulus of element 3 (E3) is reduced to simulate the debonding damage in the early stage. Root mean square deviation (RMSD) is chosen as the damage indicator in order to measure damage severity quantitatively as follows:

\[
\text{RMSD} = \left( \frac{100}{n} \sum_{i=1}^{n} \left| Z_i(a_0) - Z_i(a_f) \right|^2 \right)^{1/2}
\]

where \( Z_i(a_0) \) is the impedance of the PZT measured at a previous stage, which might agree with the healthy condition of the structure, and \( Z_i(a_f) \) is the corresponding value at a subsequent stage, which might agree with a post-damage stage, at the \( i \)th frequency point; \( n \) is the number of frequency points. In this work, the appearance of debonding in FRP reinforced beam would lead to variation of output impedance signatures in high frequency range particularly, and this incipient damage can be evaluated by using RMSD as damage indicator. It is obvious that RMSD is directly associated with the appearance of damage and increases with the developing of damage severity from 30% to 70%. Therefore, the EMI method is proved to be sensitive enough to identify structural damage such as FRP debonding in this case.

Figure 5 RMSD in different damage level
CONCLUSIONS

A one-dimensional spectral element method was presented in this work. The proposed method was established in frequency domain by using DFT and is able to capture EMI signature in high frequency range. Although very limited elements were employed, its precise is validated by using experimental results. Moreover, numerical simulation is performed to prove that the minor debonding damage of FRP strengthened concrete beam can be reflected according to the variations of the impedance output by introducing RMSD as damage indicators.

ABSTRACT

Bond behaviour plays an important role in reinforced concrete structures design and performance. In this study, bond performance of glass fibre reinforced polymer (GFRP) reinforced Geopolymer Cement (GPC) concrete and steel reinforced GPC concrete are analysed and compared. The bond failure mode, the average bond strength and the free end bond-slip curves are used for the comparison. Furthermore, Tepfers’ concrete ring model is used to further analyse the splitting failure in ribbed steel and GFRP bar specimens. The results showed that failure mode of the specimen plays a significant role on the average bond stress at failure. Pull-out failure resulted in higher bond strength for ribbed steel bars whereas splitting failure caused higher bond stress for GFRP bars, showing the difference in the bond mechanism between the two bars. For the specimens with splitting failure mode, the ribbed steel bar specimens displayed a higher bond-angle than the GFRP bar specimens explaining the ribbed steel bars higher splitting tendency.

INTRODUCTION

Bond behaviour is an important part of both design and performance of reinforced concrete structures. Bond allows forces to be transferred from the reinforcement to the surrounding concrete. Thus the bond behaviour between constituent elements of a structure determines its performance as a whole. Due to the good bond between ribbed steel bars and concrete, steel reinforced concrete is one of the most successful construction materials. However, due to corrosion of steel bars and environmental issues associated with cement production, engineers are looking for alternative materials. Glass fibre reinforced polymers (GFRP) reinforced geopolymer cement (GPC) concrete stand out to be an ideal solution. GFRP bars are manufactured from thermoset polymers vinyl ester and glass fibres and are characterised by high tensile strength, high durability, light weight, and electromagnetic permeability (Bank 2006). Geopolymer cement binder is produced by activating by-product materials that are rich in silica and alumina, such as fly ash and rice husk ash with alkali liquids such as metal hydroxide and/or alkali silicate. In addition to environmental benefits, GPC also provide a rapid rate of strength development, resistance to sulphate attack, acid resistance, little drying shrinkage, low creep, improved resistance to fire, and prolonged handling time (Hardijito and Rangan 2005, Junaid et al. 2014, 2015a, 2015b). Various studies have been carried out on steel reinforced OPC concrete, steel reinforced GPC concrete, and GFRP reinforced OPC concrete (Tepfers 1979, Malvar 1992, Cui and Kayali 2013, Sofi et al. 2007). Based on these studies different standards have been developed to assist in the design of reinforced concrete structures such as ACI 408R-03. However, the knowledge on the bond performance of GFRP reinforced GPC concrete and their comparison with steel reinforced GPC concrete is limited, thus the need for this research.

EXPERIMENTAL RESULTS

The analysis of this paper is based mainly on the experimental results from Tekle et al. (2016) for GFRP reinforced GPC concrete and Cui and Kayali (2013) for steel reinforced GPC concrete. Both studies and the experimental program used pullout specimens were the reinforcement was embedded in 100 × 170 mm concrete cylinder.
Straight non-deformed sand-coated GFRP bars with a nominal diameter of 15.9 mm and elastic modulus of 62.6 GPa were used (Figure 1). These were manufactured using a pultrusion process, and made up of continuous E-glass fibres, with a minimum volume of 65 %, bound together by a modified vinyl ester with a maximum volume of 35 %. Normal ductility hot-rolled ribbed steel bars with 16 mm diameter and with a yield and ultimate strength values of 546 MPa and 633 MPa respectively were used. Plain steel bars with 16 mm diameter and with yield and ultimate strength values of 339 MPa and 507 MPa respectively were also used.

![Figure 1 Reinforcement bars: (a) plain steel bar; (b) sand-coated GFRP bar (c) ribbed steel bar](image)

The GPC concrete used in both experimental programs is fly ash based. The mix proportions and properties of the concrete are as given in Table 1. The pullout test setup used by Cui and Kayali (2013) and Tekle et al. (2016) is as shown in Figure 2.

The experimental results are summarized in Tables 2 and 3 for GFRP and steel bars, respectively. The bond stress is assumed to be uniform along the bar and is defined as the shear force per unit surface area of the bar. This definition of average bond stress is followed throughout the analysis, and is calculated as

$$\tau = \frac{P_{\text{max}}}{\pi d l_b}$$

where $\tau =$ average bond stress, in megapascals; $P_{\text{max}} =$ applied maximum pullout load, in Newtons; $d =$ nominal diameter of the bar, in millimeters; and $l_b =$ bonded/embedded length, in millimeters.

PS=Plain Steel bar; RS=Ribbed Steel bar
ANALYSIS AND DISCUSSION

Failure mode and average bond strength

As can be seen in Table 3, splitting failure mode dominated the ribbed steel bar specimens due to the relatively low confinement and longer embedment lengths of the specimens. This failure mode was also observed for the GFRP bars with longer embedment lengths, i.e. 96 mm and 144 mm specimens. Tepfers (1979) reported that the splitting failure is caused by the radial component of the bond stress. This radial bond stress generates a splitting stress in the concrete around the reinforcement bar. When this stress exceeds the tensile strength of the concrete, it results in the splitting of the specimens. Yet this type of failure was not observed in the plain steel bars despite having similar or longer embedment lengths. This depicts the poor bond between the plain steel bar and the concrete which, unlike the ribbed steel bars and sand-coated GFRP bars is not enhanced by the ribs and the sand coating, respectively.

After failure, the GFRP bars showed a thin layer of concrete on their surface as shown in Figure 3 (a). In case of the ribbed steel bars on the other hand, the concrete is intact with no damage as the specimen splits; i.e. leaving no concrete on the bar surface (Figure 3 (b)). This indicates that the bond between the ribbed steel bar and the concrete is still undamaged at the point of concrete splitting. The plain steel bar slipped out of the concrete without damaging the interface as can be seen in Figure 3 (d), depicting its poor bond strength.

Splitting failure can be considered as premature because the bond has not yet attained its maximum value. Due to their ribs, the ribbed steel bars generate a higher splitting stress than the GFRP bar. This results in the splitting of the concrete earlier than the GFRP bar specimens. Indeed, as can be noticed, the GFRP reinforced GPC concrete specimens show an apparent higher bond strength than ribbed steel reinforced GPC concrete specimens. The average bond stress at failure for G144 specimens is 15.0 MPa, whereas that of the RS120 is only 8.7 MPa. Even at higher embedment lengths, where bond stress is known to decrease (Cosezna et al. 1997, Maranan et al. 2015, Tighiouart et al. 1998 Lee et al. 2013, Okelo and Yuan 2005), GFRP specimens still show a higher bond stress than ribbed steel bar specimens at the point of concrete splitting. This lower bond stress of ribbed steel bar compared to GFRP bars in case of splitting failure was also reported by Maranan et al. (2015).

In case of pull out failure on the other hand, the specimens failed due to interface failure. The ribbed steel specimens offer a better pullout resistance due to their ribbed surface. This results in a better bond strength for ribbed steel specimens. This was observed by Maranan et al. (2015) experimental results for specimens with equal embedment length of five times the bar diameter. For the pullout failure to occur, in case of GFRP, the sand coated bar need to slip over the concrete surface. The interlock between the bar and the concrete is provided by the sand coating and the concrete between the sand grains. Thus the bond strength is only as strong as this interface interlock and the confinement provided by the concrete. Once the sand grains or the concrete start shearing, pullout will occur. However, in case of ribbed steel bars the pullout failure occurs only when shear cracks are initiated in the concrete keys between ribs. As the ribs are stronger than the sand coating, the pullout strength of ribbed steel bars is higher than sand-coated GFRP bars.
Splitting failure and bond-angle

The bond stresses between a reinforcing bar and the concrete make an angle $\alpha$ with the bar axis as schematically shown in Figure 4. This angle mainly depends on the type of reinforcing bar used and controls the bond behaviour specifically the splitting failure. Higher bond-angles result in higher splitting stress on the concrete surrounding the reinforcement. Based on the bond angle, the stresses are divided into tangential ($\tau$) and radial ($\sigma_r$) components. The radial stress component generates a hoop/circumferential stress ($\sigma_t$) around the concrete covering the reinforcement (Figure 5).

![Figure 4 Radial components of the bond force balanced against tensile stress rings (Tepfers, 1979)](image)

The splitting of the concrete cover is a common bond failure mode in reinforced concrete structures. The hoop stress generated by the radial component of the bond stresses is resisted by the tensile strength of the concrete. Once the tensile strength is exceeded by the hoop stress, splitting failure occurs. When the bond-angle increases, the radial component of the bond stress increases, and this consequently facilitates the splitting failure mode. The splitting force depends mainly on the concrete cover thickness, bar diameter and type of bar. As can be seen in Tables 2 and 3, both the deformed steel bars and the GFRP bars have specimens with splitting failure. However, despite the similar cover and diameter for both steel and GFRP bars, the splitting bond forces are different. GFRP bars with splitting failure showed an average failure load of 97 kN, whereas ribbed steel bars showed a much lower value of 60 kN. The higher radial bond force generated by the ribbed steel bar caused this early failure of the specimen.

![Figure 5 Splitting failure of ribbed steel bar specimens; (a) Radial and tangential stresses (b) RS120-1 splitting failure](image)

Tepfers (1979) analysed the state of stress in concrete due to bond forces from ribbed reinforcing bars. The radial stresses from the bond were regarded as a hydraulic pressure on the concrete wall. The concrete was modelled in three different ways; uncracked elastic, partly cracked elastic and uncracked plastic. The derived equations for each of these models respectively are as described below:

\[
\sigma_t = \tau \tan \alpha \left( \frac{(c+d/2)^2+(d/2)^2}{(c+d/2)^2-(d/2)^2} \right) 
\]

\[
\sigma_t = 1.664\tau \tan \alpha \left( \frac{c+d/2}{c-d/2} \right) 
\]

\[
\sigma_t = \frac{d}{2c} \tau \tan \alpha 
\]

where $\sigma_t$ is tangential stress, $d$ is diameter of the bar, $c$ is the concrete cover (the smallest concrete cover around the reinforcement), $\tau$ is the bond stress and $\alpha$ is the angle the bond stress makes with the axis of the bar.
Splitting failure of the specimen occurs when the tangential stress equals the tensile strength of the concrete. For comparison, the bond angles are calculated by substituting all the known parameters into Eq. 2, Eq. 3 and Eq. 4. The tensile strength of the concrete is taken as the maximum tangential stress. Table 4 summarises these results.

</tr>
</tbody>
</table>

For specimens with an approximate cover to diameter ratio of 2, Tepfers recommend using the average of partly cracked elastic and uncracked plastic models. For GFRP bars, the bond angle according to this recommendation becomes 37 degrees, whereas that of steel bars becomes 59 degrees. Tepfers and De Lorenzis (2003) also reported the smaller bond angle for sand-coated GFRP bars. In fact, they reported a bond-force angle of 35 degree for a sand-coated GFRP bars. They suggested that, the probable reason for the lower bond-angle is that the sand coated surface of the bar creates a softening layer with some ability to transfer tension in concrete close to the bar. The splitting tendency of a reinforcing bar increases with increasing of the bond-angle (Tepfers and Olsson, 1992), and thus the lower failure load of ribbed steel bars.

**Bond-slip curves**

For splitting failure, the bond-slip curve can be divided into two parts; the linear region and the nonlinear region. In addition to these regions, a softening branch is found in pullout failure specimens. Figure 6 shows different bond-slip curves for GFRP, plain and ribbed steel bar specimens. The GFRP bar specimens displayed a longer nonlinear region compared to the ribbed steel bars. This is due to the much brittle failure of the specimens with ribbed steel bars. Despite their ribbed bar counterparts, the plain steel bar specimens, displayed a longer nonlinear curve compared to the GFRP bar specimens. The small amount of slip observed at the free end of ribbed steel bar specimens further portrays the sudden brittle failure. The average slip recorded for both RS120 and RS150 specimens for instance is only 7 microns, which shows a negligible amount of bar displacement at the free end when the concrete splits.

![Figure 6 Bond-slip curves for GFRP, plain and ribbed steel bar specimens](image)

**CONCLUSIONS**

This paper has presented the comparison of bond properties of GFRP reinforced GPC concrete and steel reinforced GPC concrete. From the analysis, it was observed that ribbed steel bars have a better bond performance which was verified by their better bond strength in case of pullout failure, but a higher splitting tendency and thus lower bond stress at the point of splitting. The average bond stress at the point of splitting failure is about 16.4 MPa and 8.9 MPa, respectively for sand-coated GFRP bars and ribbed steel bars, showing the more brittle and sudden splitting of specimens with ribbed steel bars. Bond angles of 59 and 37 were determined for ribbed steel bars and sand-coated GFRP bars, respectively explaining the higher splitting tendency of ribbed steel bars.

PULL-OUT BEHAVIOR OF CFRP GROUND ANCHORS WITH TWO-STRAP ENDS

Haifeng Fan, Anastasios P. Vassilopoulos and Thomas Keller
Composite Construction Laboratory (CCLab), École Polytechnique Fédérale de Lausanne (EPFL),
Station 16, Bâtiment BP, CH-1015 Lausanne, Switzerland

ABSTRACT
Pull-out experiments were performed on three carbon fiber-reinforced polymer (CFRP) ground anchors simulating their applications in different rock types which provided different confinement levels. The CFRP tendons comprised, on the ground side, a prefabricated conical anchor body of high-strength grout in which two CFRP straps were embedded. The anchors reached an average load-bearing capacity of 1384 kN with final failure occurring in the CFRP straps. Grout failure was successfully prevented by an adequate grout selection and installation of CFRP confinement rings to balance spreading forces at the strap ends. The confinement level provided by the surrounding media influenced the activation of the CFRP components in the anchor body by influencing the friction at the CFRP/grout interfaces.

KEYWORDS

INTRODUCTION
Fiber reinforced polymer (FRP) tendons are increasingly used to replace conventional steel tendons in ground anchors, taking advantage of their high strength-to-weight ratio and good corrosion resistance. The applications of AFRP and CFRP tendons, especially in permanent prestressed cases, have been reported since 1990 (Tokyo Rope Co. Ltd 2016). Conceptually similar to steel strands, FRP strands were also developed by twisting a certain number of small-diameter wires. A high load-bearing capacity could be achieved by forming a FRP cable assembled from several strands, for example in the Carbon Fiber Composite (CFCC) system commercialized by Tokyo Rope in Japan (Benmokrane et al. 1997, Tokyo Rope Co. Ltd 2016). FRP Cables with a similar concept, assembled from rods with nominal diameters of 4.0 mm (Wang et al. 2015) or 12.6 mm (Zhang et al. 2014), were also developed and studied.
To anchor the tendon on the air and ground sides, mechanical or bonded anchors are commonly used (Schmidt et al. 2012). However, two problems exist in these types of CFRP anchors, which could lead to a premature failure in the anchor and thus not allow to exploit the full tendon capacity: 1) high shear and through-thickness stress concentrations existing at the anchorage are critical due to the anisotropic properties of CFRP fibers; 2) uneven load distributions among the assembled strands or rods occur, i.e. some of them were obviously less loaded compared to others (Wang et al. 2015).

Figure 1 Prestressed and permanent CFRP ground anchor with multi-strap end
A simpler and much more material-tailored anchorage method, based on strap ends, was thus developed (Winistoerfer 1999). A new application of this strap anchorage method for permanent prestressed CFRP ground anchors was recently proposed (Fan et al. 2016), which consists of a CFRP tendon with a multi-strap end on the ground side, embedded in a prefabricated high-strength grout cylinder confined with CFRP rings, as shown Figure 1. The main purpose of the rings is to deviate the spreading forces at the embedded strap ends into the cylinder’s axial direction and not to increase the grout strength. The grout cylinder is thus stepwise axially loaded by the axial components of the spreading forces. The ground anchor with the prefabricated anchor body can be 20–80 m long and coiled, then transported to the construction site, inserted into the borehole, anchored by injecting fresh standard (normal-strength) grout and finally prestressed to 60% of the design load.

In a first stage, a CFRP ground anchor with a single-strap end on the ground side was developed (Fan et al. 2016). A CFRP confinement ring, according to the anchor concept (see Figure 1), was installed at the strap end to deviate the spreading forces. A load-bearing capacity of around 500 kN was achieved in pull-out experiments, which is well-tailored for soil applications.

This paper reports on a second development stage, where a two-strap end was conceived on the ground side to increase the load-bearing capacity to more than 1000 kN, which normally need a rock media to be anchored. Anchor specimens were pulled out from mortar cylinders confined by steel tubes of different thicknesses which simulated different confinement levels of the rock mass.

EXPERIMENTAL PROGRAM

CFRP ground anchor specimens

The CFRP tendons used in this study were produced by Carbo-Link, Fehraltorf, Switzerland, as shown in Figure 2. The tendons were composed of unidirectional UTS50 F24 24k 1600tex D carbon fibers impregnated with XB 3515 AD1571 ACC1573 epoxy resin; the fiber volume fraction was 60 ± 2%.

The two-strap end of the CFRP tendon was embedded in a 1060-mm-long high-strength grout body with inclined and corrugated surface on the ground side, as shown in Figure 3. A non-shrink sand/cement high-strength grout (SikaGrout-212 provided by Sika Schweiz AG, Switzerland) with a maximum aggregate size of 4 mm was used. Three 150-mm-long and 2-mm-thick identical CFRP confinement rings, consisting of the same materials as the tendon, were installed around the two strap ends and the division point. The anchor body geometry was designed to fit in boreholes with a minimum diameter of 130 mm.

The prefabricated anchor body was inserted into a 1200-mm-long steel tube, simulating a rock mass as shown in Figure 4. The tube was then filled with a fresh sand/cement grout (Sika normal rock anchor mortar, provided by Sika Schweiz AG, Switzerland) with a maximum aggregate size of 0.8 mm. Pull-out experiments were conducted on three anchor specimens with two different tube thicknesses to study the influence of the rock stiffness on the load-bearing capacity of the anchor; an overview of the experimental series is shown in Table 1.

Experimental setup and instrumentation

The pull-out experiments were conducted on a Trebel 10MN machine, as shown in Figure 5. The anchor was suspended at the air side through a steel pin to the top fixed beam of the machine. The pulling load was applied to the top surface of the anchor body through a loading frame consisting of a bearing plate, two cross beams, two transverse reinforcements and 18 thread bars; the bars were fixed to the cross beams on one side and to the bottom movable beam of the machine on the other side. The loading was applied to the bottom movable beam in displacement-control mode at a rate of 1 mm/min. After four load cycles up to 100, 300, 500 and 700 kN respectively, the anchor was loaded up to failure.

![Figure 5 Experimental set-up (dimensions in [mm], DIC white-black paint on tube)](image)

The instrumentation layout is shown in Figure 6. Three types of instruments were used: Linear Variable Differential Transformer (LVDT) transducers, strain gages and Digital Image Correlation (DIC). Two LVDTs were symmetrically fixed on the rod at a distance of 115 mm from the top surface of the 50-mm-thick bearing plate to obtain an average pull-out displacement.
RESULTS AND DISCUSSIONS

Load vs pull-out displacement responses and failure modes

All specimens exhibited similar load vs pull-out displacement responses in the failure cycle up to a first peak, as shown in Figure 7. An almost linear response was observed, except a slight nonlinear behavior at the beginning; the latter was attributed to a progressive debonding at the CFRP/grout interface, which also caused a small residual displacement after the four initial load cycles up to 700 kN, as shown in Figure 7 for anchor ST5. The stiffness in the linear range, $K_{exp}$, assumed as being the slope of the linear segment between 500 and 1200 kN, was similar, as shown in Table 1; anchor ST5 exhibited only 6.3% lower stiffness than the ST10-1/2, which could be attributed to a slightly larger deformation due to the weaker confinement.

The three anchors reached similar loads at the first peak, indicating that the confinement level had low influence on the load-bearing capacity of the anchor. At this first peak, delamination was observed in the visible air-side straps in anchors ST10-1/2, while no damage was recognizable in ST5. After the first peak, the load dropped and increased again to a second peak in all specimens where partial or complete rupture of the air-side strap occurred in anchors ST10-2 and ST5 respectively, see Figure 8. The obtained peak loads are listed in Table 1.
Figure 8 Failure modes: (a) cut view of anchor ST10-1; details in (b) ST10-1, (c) ST10-2, (d) ST5
After failure, the specimens were cut into two halves in the strap plane, see Figure 8. All anchors exhibited rupture in the embedded CFRP tendons; no compression failure in the grout parts was observed, except small cracks located in the normal-strength grout at the end of the CFRP rings, see Figure 8 (a). In anchor ST10-1, the large and small straps were completely separated from the rod at the division point on one side, while partial rupture or delamination occurred in the semicircles of the small or large straps, see Figure 8 (b). In anchor ST10-2, complete rupture was visible at the division point of the large strap and in the semicircle of the small strap. Furthermore, partial rupture or delamination occurred in the semicircle of the large strap and the division point of the small strap, see Figure 8 (c). In anchor ST5, complete rupture occurred in the semicircle of the large strap and partial rupture in one straight part of the large and at the end of the small strap; no damage was visible at the division point.

Figure 9 Load vs tensile strain responses of ground-side large strap: (a) along straight segment; (b) at strap end
Load vs tensile strains in CFRP tendons

The load vs tensile strain responses in fiber direction of the embedded (ground-side) large and small straps are shown in Figs. 9 and 10 respectively. In all the anchors, the straps were activated progressively from the division point to the small and then to the large strap end due to the progressive loss of bond and subsequent friction at the CFRP/grout interface. The gages close to the division point (T7/8) thus started responding firstly, at lower loads (below 150 kN), while the gages around the large strap (T1/2/14) were activated lastly, at much higher load (above 350 kN).

The strap activation sequence also depended on the confinement level, i.e. at the higher confinement the strap was activated later due to the higher friction at the CFRP/grout interface. Accordingly, the semicircular parts of the large straps (positions T1/2/14) and small straps (T5/13) in anchor ST10-2 were activated later (at around 450 and 350 kN respectively) compared to ST5 (at around 380 and 270 kN respectively). After the activation, the strain rates in ST10-2 were also slightly lower than in ST5 due to the higher friction.

Due to the early activation, positions T7/8 generally exhibited the maximum strains. However, gages T4/7/8 stopped measuring after certain loads due to the propagating slippage at the CFRP/grout interface. The maximum strains were measured in the small strap of anchor ST5 due to the earlier activation compared to the large strap and lower confinement level; they approached the ultimate strain of the CFRP material. The strains in the large straps, however, remained far below the ultimate strain.

Furthermore, complete recovery of the strap deformation during unloading was prevented by the friction behavior as well, which also led to the residual displacements after unloading during the first four cycles, shown in Figure 8. The amount of strain recovery also depended on the strap location, i.e. more strain recovery was observed closer to the division point due to the smaller friction, see Figures 11 (b) and 12 (b).

CONCLUSIONS

Pull-out experiments were performed on three CFRP ground anchors with two-strap ends embedded in a prefabricated high-strength grout anchor body on the ground side. The anchor body was embedded in normal strength grout confined with steel tubes of different thicknesses to simulate the confinement of different rock masses.

The results showed that the targeted 1000-kN anchor capacity was reached. Failure occurred in the CFRP tendons at different positions on the embedded air- and ground- sides which proved an almost uniform use of the capacities of the different strap components. Furthermore, the conceptual elements to prevent grout failure, i.e. selection of high-strength grout in the anchor body, CFRP confinement rings to balance and deviate spreading forces and the complex conical anchor body shape to introduce the forces into the normal grout proved to be effective and well-tailored, grout failure did not occur.

ABSTRACT

Existing bond models for FRP reinforcements are based on limited number of parameters only. Present study includes the description of an extensive experimental work, as well as an analytical part for modelling the bond behaviour of FRP rebars in plain and in fibre-reinforced concrete. Experimental parameters consisted of: (1) type of FRP rebar (carbon, glass or basalt fibres) including different surface characteristics and moduli of elasticity, (2) concrete strength and type (four different grades of conventional concrete and two SCC mixes), (3) type of fibres in concrete mixes (no fibres, steel, synthetic micro or synthetic macro polymer fibres), resulting 216 pull-out tests and 144 additional material property tests (concrete compressive strength tests and concrete splitting tensile strength tests). All bond test results were analysed for possible ways to refine bond modelling. Conclusions are drawn on bond behaviour and modelling by using the studied parameters.

KEYWORDS

FRP, carbon, glass, basalt, FRC, short fibres, bond behaviour, modelling of bond.

INTRODUCTION

Mild steel rebars have been extensively used for reinforced concrete structures as internal reinforcements owing to their numerous advantageous properties such as: ductility, high tensile strength, bendability etc. However, they present some disadvantages too being the most significant one is that steel reinforcement is susceptible to corrosion. One of the main advantages of Fibre Reinforced Polymer (FRP) reinforcing materials is their excellent corrosion resistance (Baena et al. 2009 and Boroszyó 2014).

Numerous studies can be found in literature underlining the significance of the bond behaviour of reinforcement in concrete. Yet, in case of FRP rebars there are still open issues owing to the high number of parameters which affect the bond.

During the last decades, numerous experimental studies have been conducted to investigate the bond strength of FRP rebars in concrete. The studies also investigated the influence of the parameters, such as rebar diameter, concrete strength, concrete cover, embedment length, surface treatment, etc. on the bond characteristics of FRP rebars (Achillides and Pilakoutas 2004, Baena et al. 2009 and Haffke et al. 2015). On the other hand, less attention was payed to determine analytically the bond stress-slip constitutive law for FRP rebars, which is essential for finite element analysis of FRP reinforced concrete structures. Therefore, only few FRP bond stress-slip models have been reported so far, and the suitability and capability of these models for numerical modelling of FRP reinforced concrete structures have not been confirmed yet.

One of the numerous bond affecting parameters that still calls for further investigation is the effect of short fibres, mixed into the concrete matrix. Mixing short fibres into the concrete matrix represents a possible way to confine the concrete in compression zone and provide it with additional strain capacity.

The placement of fibre reinforced concrete can be difficult due to clumping of the fibres. Moreover the use of poke vibrator can be difficult as well. These problems may be overcome by using self-compacting concrete which contains short fibres (Sólyom and Balázs 2016). Available studies show that FRC has improved tensile strength, strain capacity and ductility over normal concrete (Czoboly and Balázs 2015).
Combining fibre reinforced self-compacting concrete with FRP reinforcing bars holds major benefits, because the additional strain capacity allows an increase in flexural strength over the equivalent conventionally reinforced beams (Ibell et al. 2009).

An overview of the combined use of FRP rebars with FRC is provided in Sólyom et al. (2015) and will be briefly summarized herein.

In the research by Belarbi and Wang (2004) Glass Fibre Reinforced Polymer (GFRP) and Carbon Fibre Reinforced Polymer (CFRP) rebars were used. GFRP rebars had 12.7 and 25.4 mm in diameter, surface wrapped with helical fibre strand and additionally sanded afterwards. CFRP rebars were 12.7 mm in diameter, with smooth surface. The fibres added to the concrete mix were commercially available polypropylene short fibres, with maximum length of 57 mm. From the experimental data (27 pull-out specimens) it was concluded that the addition of polypropylene fibres did not increase the bond strength, but larger slips were recorded. The large slip values made the bond behaviour more ductile and the failure mode changed from splitting to pull-out. This is in contradiction with the results reported by (Ding et al. 2014). The authors claim, that the addition of short fibres to concrete can enhance the bond strength of GFRP rebars and also reduces the slip corresponding to the bond strength. Others (Won et al. 2008) have found also that the addition of short fibres to concrete increases the bond strength of FRP bars.

It can be concluded from the above review, that there are inconsistencies in the available results and further research is needed.

In this paper two bond stress versus slip models will be assessed. They show how the parameters of the models change according to the studied bond influencing factors, namely: FRP fibre type and surface characteristics, short fibre type and concrete compressive strength.

**EXPERIMENTAL STUDIES**

The pull-out test is the most frequently chosen method for comparing the bond behaviour of different FRP rebars in various concrete compositions. This test is a powerful tool to study the effect of different parameters on bond strength, owing to its simplicity and ease of application.

150 mm cubic moulds were used to manufacture the pull-out specimens. The bars were vertically placed in the centre of the moulds with 5Ø bond length in the lower part of the moulds (Ø - rebar diameter). Following the pouring, the specimens were left in the moulds under laboratory ambient conditions for one day. Thereafter, the concrete cubes were demoulded, marked and placed under water for 6 days. After this period of time the concrete specimens were taken out of water and kept in laboratory air until testing (mixed curing was applied).

The concrete pull-out specimens were placed into a metal frame and the FRP rebars were gripped by the test machine. This gripped portion was considered as the loaded end of the test specimen and the relative displacement between the FRP rebar and concrete was measured with three Linear Variable Differential Transducers (LVDT). At the other end, usually referred to as unloaded or free end, the slip was measured by one LVDT. Displacement controlled test was selected on the loading machine to capture post-peak behaviour. The load was applied to the rebar at a rate of 1 mm/min and measured with the electronic load cell of the testing equipment (Instron 600 kN). An automatic data acquisition system was used to record the data transmitted by LVDTs. Three nominally identical specimens for each configuration were tested.

In order to study the influence of concrete strength on bond development between FRP bars and concrete six different concrete grades were used (mean values of concrete compressive strength ranging between 27.7 and 91.9 MPa measured on three 150 mm cubic specimens). Three different type of FRP bars were used, carbon, glass and basalt. CFRP and GFRP bars had similar surface characteristics (sand coated) and diameter (9.5 mm) as well. The Basalt Fibre Reinforced Polymer (BFRP) bars were 12.7 mm in diameter and had a surface with helical wrapping. Three different short fibres were added to the concrete matrix: steel, synthetic micro and synthetic macro polymer fibres.

The symbols of concrete mixes consist of 3 characters, the first C or S stands for traditional and self-compacting concrete, respectively. The second character represents the concrete strength, the higher value of the character, the higher the concrete strength is. The third character mix refers to the type of short fibres in concrete, namely: 1 represents that no short fibres are mixed to concrete, while 2 refers to synthetic macro, 3 to steel and 4 to synthetic micro fibres. For example C11 represents traditional concrete prepared according to composition C1 without short fibres, while S23 stands for self-compacting concrete prepared according to composition S2 with steel fibres.
The main objective of this experimental series was to examine the effect of the short fibres if added to concrete matrix on the bond strength and bond behaviour of FRP bars. Nevertheless, other additional factors that need further research to better understand their final influence on bond behaviour were also considered. The parameters taken into consideration during this study are: short fibres, type of FRP rebar fibre (modulus of elasticity), rebar surface characteristics and concrete strength.

RESULTS AND DISCUSSION

The results of the experimental part of this study along with the conclusions is presented in the authors’ previous paper (Sólyom and Balázs 2016). In this paper authors focus on analytical modelling, more specifically on curve fitting parameters of two already available analytical models: modified BPE (mBPE) (Cosenza et al. 1997) and CMR (Cosenza et al. 1995) models. These models are discussed in some papers (e.g. Baena et al. 2009), therefore only the necessary equations will be presented herein.

To perform numerical and analytical analysis of the behaviour of reinforced concrete members and structures including the interaction between concrete and reinforcement to determine for example the anchorage length, the crack width, etc. an analytical model of the bond stress - slip constitutive law is necessary.

Table 1 shows the results of curve fitting procedure for the selected two analytical models in case of BFRP rebars. The accuracy of each analytical model was evaluated by calculating the discrepancy (standard error) between the experimental bond stress values ($\tau_{exp}$) and the corresponding analytical predictions ($\tau$) for each registered slip value ($s$). Results, calculated by equation (Eq. 1), are presented in columns: 5, 9 and 16:
\[ SE = \sqrt{\frac{\sum_{i=1}^{n}(\tau_i - \tau_{\text{exp}})^2}{n}} \]  

where \( n \) is the number of experimental values registered during the pull-out test in case of one specimen (ascending or descending branch), while \( \tau \) is calculated as a dependant of the assessed analytical model.

In case of the Double Branch (mBPE) model (Cosenza et al. 1997) the equations for calculating the bond stresses are as follows (Eqs 2 and 3):

- ascending branch \((0 \leq s \leq s_m, \text{ where } s_m \text{ is the slip corresponding to the maximum bond stress, } \tau_{\text{max}})\)
  \[ \tau = \tau_{\text{max}} \left( \frac{s}{s_m} \right)^\alpha \]  
  (2)

- descending branch \((s_m \leq s)\)
  \[ \tau = \tau_{\text{max}} \left[ 1 - p \left( \frac{s}{s_m} - 1 \right) \right] \]  
  (3)

where \( \alpha \) and \( p \) are parameters to be calibrated on the basis of curve fitting of the experimental data.

- the third branch, where the bond stress is constant, it is not taken into consideration because it was not observed on the experimental bond stress vs. slip diagrams (most probably due to the limitation of LVDTs).

In case of CMR model (Cosenza et al. 1995) the bond stress can be calculated by using Eq. 4:

\[ \tau = \tau_{\text{max}} \left[ 1 - e^{-(s/s_r)} \right]^\beta \]  

(4)

where \( \beta \) and \( s_r \) are parameters to be calibrated based on curve fitting of the experimental data.

In case of each concrete mix three specimens were tested, their mean obtained test data is presented in Table 1, columns: 2, 6, 10 and 13 (defined by curve fitting of the analytical model). In column 4 the standard deviation of the three values (in case of parameter \( \alpha \)) are calculated using Eq. 5.

\[ SD = \sqrt{\frac{\sum_{i=1}^{n}(\alpha_i - \alpha_{\text{avg}})^2}{n-1}} \]  

(5)

Similarly, the same equation (Eq. 5) can be used to calculate the values in columns 8, 12, and 15, only the studied parameter needs to be changed accordingly.

To be able to study the effect of concrete strength on the curve fitting parameters, the mean values of each concrete composition are defined in columns 3, 7, 11 and 14.

Similarly to Table 1, tables for GFRP and CFRP rebars were prepared. However, because of the limitation of the paper they are not presented herein, only a part of the results is given in Figure 1.

Analysing Table 1 and Figure 1, the following observations can be made if attention is given to BFRP rebar, which is relatively new on the market.

mBPE model (ascending branch), parameter \( \alpha \):

- slightly increases with the addition of short fibres, which in turn represents a less stiff bond stress vs. slip diagram. As \( \alpha \) increases the ascending part of the diagram is approaching to a linear function.
- the highest increase is in case of synthetic micro and steel fibres, Table 1, column 2.
- slightly increases with the increase of the strength of concrete, which in turn represents a less stiff bond stress vs. slip diagram, Table 1, column 3.

mBPE model (descending branch), parameter \( p \):

- increases with the increase of the concrete strength, which represents a steeper descending branch of bond stress vs. slip diagram, Table 1, column 7.
- no clear tendency for the effect of short fibres can be observed, Table 1, column 6.

CMR model (ascending branch), parameter \( \beta \):

- slightly increases with the increase of the strength of concrete (C0 and S2 are exceptions), which represents a negligible stiffness increase of the ascending branch of bond stress vs. slip diagram, Table 1, column 11.
- no clear tendency for the effect of short fibres can be observed, Table 1, column 10.

CMR model (ascending branch), parameter \( s_r \):

- increases with the increase of the strength of concrete, which represents a less stiff ascending branch of bond stress vs. slip diagram, Table 1, column 14.
- decreases with the addition of short fibres, which represents a stiffer ascending branch of bond stress vs. slip diagram. The highest decrease is achieved with synthetic macro fibres, Table 1, column 13.

Since the scatter of these parameters in case of BFRP rebars is relatively low, generally valid parameters for this specific BFRP rebar can be estimated as the resultant of these values, which are presented in the last row of Table 1: \( \alpha = 0.28, \beta = 0.49 \) and \( s_r = 1.81 \). However, if we do not take into consideration the values of C0 concrete.
composition, which seem to be outsider, they become: \( \alpha=0.29, \beta=0.41 \) and \( s_r=2.12 \). These values offer a satisfactory agreement with the results reported by (Baena et al. 2009) \( \alpha=0.18 \) to 0.23, \( \beta=0.36 \) to 0.84 and \( s_r=0.04 \) to 0.06 for GFRP rebar with similar diameter and slightly lower modulus of elasticity. The surface treatment consisted of helical wrapping and sand coating. The significant difference in \( s_r \) can be explained by the fact that different slip values (at loaded and unloaded end, respectively) were considered in different studies. Slightly different results were reported by (Yoo et al. 2015) for these parameters: \( \alpha=0.18, \beta=0.49 \) and \( s_r=0.22 \) for a GFRP rebar with similar diameter and helically wrapped surface.

Analysing Figure 1 the following observations can be made. Values of parameter \( \alpha \) in case of CFRP rebars (filled symbols) are the highest which leads to the conclusion that the higher the modulus of elasticity, the higher the parameter \( \alpha \) is, since CFRP and GFRP have similar surface characteristics and diameters. Furthermore, parameter \( \alpha \) is higher in case of rebars with sand coated surface treatment when compared to rebars with helically wrapped surface. BFRP and GFRP rebars have similar modulus of elasticity and diameters, however \( \alpha \) parameters are lower in case of BFRP rebars (unfilled symbols) than in case of GFRP rebars.

![Figure 1 Parameter α for mBPE model](image1)

**Figure 1** Parameter \( \alpha \) for mBPE model (each symbol represents an average value of three specimens). C, G and B stand for CFRP, GFRP and BFRP, respectively. Re – reference concrete (no short fibre) and concrete with synthetic macro (Ma), steel (St) or synthetic micro (Mi) fibres

![Figure 2 Experimental and analytical bond stress vs. slip diagrams](image2)

**Figure 2** Experimental and analytical bond stress vs. slip diagrams, C13 and C14 concrete mixes

In Figure 2 comparisons between experimental and analytical results are presented. It is straightforward that both mBPE and CMR models are in good agreement with the experimental results (Figure 2, left), however CMR have higher accuracy (see also Table 1, columns 5 and 16). Nevertheless, in Figure 2, just where the local maximum point in the bond stress vs. slip diagram is more accentuated, the similarity between experimental and analytical results is smaller, though it is still acceptable. At low slip values, the analytical models slightly overestimate the bond stresses, while as the slip increases this tendency changes. It needs to be highlighted, even though there are
only two of the numerous studied bond slip laws are presented here, the rest of the results are similar to the ones presented in Figure 2. The local maximum points are fairly typical for this type of helically wrapped BFRP rebars. More details on this phenomenon and the possible reasons of it can be found in the authors’ previous paper (Sólyom and Balázs 2016).

Finally, please note that, the experimental values were taken for $\tau_{max}$ and $s_m$, alternatively these parameters could have been estimated by formulae available in literature.

Table 2 Values for parameters defining the relation between $\alpha$ and concrete compressive strength

$\alpha = a f_c^2 + b f_c$ (6)

where $a$ and $b$ are parameters which need to be defined by a curve fitting procedure (Table 2). It is worth mentioning, that the values in Table 2 are based on a limited number of specimens and further data is needed for the validation of this equation and these parameters.

CONCLUSIONS

In the present paper the interfacial bond behaviour between three types of FRP rebars (Glass, Basalt and Carbon fibres) in six different concrete compositions have been analysed. Since the experimental results have been presented in a previous paper, here the focus was given to analytical modelling, more specifically parameter fitting of two already available analytical models, namely: modified BPE and CMR models. Results of 24 mixes (216 pull-out tests) were considered. Studied parameters: concrete compressive strength, FRP fibre type and surface characteristics and short fibre type. Based on the results of the presented study the conclusions can be presented as follows.

Parameter $\alpha$ (mBPE model) increases with the increase of the compressive strength of concrete in case of all the investigated FRP rebars (basalt, carbon and glass). However the effect of short fibres is not straightforward, but it seems that $\alpha$ increases with the addition of short fibres, which in turn provides a less stiff bond stress vs. slip diagram. Values of $\alpha$ are higher in case of sand coated FRP rebars when compared to helically wrapped surface. Furthermore, increase of modulus of elasticity of FRP rebars results in an increase in the values of parameter $\alpha$. Similarly, parameter $\beta$ (CMR model) slightly increases with the increase of the compressive strength of concrete in case of all investigated FRP rebars. Values of $\beta$ are higher for sand coated rebars when compared to helically wrapped ones. Moreover, increase of modulus of elasticity of FRP rebars results in an increase of the values of $\beta$.

ABSTRACT

The experimental investigation is intended to study the influence of some parameters on the quasi-static and the fatigue behaviour of the bond between glass fibre reinforced plastic (GFRP) rebars and concrete. This is an important aspect in FRP reinforced concrete structural elements and of relevant importance in thin reinforced concrete panels extensively adopted as façade or pavements. The pull-out test set-up with eccentrically positioned GFRP ComBAR® bar was adopted to measure the effect of two parameters on the bond mechanical features: thickness of the concrete cover and concrete mechanical properties. For cycling tests, another parameter, the maximum load in the cycle, was introduced to estimate the fatigue life under different load levels. Quasi-static tests showed that concrete compressive strength influence on bond properties is much more pronounced than that of the concrete cover. Cyclic tests at highest load level revealed that higher concrete quality attained longer fatigue life.

KEYWORDS

GFRP rebars, eccentric pull-out test, GFRP-concrete bond, fatigue.

INTRODUCTION

Constructing using newly developed materials presents new wave of modern aspirations in civil engineering society. Since first vanguard applications in last decades of XX century, new FRP (fibre reinforced polymer) reinforcement is nowadays present in many practical design codes, endeavouring to take more and more share in global usage of reinforcement for concrete structures. Existing design codes and guidelines treat well the requirements and checks for proper design of FRP reinforced structures, but still missing some parts or underestimating real material characteristics due to insufficient knowledge concerning certain issues. One of the most important issues related to reinforced concrete design is bond that makes secure and balanced transfer of forces from reinforcement to surrounding concrete. Bond of FRP reinforcement is still treated as area of many aspects to research about (Sólyom et al. 2015). One of the simplest, but still effective method for experimental assessing of bond properties is standard pull-out test, recommended by Rilem (RILEM TC9-RC 1994). With the aim of simulating better real conditions in structure, but also for estimating concrete splitting tendency, pull-out test with eccentric placement of the bar is recommended by fib Bulletin 10 (Fib Task Group Bond Models 2000). Eccentric pull-out test is conducted in this research for estimating the possibilities of application low concrete cover in combination with FRP reinforcement. This was particularly investigated for the sake of application in thin plate elements that are usually prefabricated and used as façade panels, pavement or layer of sandwich composite plates. Non-corrosive nature of FRP bars and prefabrication of plate elements enable maximal lowering of the concrete cover, leaving the only concern about correct transfer of forces through so formed bond. Low concrete cover stands in favor of FRP bars due to its softer surface, comparing to steel bars, leading to lower local stress concentrations in bond, delaying splitting of concrete cover (Tepfers and De Lorenzis, 2003). Stress distribution necessary for developing the ultimate splitting crack pattern highly depends on the type of bar surface. Helically wrapped and sand coated GFRP (Glass Fibre Reinforced Polymer) bars exhibited earlier cover cracking for higher concrete mechanical properties (Tepfers and De Lorenzis, 2003) and GFRP bars with trapezoidal ribs showed delayed concrete cover cracking, comparing to specimens reinforced with classical steel rebars (Weber 2005). The concrete cover determines the bond failure mechanism. Cover of one Ø (Ø = bar diameter) generates splitting failure mechanism, while cover of 2Ø or more, generates pullout or fracture of bar (Ehsani et al. 1996).
One of the main field of application of FRP reinforcement is in bridge engineering, due to plenty of problems these structures experienced that were caused by corrosion of steel reinforcement. As fatigue is considered to be important phenomenon in bridge design, particular attention should be dedicated to fatigue of bond in FRP reinforced structures. Different researches showed different bond strength before and after cyclic loading (Shield et al. 1997) (Ceroni et al. 2006) (Wang and Belarbi 2010) (Alves et al. 2011). Fatigue is considered more significant damage factor in steel, than in FRP, reinforced structures, due to higher stiffness of steel material causing higher damage of bond interface during cyclic loads (Shield et al. 1997) (Ceroni et al. 2006). The best fatigue bond properties were observed in case of GFRP rods with stiff external layer of polymer and large deformations in it to increase the adhesion (Katz 2000). Helical wrapping and sand coating of FRP rods considerably reduced the rod and bond strength to cyclic loading (Katz 2000) (Lee et al. 2009).

Although a plenty of work is done, considering static bond behaviour, and some general conclusions are present, there are still some unsolved related issues. Unlike static bond behaviour, fatigue behaviour of FRP/concrete bond is still quite unknown topic.

The influence of some parameters affecting the bond of GFRP bar and concrete is experimentally investigated in the present paper. The centric and eccentric pull-out set-ups with GFRP ComBAR® and steel bars of diameter 8 mm were adopted to measure the effect of: position of the bar regarding the element edge, concrete mechanical properties and, for fatigue test, the cyclic load level. This research gives overview on best FRP/concrete bond performances considering all mentioned input parameters.

MATERIALS

Unidirectional E-glass FRP rebars, named ComBAR® (ComBAR GFRP Reinforcement 2015), were adopted with diameter 8 mm. The GFRP rebars are produced by pultrusion technique with vinyl-ester resin. They have external ribbed surface cut into the bar after curing (Figure 1). The mechanical properties of the rebars in the direction of the bar axis are: tensile strength 1500 MPa; elastic modulus 60 GPa (Combar GFRP Reinforcement 2015). For the sake of comparison, tests with conventional steel ribbed bars (grade B500B) of the same diameter (8 mm) were carried out.

![Figure 1. Surface of the GFRP rebars ComBAR.](image)

In total, four different concrete classes were used, with following designations: C1 (C20/25), C2 (C30/37), C3 (C45/55) and C4 (C50/60). The experimentally measured average (of 12 tests for each class) compressive cubic strengths of the concretes are listed in Table 1.

EXPERIMENTAL SETUP

This experimental campaign uses typical centric as well as eccentric pull-out tests. The geometry of the latter was slightly modified comparing to suggestions of fib Bulletin 10. Centric specimens are cubic with the 200 mm side and eccentric specimens have dimensions 200x200x150 mm (see Figure 2). Height of the eccentric specimens is not the same as suggested by fib Bulletin 10, but approx. 6 times higher than embedment length, which is positioned in the top part of the specimen. Such layout helps to avoid impact of compressive stresses resulting from reaction of support due to pulling out of the bar. The specimens were casted with bars in the side position, orthogonal to the direction of concrete casting, to ensure flat even surface of the concrete block side that is relying on bottom steel plate of the testing frame. Thereby it was enabled transferring the pressure uniformly from concrete block to steel plate. The geometry of the eccentric specimen that was slightly modified from cubic shape to allow anchorage to the loading frame and avoid excessive movements during cycling loading. Specimen geometry and relative bar position is shown in Figure 2a,b, where l is the bar free length from the adhesion zone to the grip tabs, Ø is the bar nominal diameter and c is the concrete cover.
Position of bars in tests was centric or with cover of 10, 15 and 20 mm regarding the specimen side. The length of bond zone between bar and concrete was selected as 5Ø, inserting an aluminium pipe to prevent forming of bond on the remaining part of the bar. Three specimens were quasi-statically loaded for each combination presented in Table 2, which is also showing specimen designation (first letter stands for bar type (G=GFRP, S=Steel), followed by concrete class (C1 – C4, for corresponding concrete class as in Table 1) and bar position (c=centric, 20, 15 and 10 for corresponding concrete covers).

Fatigue tests were performed only for GFRP bar, for each combination of concrete C2 and C3 and cover 10 and 20 mm. The loading levels for cyclic loading were selected according to the average static strength assuming R = 60 and 70%, where R represents ratio of the maximum load in the cycle and the static bond strength (R=τ_{max}/τ_u). Ratio of the minimum and maximum force in each cycle was selected as 0.1. For each combination and load level at least three specimens were cyclically loaded. Pull-out experimental test setup is shown on Figure 2c. To allow dilatation of the concrete in the direction perpendicular to the bar, a PTFE sheet was positioned between the steel plate and the concrete specimen. The bars were gripped with a cylindrical sleeve. Two displacement transducers (LVDT) were placed on the top of the cube to continuously measure displacement: one of the bar and another of the concrete surface next to the bar (Figure 2c). The difference of these displacements gives the slip between the bar and the concrete. Static pull-out tests were displacement controlled, with rate of 1 mm/min. Cyclic loading was force controlled with 5 Hz frequency, while the displacements were recorded continuously with 300 Hz acquisition frequency. Tests were running until reaching bond failure or one million cycles. In the latter case, bar was pulled out quasi-statically to estimate the residual bond strength.

RESULTS AND DISCUSSIONS

Static tests

Considering centric pull-out specimens statically loaded, this experimental work involved specimens of three different concrete classes: C1, C2 and C3 and ComBAR® GFRP bars of diameter 8mm (with external ribbed surface). This bar and specimen type are very similar to the one used in research of Baena in 2009, which detected less damage in the bars and more in the concrete for lower concrete strengths, and vice versa. General rule was
‘the higher the concrete strength is, the higher the bond strength is’ (Baena et al. 2009). As stated in the technical description of the producer (Schoeck Bauteile GmbH August 2013), using ComBAR, the bond behaviour is controlled by strength of concrete for compressive strength <60MPa. The present research mainly confirmed cited observances, as presented in Figure 3a, b. The bond strength, defined as the maximum of the average shear stress $\tau_{\text{max}}$ on the bond surface, was increasing with increasing of concrete compressive strength (Figure 3a). Damage mode involved shearing off the concrete ribs and slight grooves visible on the bar surface (Figure 3c). Similar damage mode was observed for all the concrete classes considered.

Considering eccentric pull-out specimens statically loaded, experiments comprised all combinations of: four concrete classes (C1 – C4) and GFRP bar cover of 10 and 20mm. Beside, 15 mm cover was combined with GFRP bar and concrete C4. Steel bars were considered in concrete C4 with cover of 10 and 20 mm (see Table 2). Some results of the considered combinations are collected in Figure 4, comparing: the different concrete qualities and covers for the GFRP bar in Figure 4a; two concrete covers and the centric position of the GFRP bars in the three concretes (Figure 4b); the GFRP and steel bars for three covers in the same concrete (Figure 4c).

Results for GFRP bars don’t give significant difference in bond strength with increasing the concrete cover, for each concrete class (Figure 4a). Comparison of the eccentric and centric pull-out tests shows tendency of the bond strength to decrease with increasing the confinement for the lower concrete qualities (Figure 4b). The effect of
concrete cover on bond strength of this type of GFRP bars becomes less pronounced as concrete class increases. Other investigations are supposed to better clarify this trend.

More important, than value of cover, is concrete class that significantly improves bond characteristics (Figure 4a). GFRP and steel bars show comparable values of bond strength for 10 and 20 mm concrete cover (Figure 4c).

Figures 5a,b show typical bond shear stress vs. bar slip curves, for covers 10 and 20 mm, and concrete classes C1 – C3. Bond strength doesn’t have relevant variation increasing the cover, but different post peak behaviour was observed. The higher concrete cover shows a higher fracture energy, i.e. the area underneath the $\tau_{\text{max}}$-slip curves. Figure 5c shows comparison of steel and GFRP bars with covers 10 and 20 mm and concrete C4. The main difference is the highest area underneath the curves of GFRP, meaning a higher energy to have a complete separation of the bar and concrete. Bond failure modes observed for all concrete qualities were, as in (Tepfers and De Lorenzis 2003): splitting of the concrete cover and pulling out of the bar. Visual inspection showed that for concrete cover 10 mm splitting of the concrete occurs and for all other cases pull-out of the bar was recorded.

**Fatigue tests**

The estimated mean bond strength allowed to set the loading levels for fatigue test of certain combinations including: concretes C2 and C3, GFRP bar cover of 10 and 20 mm and centric bar. The first loading level was selected as $R = 60\%$ in order to get a reference for succeeding tests. All groups of specimens exhibited very good behaviour for this load level. None of the combinations failed after one million cycles. The second load level for fatigue test was $R = 70\%$. For this, bond failure of almost all specimens was obtained before one million cycles. Different fatigue life occurred for different specimen types, as presented in Figure 6.

![Figure 6. Fatigue life for load level R = 70%](image)

**Figure 6. Fatigue life for load level R = 70%.**

Selecting 10 mm concrete cover, significantly longer fatigue life is achieved by specimens of higher concrete class (GC3_10), about a difference of one order of magnitude comparing GC2_10 (Figure 6). For cover of 20 mm, more similar values of the average fatigue lives were obtained for both concrete classes. The specimens of concrete C2 with centric bar (GC2_c) exhibited very good fatigue behaviour at loading level $R=70\%$, showing the tendency to survive one million cycles even with such high value of cyclic load. However, due to insufficient data for this specimen type, it still remains issue to be reassessed in next investigations. Increasing the concrete quality, specimens with centric bar (GC3_c) showed a reduction of the fatigue life, that is consistent with the behaviour
recorded for the quasi static loading (see Figure 4b). After one million cycles without failure for the load level R=60%, quasi-static pull-out of the bar was performed. Resulting bond strength did not have a reduction, in some case an increase (see Figure 7), but in the experimental scatter band of the pre-fatigue quasi-static bond strength.

CONCLUSIONS

This experimental campaign was performed to clarify some issues regarding GFRP/concrete bond under quasi-static and fatigue loading. The main conclusions are:

- Reducing the thickness of the cover from 20 mm to 10 mm, for this type of the bar of diameter 8 mm, affects bonding conditions in different manner: it lowers bond fracture energy, but it does not lower the value of the bond strength. Moreover, the concrete compressive strength influence on bond properties is much more pronounced than that of the concrete cover.
- Specimens of all combinations did not fail after one million cycles of cyclic loading at R = 60%. Moreover, they showed an unchanged post-fatigue bond strength compared to the pre-fatigue quasi-static one.
- For cyclic loading with R = 70%, the higher concrete quality demonstrated a longer fatigue life with the lower concrete cover, that is consistent with the results of the quasi static pull out tests.

The results will be used as a reference for analytical and numerical modelling of bond behaviour as well as for further investigations using real size structural members.

RELIABILITY ANALYSIS OF ADHESIVELY BONDED CFRP-TO-STEEL DOUBLE-LAP SHEAR JOINTS WITH THIN OUTER ADHERENDS

ABSTRACT

In this paper, a comprehensive database of experimental results of CFRP-to-steel double lap shear joints is compiled and a probabilistic analysis of the data is conducted. The compiled experimental results are compared with the bond strengths predicted by the widely adopted Hart-Smith model for thin adherends and the model uncertainty is characterized, for five popular structural epoxy adhesives and two types of surface preparation techniques. Considering the mechanical and geometrical uncertainties of constituent materials, two reliability-based approaches, First-Order Reliability Method (FORM) and Monte-Carlo Simulation (MCS), are used to calculate the resistance factor at a target reliability index of 3.5. It is found that these two approaches agree well and the resistance factor varies with adhesives, surface preparation techniques, and CFRP type. The importance vector of random variables reveals that the model uncertainty contributes most to the variation of the limit state function.

KEYWORDS

Adhesive, surface preparation, double lap shear, model uncertainty, reliability, bond strength.

INTRODUCTION

The use of carbon fiber-reinforced polymer (CFRP) to repair, rehabilitate and strengthen steel beams has been widely researched in recent years (Sen et al. 2001, Tavakkolizadeh and Saadatmanesh 2003; Rizkalla et al. 2008. Fernando et al. 2009; Teng et al. 2012; Colombi and Giulia 2012; Zhao 2014). Debonding is a key failure mode associated with CFRP strengthened steel beams (Liu et al. 2001; Tavakkolizadeh and Saadatmanesh 2003; Schnierch 2005; Dawood 2008). Experimental studies on adhesively bonded CFRP-to-steel double-lap shear (DLS) joints showed that the debonding load exhibits high variability compared with that of other failure modes such as steel yielding and CFRP rupture (Harris and Dawood 2012). The uncertainty of the bond strength stems from material variability, joint geometry, manufacturing process, and uncertainties inherent in the use of simplified models to predict debonding. However, this uncertainty has not been quantified and the resistance factor of CFRP-to-steel bonded joint design is unknown. Quantifying the uncertainty of the predicted bond strength from the widely-used Hart-Smith (1973) model would be beneficial for design (Wu et al. 2012). In this research a survey of the experimental results on CFRP-to-steel bonded DLS joint was conducted and a database of results was compiled. The database was used to quantify the uncertainty associated with different key parameters that influence the bond, including adhesive type, surface preparation technique, dead load-to-live load ratio, and modelling uncertainty through a reliability-based analysis. Similar techniques have been applied to FRP strengthened concrete structures (Plevris et al. 1995; Okeil et al. 2002; Val 2003), however, reliability analysis for FRP strengthened steel structures is still in the early stages.

RELIABILITY ANALYSIS

The reliability analysis was conducted for a selected design space in which the analytical results are applicable. The statistical characteristics of each random variable was quantified and the limit-state function was defined in order to apply reliability methods.

Design Space

The experimental database is comprised of 242 CFRP-to-steel DLS coupons form 14 studies (Fawzia et al. 2005; Bocciarelli et al. 2007; Lam et al. 2007; Yu 2008; Chiew et al. 2008; Bocciarelli et al. 2009; Fawzia et al. 2010;
Liu et al. 2010; Nguyen et al. 2011; Al-Zubaidy et al. 2012; Wu et al. 2012; Wu et al. 2013; Fawzia et al. 2013; Kim et al. 2013), all of which failed by debonding, i.e. specimens that failed by CFRP rupture were excluded. The joint configurations covered by these studies are listed in Table 1. For all the DLS joints studied here, the axial rigidity of the inner adherend is higher than the outer adherends and the outer adherends are thin enough to neglect the peel stress (Hart-Smith 1973). For this preliminary assessment of uncertainty, this simplification helps to exclude the influence of peeling stresses which add additional uncertainty.

**Statistical characteristics of design parameters**

The model uncertainty, $\xi_R$, defined by the ratio of the measured and predicted resistance, was evaluated to characterize the uncertainty associated with using the Hart-Smith model to predict the bond strength. Material and geometry properties from the literature were used to calculate the bond strength for different joint configurations the measured and predicted bond strengths were compared. Therefore, the mean and coefficient of variation (COV) of the model uncertainty, $\mu(\xi_R)$ and COV($\xi_R$), for different adheres and surface preparation techniques can be calculated, as shown in Table 1. A Chai-squared test (Ang and Tang 2006) shows that the Weibull distribution represents the statistical distribution of the bias well.

Note: *A=Araldite 420; S=Sikadur 30; TT=Tyfo TC; TS=Tyfo S; MB=MBrace Saturant; SB=sand-blasted steel surface; AG=angle-ground steel surface; WL=wet-layup CFRP; PL=pultruded laminate.

The statistical characteristics of all the random variables are summarized in Table 2. The adhesive layer thickness ($t_a$) was treated as a random variable, and the thicknesses of pultruded CFRP laminate ($t_{\text{CFRP}}$) and steel plate thickness ($t_{\text{steel}}$) were treated deterministically. The thickness of the wet-layup CFRP laminate ($t_{\text{CFRP}}$), however, was treated as a random variable (Atadero et al. 2005). The statistical characteristics of the adhesive properties (shear strength $\tau_p$, shear modulus $G_s$, plastic shear strain $\gamma_p$) were assumed to be similar to another paste epoxy structural adhesive (Bresson et al. 2013). The moduli of pultruded CFRP laminate ($E_{\text{CFRP}}$) and steel plate ($E_{\text{steel}}$) were treated as deterministic variables. For wet-layup CFRP, however, the modulus ($E_{\text{CFRP}}$) was treated as a random variable (Atadero et al. 2005). The statistical characteristics of the loads (dead and live load uncertainty, $\xi_{DL}$ and $\xi_{LL}$) came from literature (AASHTO 2001, Allen et al. 2005).

a. See in Table 1.
Limit State Function

The methodology for reliability analysis follows the similar procedure as reported in NCHRP Report No. 368 (Nowak 1999). The limit state function considering the variability of the design parameters is written as

\[
g(X) = \xi_R \left( \frac{\gamma_p^2 + 2\gamma_p \gamma_d}{\gamma_d} \right)^{n_p} \left( 1 + \frac{2E_{CFRP}t_{CFRP}}{E_{steel}t_{steel}} \right) - \frac{\phi R_n}{\gamma_{DL} + \gamma_{LL} \gamma_L} (\zeta_{DL} + \zeta_{LL} \gamma_{LL})
\]

Where, \( \phi \) is the resistance factor, \( R_n \) is the nominal resistance, \( \gamma_d \) is the live load to dead load ratio, and \( \gamma_{DL} \) and \( \gamma_{LL} \) are the load factors for dead load and live load, respectively.

RESULTS AND DISCUSSIONS

The importance vectors, which represent the relative contribution of different random variables to the variation of the limit state function, for four selected design scenarios are shown in Table 3. The other design scenarios generally follow the same trend as the ones presented here. Among them, the model uncertainty, \( \xi_R \), has the greatest influence on the overall uncertainty. Among the material properties, the CFRP modulus has the highest importance value, and the adhesive shear strength and plastic shear strain contribute more than does the adhesive shear modulus. The shear modulus is a demand type variable since it influences the formation of shear stress concentrations near the plate end where debonding initiates. The adhesive layer thickness has the least impact on the reliability index compared to other random variables, but this may differ if the peel stress is considered.

Considering a target reliability index to 3.5, the resistance factors for different design scenarios were calculated by FORM analysis and MCS for different live load-to-dead load ratios (\( Q_{LL}/Q_{DL} \)) and different types of CFRP (pultruded vs wet-layup), as shown in Figure 1. The FORM results agree well with MCS results in general, and the discrepancy between the two is less than 6%.

Larger adhesive ductility is preferred to achieve high bond strength, however, the material ductility might not be realized if, failure occurs at the bonded interface due to poor surface preparation. The results in Figure 1 highlight the complex interaction between adhesive type and surface preparation techniques. As shown in Figure 1(e), the resistance factor is very low for Tyfo TC adhesive with angle-grinding surface preparation, although this is the most ductile adhesive among the five adhesives considered. In contrast, Sikadur 30 is brittle but the corresponding resistance factor is above 0.75 for all design cases, regardless of surface treatment techniques and load ratios.

As shown in Figure 1(a), (c) and (g), sand-blasting consistently gives resistance factors greater than 0.6, and typically above 1.0 for these three adhesives: Araldite 420, Sikadur 30 and MBrace Saturant. However, surface preparation using angle-grinding technique gives inconsistent resistance factors. For example, for Tyfo TC, Tyfo S, and MBrace Saturant, angle-grinding led to resistance factors, \( \phi \), of less than 0.1, indicating high uncertainty in the results. In contrast, for Sikadur 30 and Araldite 420, angle-grinding resulted in resistance factors that were typically greater than 0.9.

In most LRFD-based structural design codes, live loads and dead loads are treated differently. Since double-lap shear coupons are not explicitly designed for a specific set of loads, different live load-to-dead load ratios were considered to illustrate the effect of this parameter on the reduction factor (and reliability) of steel-to-CFRP bonded joints as illustrated in Figure 1. Live load-to-dead load ratios up to 4 were considered to represent the reasonable range of values in typical structural applications. The resistance factor, \( \phi \), typical varies by about 0.2 at low live load-to-dead load ratios and typically converges for moderate to higher live-to-dead load ratios. Considering that the dead load of metallic structures typically represents a smaller portion of the total load, the asymptotic values at higher live load-to-dead load ratios may be more appropriate for typical designs, although the more conservative lower bound values should be used if the live load-to-dead load is low, or if it is unknown and could be low.

(h) MBrace Saturant with angle-grinding
Implications of constant resistance factor $\phi = 0.65$

In order to study the effects of a constant resistance factor on reliability indices, a resistance factor of 0.65, which is consistent with many brittle failure modes in North American codes and standards, was selected to compare the reliability indices for different design scenarios. Due to the significant impact of surface preparation techniques on the bond strength, the design scenarios were grouped by different surface preparation techniques, as shown in Figure 2. It was found that this resistance factor yields reliability indices above 3.0 for all design scenarios if sand-blasting is used, as shown in Figure 2(a). By a similar analysis if a target reliability of 3.5 needs to be strictly met for all design scenarios, one should use a resistance factor of 0.5. Angle-grinding yielded lower reliability indices except for Araldite 420 and Sikadur 30 adhesives, as shown in Figure 2(b).

![Figure 2: Reliability indices for different surface treatment techniques (a) sand-blasting and (b) angle-grinding](image)

**SUMMARY AND CONCLUSIONS**

This paper studied the reliability of adhesively bonded CFRP-to-steel DLS joints with thin outer adherends, for different design scenarios. The major findings of this paper are:

- The modeling uncertainty is highly influenced by the design scenario being considered and it is the most important random variable affecting the reliability index. This suggests that developing accurate and robust bond models can have a significant impact on the reliability of bonded joints in design applications and could dramatically influence the resistance factors that are used for bond.
- The adhesive shear strength and plastic shear strain have a greater influence on the bond reliability than the adhesive shear modulus. However, large adhesive ductility does not necessarily lead to high resistance factors due to the effect of surface preparation on the bond behavior.
- Surface preparation using sand-blasting gives consistently high resistance factors for the cases considered in this study, suggesting a lower degree of uncertainty. Angle-grinding led to inconsistent reliability for different cases.
- For Araldite 420, MBrace Saturant and Sikadur 30 using sand-blasting, a resistance factor of 0.65 gives reliability indices greater than 3.0 while a resistance factor of 0.5 gives reliability indices greater than 3.5.

ABSTRACT

In this paper, the fatigue durability of the adhesively bonded joints between steel plate and CFRP laminates were investigated experimentally aiming at the debonding in the end of CFRP laminates. Fatigue tests were conducted using the coupon specimens composed of the steel flat bar adhesively bonded by multi-layered CFRP laminates varying the stress range and the number of layers of CFRP laminates. The debonding lengths were measured utilizing the crack gauges attached at adhesively bonded joints. The result indicated that the fatigue life of adhesively bonded joints can be evaluated and its regression line equation can be proposed in the function of principle stress range independently to the number of layers of CFRP laminates.

KEYWORDS

CFRP laminates, adhesive joint, debonding propagation, fatigue durability.

INTRODUCTION

Recently, externally bonded patch plates, especially CFRP laminates, have proven to be effective for the application of repairing or strengthening the steel structures (JSCE 2012; JSCE 2013; Zhao 2013). However, there are problems remain for the design method of steel structure repairing or strengthening by CFRP laminates. One of the major points of concern in the use of this method is the adhesively debonding from the end of CFRP laminates which usually occurs ahead of the yielding of steel members or CFRP laminates (Lin et al. 2011; Nakamura et al. 2005). Moreover, although a number of studies have focused on bond behavior under static loading, there is a gap in understanding and lack of data under fatigue loading (Bocciarelli et al. 2009; Colombi et al. 2003; JSCE 2012; JSCE 2013; Lin et al. 2009; Liu et al. 2005).

The occurrence of the shear stress and normal stress simultaneously can be considered as the cause of the adhesively debonding from the end of CFRP laminates since there is a sudden change of cross-section at the end of CFRP laminates (JSCE 2013). Yet, there is no design recommendations related to this issue in Japan. In addition, to evaluate the fatigue durability of the repaired or strengthened steel structures by CFRP laminates, it is very essential and necessary to clarify the estimation method of the debonding propagation of the adhesive.

In this paper, toward the establishment of repair or strengthen method of steel structures by CFRP laminates, the fatigue strength and debonding progress of adhesively bonded joints under cyclic loading are experimentally evaluated.

EXPERIMENTAL PROCEDURES

Specimen Geometry and Materials

Figure 1 shows the shapes and dimensions of the steel plate and CFRP laminates adhesively bonded joint specimen. It consisted of a steel plate (500×50×9 mm) adhesively bonded by two CFRP laminates (300×50×1.2 mm per layer) at both sides of the steel plate. Here, the length of the CFRP laminates was set to 300 mm due to the limitation of the fatigue testing machine’s grip distance, and to make sure that there is no occurrence of the shear stress at steel plate’s center part. Two-pack type ambient-curable (cold hardening type) epoxy resin of Konishi E250 was used.
as adhesive. The thickness of the epoxy resin was controlled to approximately 0.4 mm. Table 1 presents the material properties of steel plate, epoxy resin and CFRP laminates. Here, the orthotropy was taken into account for the elastic modulus, Poisson’s ratio and modulus of rigidity values of CFRP laminates, (1: longitudinal direction, 2: width direction, 3: thickness direction).

**Design of Specimen**

As mentioned above, the debonding usually takes place and progresses from end of the adhesive and CFRP laminates due to the occurrence of high shear stress and normal stress. Therefore, in this study, the fatigue strength of the adhesive was evaluated utilizing the principle stress $\sigma_{ep}$, which is the combination of the shear stress $\tau_e$ and normal stress $\sigma_e$. The principle stress $\sigma_{ep}$ at the middle thickness of the adhesive can be calculated using the following equation (Eq. 1).

$$\sigma_{ep} = \frac{\sigma_e}{2} + \sqrt{\frac{\sigma_e^2}{2} + \tau_e^2}$$  \hspace{1cm} (1)

where $\sigma_e$ and $\tau_e$ are, respectively, the normal stress and shear stress of adhesive. In this paper, $\sigma_e$ and $\tau_e$ were analytical obtained using Finite Element Analysis program (MSc. Marc2013). The appropriate number of mesh refinement of the thin adhesive joint in order to obtain the accurate stress values were considered.

In order to investigate the debonding progress at the end of adhesive, it is necessary to decide the appropriate stress value occurs at the end of adhesive. Regarding to the results of static loading tests with the high-strength type of CFRP laminates as presented in Table 1, there are some cases which the debonding did not occur or progress although the steel have already reached the yield point (Tezuka et al. 2012). In this study, therefore, the number of layers of CFRP laminates were raised to make the incensement of principle stress at the end of adhesive. Thus, 3 cases, CFRP with 1 layer, 5 layers and 7 layers, were selected to evaluate in this experiment. The $\xi_s$ of specimens with 1 layer, 5 layers and 7 layers were, respectively, 0.83, 0.50 and 0.45, which were calculated using the following equation (Eq. 2).

$$\xi_s = \frac{E_{Is}}{E_{Is} + E_{It}}$$  \hspace{1cm} (2)

where the subscript $s$ and $c$ refer to steel plate and CFRP laminates, respectively, and $t$ is the thickness.

Table 2 shows the conditions of the fatigue test. Taking into account the capacity of the fatigue testing machine, 5 cases (100, 120, 140, 160, 180 MPa) of nominal stress range $\Delta \sigma_{sn}$ were chosen. The stress ratio $R$ is set to 0.1 in all cases. Thus, from all 3 cases of different number of layers of CFRP laminates combining together, the principle stress range $\Delta \sigma_{ep}$ is from 12.5–33.5 MPa.

#### Specimen Preparation

The CFRP laminates with 1, 5 and 7 layers were prepared in advance utilizing the same epoxy resin (E250). The average thickness of each adhesive layers of CFRP laminates is approximately 0.1 mm. Before bonding between steel plate and CFRP laminates, the surfaces of steel plate were blasted by alumina (#40), and the surfaces of CFRP laminates were sanded by sand papers (#150). The thickness of adhesive layer between steel plate and CFRP laminates were managed to 0.4 mm using the 0.4 mm glass beads (Jiang et al. 2006). After debonding, the specimens were cured at at 40 °C for 24 hours.

#### Test Setup and Experimental Conditions

The specimens were subjected to cyclic load with the frequency of $f=10–18$ Hz (high for the large stress range and low for the small stress range) as presented in Figure 2. The fatigue testing machine used in the experiment was electro-hydraulic servo type material strength testing machine (Shimadzu Servo Pulsar EHF-UB100kN). The friction welding high-strength bolt M16 was used for the grip section. The length of each grip sections was set to 70 mm. The lower part was fixed, and the upper part is allowed to act the tensile load. The waveform of the load was a sine wave, and the load, displacement and each strain values were measured at 5/10000 seconds interval using the dynamic strain-meter (Keyence NR-600). The series of tests were carried out at room temperature (approximately 15 °C).

To obtain the uniform of tensile stress, the strain gauge was applied at both sides of steel plate at the position of 15 mm from the grip section, and both sides of which crack gauge is applied. The setup position of the specimens were readjusted in case the variation of the strain value was large.

Furthermore, the below end of the CFRP laminates was fixed by fixture (Figure 2) in order to control and observe the debonding progress at the upper end of the CFRP laminates. Regarding to the existence of fixture, it should be noted that the influence of the presence or absence of fixture was already investigated.

![Fixture](image1.png) ![Overall view](image2.png) ![Crack gauge](image3.png)

---

Figure 2 Specimen setup
Debonding propagation measurement method

Crack gauges were determined to measure the debonding length in the experiments of this research. The crack gauges used were KV-25B manufactured by Kyowa Electronic Instruments that have the measurement capacity up to 25 mm with 1 mm intervals. The crack gauges were attached on both surfaces of the adhesive end part (upper). The debonding lengths were measured due to the cutting (disconnection) of the crack gauges’ grid lines at the same time along with the occurrence of the debonding of adhesive.

The crack gauge was attached at the position of 2 mm from the adhesive end in the direction toward the centre of the specimen. Therefore, the number of cycles at initial debonding refers to the number of cycles when the debonding tip reached the position of 2 mm from the adhesive end in all. This was applied to all cases of specimens. The debonding lengths were measured from 2 mm to 27 mm at 1 mm intervals. It should be noted that strain gauges (length of 3 mm) were also installed to the centre part of CFRP laminates at the position of 5 mm from the CFRP laminate end.

RESULTS AND DISCUSSIONS

Table 3 presents the result of each specimens, the number of cycles from the test start (debonding length of 0 mm) to the debonding length of 2 mm, from the debonding length of 2 mm to 27 mm, and from the start to the debonding length of 27 mm. As described above, the initial fatigue life was considered as the number of cycles from the test start until the debonding length reached 2 mm.

From the result in Table 3, in the case of specimen of CFRP laminates with 1 layer (CL1FT), with the nominal stress of range $\Delta\sigma_{\text{sn}}=180$ MPa, there was no sign of debonding progress from the adhesive end or changes of strain value until the number of cycles reached $10^7$ times. CL1FT180 can be considered as the fatigue limit. However, this matter will be discussed later by comparing to the other test results. For the series of CFRP laminates with 5 and 7 layers, the debonding propagation from the adhesive end can be confirmed in every specimens. It should also be noted that in each case of experiments, the strain values of steel plates did not reach the yielding point.

*CL5FT100 listed the number of cycles at 15 mm due to the completion of the test.

Figure 3 shows the results of initial fatigue life (the number of cycles require for the debonding progress from 0-2 mm) in the function of nominal stress range. The black line (A–H) are $S$–$N$ curves of the general steel welded joint designed in guidelines called “Fatigue Design Recommendations for Steel Structures” by Japanese Society of Steel Construction (JSSC 1993). The blue line is the regression line resulted from the experiments. Result shows that it cross the D–H grade of fatigue strength grades of JSSC guidelines. Moreover, it can be seen that the more the nominal stress range increases, the more the fatigue strength grade decrease. Regarding to the fatigue limit, CL1FT180 case is out of the evaluation when organizing in nominal stress range, and the variation can be identified in the figure.

Figure 4, Figure 5 and Figure 6 present the $S$–$N$ curve evaluated by shear stress range, normal stress range and nominal stress range, respectively. In Figure 4, the fatigue limit of CL1FT180 cannot fully explain, and in Figure 5, the fatigue limit of CL1FT180 are fairly low. In contrast, in Figure 6, both the fatigue limit and the fatigue strength can be evaluated regardless to the number of layers of CFRP laminates. This is due to the consideration of nominal stress range which is the combination of shear stress and normal stress. From the result of the fatigue life evaluated by nominal stress range, the fatigue limit is considered to be approximately 15 MPa instead of 12.5
MPa (CL1FT180’s result). This value is very close to the result recalculated from (Lin et al. 2009) as well, in which the value of fatigue limit is 15.1 MPa.

Eq. 3 below refers to the equations and the correlation coefficients of each regression lines indicated in Figure 6, Figure 7 and Figure 8. It should be noted that the equations and the correlation coefficients were not included the result of the fatigue limit of CFRP laminates with 1 layer.

\[
\Delta \sigma_{sn} = 405.99N^{-0.091}, \ R = 0.90
\]

\[
\Delta \tau_{e} = 39.42N^{-0.094}, \ R = 0.92
\]

\[
\Delta \sigma_{e} = 60.18N^{-0.099}, \ R = 0.93
\]

\[
\Delta \sigma_{ep} = 77.88N^{-0.096}, \ R = 0.93
\]

Figure 7 shows the S–N curve of the fatigue strength at the debonding length of 0–2 mm and 0–27 mm. From the figure, when the nominal stress range increase, the initial fatigue life tends to decrease. Figure 8 shows the S–N curve of the debonding propagation life of adhesive in the range of 25 mm (debonding length of 2–27 mm). Eq. 4 below refers to the proposed equations of the fatigue strength (0–2 mm and 0–27 mm) and the debonding propagation life (2–27 mm) along with their correlation coefficients of each regression lines indicated in Figure 7 and Figure 8.

\[
\Delta \sigma_{ep, \ 0–2 \ mm} = 77.88N^{-0.096}, \ R = 0.93
\]

\[
\Delta \sigma_{ep, \ 0–27 \ mm} = 158.29N^{-0.146}, \ R = 0.93
\]

\[
\Delta \sigma_{ep, \ 2–27 \ mm} = 171.37N^{-0.100}, \ R = 0.83
\]
CONCLUSIONS

To sum up, the experimental results lead us to the following conclusions.

1. The fatigue life of adhesively bonded joints can be evaluated and its regression line equations can be proposed in the function of principle stress range independently to the thickness (number of layers) of the CFRP laminates.

2. The fatigue limit adhesively bonded joint is considered to be approximately at the principle stress range \( \Delta \sigma_{ep} = 15 \) MPa.

3. When the nominal stress is increased, the initial fatigue life tends to decrease.

ABSTRACT

In this article, the effects of electrochemical oxidation and sizing treatment of PAN-based carbon fibers (CFs) on the tensile properties, surface characteristics and bonding to epoxy resin were investigated. Electrochemical oxidation treatment of the carbon fibers was shown to improve the tensile strength by 9.8%, which is ascribed to the removed surface defects and impurities of the carbon fibers. Further sizing treatment exhibited a negligible effect on the tensile strength. Both oxidation and sizing treatments significantly improved the wettability and surface energies of the CFs by introducing oxygen-containing functional groups on the surface of the CFs. Microbond pull-out test was conducted to characterize the interfacial shear strength (IFSS) between a single carbon fiber and an epoxy droplet. As found, the oxidation treatment slightly increased IFSS from 71.24 MPa to 73.62 MPa. This is due to the formation of chemical bonds between resin matrix and carbon fibers, and the decrease of the mechanical interlocking. Further sizing treatment can significantly enhance the IFSS to 81.03 MPa due to the formation of vast chemical bonds. The effect of fiber treatment on the hydrothermal aging behavior of the bond between single carbon fibers and epoxy droplets was studied. It was found that the hydrothermal aging dramatically deteriorate IFSS of untreated fibers to resin matrix. However, the oxidation and sizing treatment can effectively improve the retention rate of IFSS.

INTRODUCTION

Carbon fiber reinforced polymer (CFRP) composites are increasingly used in civil engineering because of their high specific strength/modulus and corrosion resistance. Durability of CFRP composites is one of the serious concerns when considering the long service lives of the civil engineering structures (generally more than 50 years). It is well known that the mechanical properties of CFRP composites are fundamentally determined by the tensile strength of the carbon fibers (CFs) and resin matrix as well as the interfacial bonding strength (Drzal and Madhukar 1993). Good interfacial adhesion allows more effective stress transferring from resin matrices to reinforcements, enhancing the ultimate strength. However, if the carbon fibers do not undergo any surface treatments after carbonization, the surfaces of CFs exhibit inertness (Zhang, Liu et al. 2013) in bonding and wetting to resin matrices. Furthermore, the interface between CFs with resin matrix, generally considered as the weakest region (Xu, Huang et al. 2007), tends to be damaged by the moisture or water ingress. Recent studies (Hong 2012, Li 2012) revealed that the epoxy resins showed insignificant degradation subjected to water immersion for a long time. However, remarkable deterioration of CFRP was observed, which is expected to be mainly coming from the damage of the interface.

In the present study, the effects of the electrochemical oxidation treatment and sizing treatment on the mechanical properties of single CFs and IFSS between fiber and epoxy resin were investigated. The study aimed to bring in an understanding of the effects of oxidation and sizing treatment on the mechanical properties of CFs, as well as the durability of the carbon fiber-resin bonding.

EXPERIMENTATION

Raw Materials
PAN-based CFs (800 tex) with diameter of 7 µm were investigated. The resin matrix used in this study was a commercial epoxy with a brand name of E51 (Xing-Chen Chemicals Co. Ltd., Wuxi, China), similar to EPON...
The curing agent was methyl tetrahydrophthalic anhydride (MeTHPA from Qing-yang Chemistry Co. Ltd., Jiaxing, China). The accelerator was a tertiary amine, tris (dimethylaminomethyl) phenol (DMP-30, from Shan-feng Chemical Industry Co. Ltd., Changzhou, China). Resin was mixed with the curing agent and accelerator at 100:80:2 by weight. Curing conditions were 3 h at 120°C, followed by 3 h at 150°C.

Characterization

The morphologies of untreated, oxidized and sized CFs were characterized with a Quanta 200F scanning electron microscope (SEM, USA). The chemical elements of the CF surfaces were detected using a Thermo Fisher Scientific K-Alpha X-ray photoelectric spectroscopy (XPS, USA) with an Al Kα X-ray (1486.6 eV) source.

Single carbon fiber tensile tests were carried out at ambient temperature with a crosshead speed of 0.00125 mm/s, according to ASTM D3379-75 using a JQ03A single fiber tensile tester (Zhongchen Digital Technic Apparatus Co. Ltd., Shanghai, China). The test gauge length was set as 20 mm. The diameters of each specimen were measured through an optic microscope before the test. At least 100 measurements were repeated for each type of CF. Tensile strength was analyzed with the two-parameter Weibull model.

The interfacial shear strength (IFSS) of CFs/epoxy composites was measured by the microbond pull-out test (Cui and Kessler 2012) with the equipment (FA-620, East Wing Industrial Co. Ltd., Japan) at a crosshead speed of 0.06 mm/min. The droplets of approximately 30–60 µm in diameter were selected to be tested. At least 50 measurements were conducted for each specimen.

For hygrothermal aging, three kinds of microbond samples were exposed to 95% RH chamber at 40°C. IFSS was measured periodically.

RESULTS

Tensile Properties of Single Carbon Fiber

As shown in Table 1, the tensile strength of the CFs is enhanced through electronic oxidation and sizing treatment. The shape parameter (m) and the scale parameter (σL) represent the variation degree and level of the tensile strength of CFs respectively. The higher the m value, the more stable the strength of the CF; the higher the σL value, the higher the strength of the CF. CFs treated by oxidation shows an increase in the shape parameter m from 5.85 to 7.47 and the scale parameter σL from 3.50 to 4.01. Meanwhile, further treatment of sizing leads to the increase of m to 7.90 and σL keeps almost constant. This means that oxidation brings in enhancement of the tensile strength and reduces the variance of the tensile strength of CFs. Furthermore, sizing treatment reduces the discreteness of the tensile strength, whereas the tensile strength is not enhanced anymore. After oxidation, both the tensile strength and the elongation at break are enhanced, while the modulus is unchanged. By further sizing treatment, only the tensile strength is enhanced. The diameter of the CFs is found to be reduced due to the electronic oxidation treatment, while the sizing treatment slightly increases the diameter. Similar results were found in (Liu, Tian et al. 2010).

![Figure 1 SEM photographs of CFs with various treatments. a) untreated fiber, b) oxidized fiber, and c) oxidized and sized fiber.](image_url)

The effect of the treatment on the surface morphology of CFs was analyzed with SEM. As shown in Figure 1a, SEM photograph of an untreated CF is rough and filled with grooves uniformly. There are some impurities and defects on the surface of the CF (Figure 1a). Oxidation seems to reduce the roughness (Figure 1b), and the grooves of the CFs become narrow and shallow. The impurities and defects on the surface of CFs are lessen and even
disappeared. This can be attributed to the fact that the oxidation reaction generally starts from the sharp edges of CFs and leads to the gentle and mild grooves and edges of CFs surfaces. Through oxidation, the micro-cracks of the surface of CFs are decreased and the stress concentration of the fiber is weakened (Liu, Tian et al. 2010). This can explain why the tensile strength was enhanced by electrochemical oxidation (see Table 1). The decrease in the modulus of CFs through electrochemical oxidation, as shown in Table 1, is due to the fact that the outside ordered sheath of the fiber is corroded by the electrolytic solution.

Further sizing produces flat and smooth CFs surface (Figure 1c). It is believed that the grooves on the CF surface are filled with the sizing agent. As believed, the sizing agent cannot change the surface structure of CFs (the ordered outside sheath), and thus it will not vary the mechanical properties of CFs as indicated in Table 1.

Interfacial shear strength between single fiber and epoxy droplet

Figure 2 shows the IFSS between three kinds of CFs and epoxy resin. Compared to the untreated fibers, oxidation of CF increases the IFSS from 71.24 MPa to 73.62 MPa. Further sizing treatment brings in a remarkable increase in IFSS to 81.03MPa. Clearly, the combination of the electrochemical oxidation and sizing significantly improves the interfacial bonding of the CF to epoxy resin, while only electrochemical oxidation does not.

The improvement in the bonding strength for the oxidized and sized CFs to epoxy resin is due to the increased active functional groups on the surface of the CFs. This can be verified by the presented chemical groups on the fiber surface detected by XPS. Compared with C-C functional groups, the C-O-C/C-OH functional groups tend to form stable bonds with the epoxy resin. Yuan et al. (Yuan, Zhang et al. 2013) indicated that the increased wettability and possibility of forming chemical bonding could account for the enhanced interfacial shear strength between the sized CF and epoxy resin. The increased surface energy of the sized CFs makes the fibers to be easily wetted by the resin solution, which increases the possibility of the molecular contact between the epoxy and the sized CFs. This has been proved by the contact angles between epoxy droplets and CFs, and surface energies of the CFs (Table 2). The interface region is formed by the penetration and curing of the sizing resin system with the surrounding resin matrix. In addition, the sizing agent is mainly composed of epoxy resin. According to the “similar dissolve mutually theory”, the chemical reactions between carbon surface, sizing agent, and E-51 resin easily occur (Viswanathan, Wang et al. 2001, Liu, Ge et al. 2012). The COOH functional groups existing on the CF surface may react with C-OH of the sizing agent and creates a strong bond. Thus, the good adhesion is obtained between the matrix and the sized CFs.

Figure 2 IFSS between E51-MeTHPA resin and CFs.
The results of XPS for different CFs are listed in Table 2. For untreated fibers, the carbon concentration on the surface is only 82.40% while the oxygen concentration is as high as 16.16%. Through electrochemical oxidation and sizing treatment, the oxygen concentration initially decreases from 16.16% to 13.36%, and then increases to 17.04%. This anomalous result of oxygen concentration through electrochemical oxidation is greatly different from literature (Cao, Huang et al. 2005, Liu, Tian et al. 2010). As believed, this may be because the untreated CFs obtained from the export of the high temperature charcoal stove carry much detached oxygen concentration from air. Through electrochemical oxidation, the detached oxygen concentration is firstly removed by the ammonium bicarbonate solution and then the carbon concentrated on the surface of fibers is oxy-generated to oxygen function groups. This assumption is validated by the subsequent analysis of functional groups on the CF surfaces. After electrochemical oxidation, the nitrogen concentration increases significantly from 1.43% to 2.21%, in agreement with a previous study (Cao, Huang et al. 2005). This indicates that the nitrogenous functional groups were created on the fiber surface by the reaction with ammonia ions in the electrolyte. Compared with the untreated CFs, oxidized fibers show a slight increase in the concentration of C-OH/C-O-C from 11.0% to 14.8%, the concentration of C=O from 5.4% to 8.3% and the concentration of COOH from 3.3% to 4.9%. The increase of oxygen-containing functional groups on the surfaces may be due to the fact that a certain number of C=O functional groups on the CF surface is reacted with the oxygen into C-OH/C-O-C, and then further oxidized into C=O and COOH during the electrochemical oxidation process. After sizing treatment, the concentration of C-OH/C-O-C increases dramatically from 14.8% to 40.7%, while the C=O and COOH functional groups disappear. The change is owing to the fact that the main component of the sizing agent, mainly composed of epoxy resin, contains a large amount of C=O active functional groups. The introduction of the active functional groups significantly improves the surface activity, polarity, and hydrophilicity of the CFs, resulting in improved wettability of CFs. At the same time, the increase of C-OH/C=O-C, C=O and COOH functional groups, which contain activated carbon atoms, can form stable chemical covalent bonds with the C-O-C functional groups in epoxy resin. This is believed to enhance the IFSS of CFs effectively.

For electrochemical oxidized carbon fibers, IFSS due to mechanical interlocking is decreased, while the portion of IFSS due to chemical bonds is increased (Table 2). Consequently, IFSS between oxidized CFs and epoxy is not enhanced remarkably (Figure 2). The CFs treated by oxidation and sizing possess a lot of C-O-C/C-OH active functional groups (Table 2). As a result, the chemical bonds are remarkably increased, leading to a significant increase in IFSS.

Figure 3 The effect of the aging on IFSS between E51-MeTHPA resin and CFs.
Furthermore, IFSS after hydrothermal aging was also investigated for three kinds of CFs based on microbond pull-out test, as shown in Figure 3. The decreases in IFSS are from 71.24 MPa to 42.29 MPa for untreated fiber, from 73.62 to 50.32 MPa for oxidized fiber, and from 81.03 MPa to 56.43 MPa for sized fiber, respectively. The retained percentages of the IFSS are 59.4%, 68.4% and 69.6% for the untreated, oxidized, and sized, respectively when the samples are aged for 24 days. Clearly, the bonding between the carbon fibers and epoxy resin are very susceptible to the hydrothermal exposure. The oxidation and sizing treatments enhance the resistance to the hygrothermal aging, but to a limited extent, especially for a long period.

CONCLUSIONS

Effects of electrochemical oxidation and sizing treatments on the tensile properties, wettability and interfacial shear strength to epoxy resin of PAN-based CFs was investigated in the present study. The following conclusions were drawn based on the testing results.

Electrochemical oxidation treatment can improve the tensile strength of CFs by 9.8% through reducing the roughness and removing the surface defect and impurity. Further surface sizing treatment only smooth the surface of CFs through filling the grooves and has a negligible effect on the tensile strength.

Combining electrochemical oxidation with surface sizing treatments can tremendously improve IFSS of CF/EP and the resistance to hydrothermal aging of the interfacial bonding. This is attributed to the formation of effective bonding to epoxy resin, due to the oxygen-containing functional groups on the carbon fibers introduced by the treatments.

ABSTRACT

The use of basalt fiber–reinforced polymer (BFRP) bars as a reinforcing material for concrete structures has gained increasing interest worldwide. Limited studies have been reported on the performance of BFRP bars in concrete when exposed to harsh environments. This paper presents the test results of an experimental study aimed at investigating the bond strength durability of BFRP bars embedded in concrete when exposed to accelerated environmental effects. The experimental program included testing and investigating BFRP deformed bars with 12-mm diameter. Pullout specimens were tested under direct tensile load after being exposed to an alkaline solution (pH=12.9) for up to 6 months at elevated temperatures of 40°C. Effects of alkali environment and exposure periods on the bond strength, degradation mechanism, and mode of failure of reinforced specimens with BFRP were investigated. The test results revealed that the average bond strength of conditioned specimens after 1.5, 3, and 6 months of exposure at 40°C were 14.8, 13.3, and 12.5 MPa, while the bond strength of unconditioned specimens was 15.5 MPa. Accelerated alkaline environments had a harmful effect on bond strength of conditioned specimens over time. After 6 months of exposure, the bond strength retention was 81% compared to that of the unconditioned specimens.

INTRODUCTION

The use of basalt fiber–reinforced polymer (BFRP) bars in construction applications is relatively new. This type of structural material is expected to provide a performance comparable or superior to that of glass-fiber–reinforced polymers (GFRP), while being significantly cost-effective [Wang et al. (2012); ElSafty et al. (2014)]. Numerous research efforts have been conducted on the bond durability of GFRP and carbon (FRP) bars in concrete [Bakis et al (2007); Davalos et al. (2008); Robert and Benmokrane (2010)]. However, very limited studies have investigated the bond durability of BFRP bars embedded in concrete when subjected to harsh environment conditions. Before the use of BFRP as reinforcement for concrete structures and inclusion in FRP standards and guides, more experimental investigations on BFRP bars are needed including mechanical properties, structural and mechanical behaviors, durability, and bond strength to concrete. It is worth mentioning that BFRP bars have not yet been incorporated into design standards and specifications. Therefore, the current paper aims at narrowing the gap in our knowledge on BFRP performance. The work presented herein is a part of a large research study on the use of BFRP bars as reinforcement. This study provides an insight into the bond of BFRP bars with concrete after long-term environmental conditioning. The findings of this work contribute to integrating BFRP bars into FRP standards and guides, such as [ACI 440.6M (2008), CSA S807 (2015), and CSA S806 (2012)].

EXPERIMENTAL WORK

Material Properties

This study investigates a 12-mm-diameter BFRP bar (nominal cross-sectional area of 125 mm²) with a deformed surface. Figure 1 shows the surface configuration of the investigated BFRP bar. The BFRP bar was made of continuous longitudinal basalt fibers bound together with vinylester resin using a pultrusion process. The basalt
fibers were produced from volcanic material with organic surface coating (ASA.TEC, Austria). Table 1 summarizes the physical and mechanical properties of the investigated BFRP bar. As seen in Table 1 the preliminary tests showed that the newly developed 12-mm BFRP bar satisfied the minimum requirements of ACI 440.6M (2008) and CSA S807 (2015) concerning their physical and mechanical properties for use as non-prestressed reinforcement for concrete structures. Different laboratory tests on the investigated bar can be found in Hassan and Benmokrane (2015). All pullout specimens were cast using a ready-mixed, normal-weight concrete with a 28-day target concrete compressive strength of 30 MPa. The concrete mixture consisted of 350 kg of Type 10 cement (corresponding to ASTM I cement), 813 kg of fine aggregate, 1032 kg of coarse aggregate, and 154 kg of water per cubic meter of concrete. The concrete compressive strength ($f'_c$), determined by testing six 100×200 mm concrete cylinders, ranged from 31 to 34 MPa. After one week of curing, all specimens and cylinders were left outside the laboratory for 4 weeks before being conditioned.

**Test Specimens and Procedures**

The pullout specimens were comprised of a 1200-mm long BFRP bar embedded centrally inside a concrete prism dimensions (200 × 200 × 200 mm). The embedded length was kept constant at 5$d_b$, where $d_b$ is the nominal diameter of BFRP bar. Plastic tubes were used at the loading end of the bar to minimize the stress concentration near the loading plate. Steel pipes were used as anchors and were cast with cement grout before testing. Figure 2 depicts typical specimen details. A total of 20 specimens were tested under direct pullout tests. Fifteen specimens were fully immersed in an alkaline solution at elevated temperatures of 40ºC for 1.5, 3.0, and 6 months while five unconditioned specimens were tested at room temperature for comparisons. All specimens were tested under pullout testing according to ACI 440.3R (2004) test method B.3. The tests were carried out using a Baldwin testing machine at displacement control mode with a maximum rate of 20 kN/min. The slip at the free-end of the BFRP bar was measured using a linear variable displacement transducer (LVDT). Figure 2 shows the test setup and instrumentation of the test specimens. The applied load and bar slippage were recorded automatically throughout the test with a data-acquisition system. The maximum bond stress at the peak load, $\tau_{max}$, was calculated assuming a uniform bond stress distribution along the embedded length of the bar in concrete, $l_d$, using Eqn. (1).

$$\tau_{max} = \frac{P_{max}}{\pi d_b l_d}$$

where $\tau_{max}$ is the maximum bond stress (MPa), $P_{max}$ is the peak load during pullout (kN), $d_b$ is bar nominal diameter (12 mm), and $l_d$ is embedded length in the concrete (=60 mm).

**Environmental Conditioning**

The pullout blocks were fully immersed in alkaline solution inside big steel tanks while the free length of BFRP bars remained freely unconditioned inside the environmental chambers. The alkaline solution compositions consisted of 118.5 g Ca (OH)$_2$ (calcium hydroxide), 4.2 g KOH (potassium hydroxide) and 0.9 g NaOH (sodium...
hydroxide) in 1 L of deionized water according to ACI 440.3R (2004). The alkaline solution pH value was 12.9. The pullout specimens were separated from each other and from the bottom of tank to allow the solution to circulate freely between and around the blocks. The top of the steel tank was hermetically sealed with a polyethylene film to prevent excessive evaporation of water during the conditioning. In addition, the water level was kept constant throughout the study to avoid the pH from increasing as a result of the water evaporation. In order to accelerate the BFRP bar-concrete bond degradation, the test specimens were placed at elevated temperatures of 40°C for exposure periods of up to 6 months. Figure 3 shows the test specimens inside the conditioning tank in the environmental chambers.

**TEST RESULTS AND DISCUSSION**

**Mode of Failure**

All conditioned BFRP-reinforced specimens failed in a typical pullout mode of failure by exhibiting slip through the free end with no signs of splitting cracks appeared in the cube specimen. Similar behavior was observed for both unconditioned and conditioned tested specimens. Figure 4 shows typical mode of failure of the tested specimens. Some prisms were split after testing for a closer inspection of the concrete surface at the location of embedded length. The visual examination at the location of embedded length showed some tiny chopped basalt fiber from the coating surface of the bar attached to the concrete surface. On the other hand, examination of BFRP bar surface showed residues of concrete between the deformations, after pullout, and minor scratches at some rib
locations (Fig. 4). The final mode of failure of the tested specimens was dominated by shearing of the concrete located at the BFRP bar-concrete interface. However, an abrasive type fracture in either the concrete or the composite bar itself could be involved.

Note: In all cases, the mode of failure was pullout; $\tau_{\text{max}}$ = maximum bond stress at the peak load (MPa).

**Bond strength and Stress-Slip Responses**

Figure 5 shows the bond stress and free-end slip relationships for all tested specimens. The free-end slip was recorded directly from the LVDT at the unloaded end. The bond stress vs. free-end slip curves showed similar trends for the unconditioned and conditioned pullout specimens; however, the bond strengths after environmental conditioning were different. The free-end slip remained zero until the bond stress reached high levels, compared with the ultimate bond stress. Thereafter, a pre-peak response was observed up to their peak bond stress then followed by a post-peak response up to 87% (on average) of their peak stress. Finally, a sudden loss of bond strength accompanied with a sudden free-slip was observed. The average bond strength (based on an average of five test results) was calculated as the pullout force over the embedded area of the bar (Eqn.1). The peak bond load and corresponding maximum bond stress of all unconditioned and conditioned specimens are reported in Table 2. As shown in Table 2, the average bond strengths of the conditioned specimens after 1.5, 3, and 6 months of alkaline environmental exposure at 40 °C were 14.8, 13.3, and 12.5 MPa, respectively, while the bond strength of unconditioned specimens was 15.5 MPa. This indicates that the bond strength of the BFRP bar-concrete interface decreased as exposure time increased. The bond strength retention after 6 months of exposure was 81%. It should be noted that the bond strength after 6 months of exposure at 40 °C was 12.5 MPa, which is higher than the specified limits for bond strength in ACI 440.6M (2008) (> 9.6 MPa) and CSA S807 (2010) (> 8 MPa).
Effect of Exposure Period on Bond Degradation

Figure 6 shows the effect of exposure period on the bond strength and strength retentions of the BFRP bars at 40°C. As seen, the bond strength trend decreased as the time of immersion increased. The suggested bond deterioration mechanism of tested specimens is described. After the environmental conditioning, gaps along the interface between the bar and concrete could be created due to the variation in coefficient of thermal expansion (CTE) of both materials which imposes radial bursting force on the concrete surface at the interface. When the developed stress in concrete is larger than its tensile strength, cracks will develop. Thus, FRP bar and concrete will not be in contact as tightly as before and thus the bond strength is decreased [Belarbi and Wang (2012)]. Furthermore, when immersed in alkaline solution, chemical ions filled these voids, which facilitate the attack of FRP bar’s polymeric matrix, especially in the outer surface and results in degradation of reinforcement itself and may contribute to the bond strength degradation [Abbasi and Hogg (2005), Chen et al. (2007), Belarbi and Wang (2012) and El Refai el al. (2014)].

CONCLUSIONS

The main objective of this study is to investigate the bond durability of BFRP bars embedded in concrete when exposed to harsh environments. A bond durability investigation was performed on BFRP-reinforced pullout specimens that were fully immersed in an alkaline solution and subjected to elevated temperatures. Based on the test results and discussions, the following conclusions can be drawn:
1. All BFRP-reinforced specimens failed in a typical pullout mode failure by exhibiting slip through the free-end. The final mode of failure was dominated by shearing of the concrete located at the BFRP bar-concrete interface.

2. The average bond strength of conditioned specimens after 1.5, 3, and 6 months of exposure at 40 °C were 14.8, 13.3, and 12.5 MPa while the bond strength of unconditioned specimens was 15.5 MPa. The bond strength results after 6 months of exposure fulfilled the minimum requirements of the bond strength for use as non-prestressed reinforcements for concrete structures according to the ACI and CSA specifications.

3. Accelerated alkaline environments had a detrimental effect on bond strength of conditioned specimens’ over time during its immersion. After 6 months of exposure, the loss in the bond strength was 19% in comparison to their counterpart unconditioned specimens.

ABSTRACT

FRP (fiber reinforced polymer) has taken advantages of the fiber reinforcement and resin matrix, possessing excellent mechanical properties and corrosive resistances, even in harsh environments. The lack of the knowledge of the durability performances of FRPs in various environmental conditions and the related degradation mechanisms of FRPs leads to significantly conservative design. Water ingress plays a critical effect on the durability of FRP, due to susceptibility of the bond between the fibers and resin matrices. In the present paper, molecular dynamics technique was used to model the moisture effect on the fiber-resin bond. The bonding performances of the epoxy on carbon fibers under dry and wet conditions were simulated. Free energy profiles were calculated to quantify interfacial adhesion. As shown from the decline of binding free energy, the water ingress led to remarkable deterioration of the fiber bonding to the resin matrix. The study is expected to be helpful for both the development of durable FRPs, and to predict the service life of a FRP subjected to hydrothermal aging accurately.

KEYWORDS

FRP, interface, water, molecular dynamics.

INTRODUCTION

FRP (fiber reinforced polymer) has been widely applied in many areas due to its lots of advantages, e.g., high specific strength/modulus, easily production, etc (Karabinis and Rousakis 2002, Nystrom, Watkins et al. 2003, Sen 2003). The service environments of FRPs such like marine may lead to deterioration of FRPs. Moreover, some application of FRP requires the material to serve for over 50 years (for example, submarines and bridges). The long-term durability of FRP is always a concern due to their broad applications. Indeed, design with respect to long-term durability has been largely based on experience(Davies and Rajapakse 2014), and safety factors are often too conservative compared to the field data. This is related to the lack of the knowledge of the durability performances in various environmental conditions, and the related degradation mechanisms. The interfaces between fibres and resin matrix were found to play a critical effect on the durability of FRP, especially in case of water ingress(Davies and Rajapakse 2014, Wang, Huang et al. 2015).

There are many experimental techniques to test the bond strength between the carbon fiber(CF)/epoxy interface, such as the fiber pull-out and the fiber push-out test. Those technologies are widely applied. However, CF/epoxy interface is intrinsically inhomogeneous and anisotropic. In addition, the bonding structure is asymmetry and the entropic constraints are provided at a phase boundary(Mansfield and Theodorou 1991). These three factors lead to the complex of the fiber-resin interface, thus make it hard to establish clear physically based models for the coupling between water ingress and mechanical behaviour concerning long-term performance(Davies and Rajapakse 2014).

Molecular simulation approaches can complement experiments by providing a detailed study of the interaction in composites(Rissanou and Harmandaris 2014). Three hundred years ago, molecular dynamics are used to study the property of interface(Dholakia, Chandra et al. 1731). Numerous molecular simulations have been reported to studied the various property of interfacial ever since, e.g., tensile strength, surface free energy, adhesive tension, etc(Dholakia, Chandra et al. 1731, Broughton and Gilmer 1983, Mansfield and Theodorou 1991, van Buuren, Marrink et al. 1993, Pasquarello, Hybertsen et al. 1998, Bizzarri and Cannistraro 2002, Kuo and Mundy 2004, Nagayama and Cheng 2004, Rissanou and Harmandaris 2014). For example, the interfaces of epoxy/concrete and
epoxy/wood have been studied using molecular simulation method in the past decade. The adhesion was estimated by pulling the epoxy molecules off the surface of silica and cellulose under dry and moisture condition. Take XG/clay for another example, the adhesion was calculated by pulling the polymer off the clay surface (Wang, Wohlert et al. 2014). The surface energy was calculated and it is proven water effectively deteriorate the interface adhesion in those interfaces. However, molecular simulations of FRP mainly focus on the properties of carbon fibers and epoxy separately, or on the interfacial adhesion between FRP and other material. Few studies have focused on the molecular simulation of CF/epoxy interfacial adhesion in FRP.

Understanding CF/epoxy interfacial behaviour at molecular level is important to judiciously select and efficiently design FRP. Molecular dynamics (MD) simulation are helpful as could provide insights into the fiber-resin bonding mechanisms, and reveals the effect of water ingress on the bonding (Haile 1992).

In the present paper, an attempt was performed to investigate the moisture effect on the fiber-polymer bonds in FRP with experimental technique and molecular dynamics technique. The FRP with carbon fiber and epoxy resin was selected which is used extensively in civil engineering, e.g., structural rehabilitation. In the current work, there is an multi-scale analysis of the water ingress effects on FRP interfacial bonding propriety.

A microbonding pull-out test (Miller, Muri et al. 1987) was performed to test the interfacial shear strength (IFSS) of the epoxy resin (DGEBA, MeHHPA and DMP30 system) to a single fiber. A short overview of the simulations and the model systems is suggested in Section 3. The adhesion between E51 epoxy and carbon fiber in our simplified model was simulated using Molecular Dynamics (MD) methods. Section 4 compares the experimental and simulated results.

**EXPERIMENTAL**

The interfacial shear strength (IFSS) of a single carbon fiber to an E51 epoxy resin was measured by the microbonding pull-out test (Qian Zhen Ming Ming 1996) with the equipment (FA-620, East Wing Industrial Co., Ltd., Japan) at a crosshead speed of 0.06 mm/min.

The resin droplets of approximately 15 µm to 20 µm in diameter were selected to test. The epoxy resin was DGEBA mixed with MHHPA and DMP30 at ratio of 100:80:2 by weight. TC36S carbon fiber (made by TaiLi Industrial Co., Ltd., Taiwan, China) in the test (Wang, Huang et al. 2015). The droplets of E51 epoxy on the fibers were cured at 120 °C for 1 hour and 150 °C for 1 hour in a hot oven.

Fifty E51/TC36S carbon fiber samples were made to study the water coupling between water ingress and mechanical behaviour concerning long-term performance in FRP. They were respectively treated 7 days, 30 days, 60 days, 90 days immersed in water, ten for each.

**SIMULATION WITH MOLECULAR DYNAMICS**

Material Studio software was used to build a carbon fiber-epoxy resin interface model. The forcefield used here is Consistant Valence Forcefield (CVFF)(Dauber - Osguthorpe, Roberts et al. 1988). The applicability of CVFF in the investigation of FRP mechanical property has been validated in many other studies (Zhou, Tam et al. 2015). The interface model consist of a simplified E51 epoxy model and a simplified carbon fiber model.
**E51 EPoxy Model**

In the epoxy model, Diglycidyl Ether of Bisphenol A (DGEBA), hexahydro-4-methylphthalic anhydride (MeHHPA) was used as the base composition. The curing agents were 2,4,6-tris-(dimethylaminomethyl) phenol (DMP-30). Figure 2 depicts the chemical reaction of the resin system.

![Chemical Reaction](image)

**Figure 2** Curing reaction of the resin system.

As shown in Figure 2, each DGEBA can is connected to another molecule through its opposite epoxide head. Figure 3(a) shows the polymer structure of DGEBA/MeHHPA cross-linkage. There are three main steps in our cross linking process, as follow:

**Construction and Pre-equilibration**

One amorphous DGEBA/MeHHPA cell with an initial density of 1.2g/cm³ was created under periodic boundary conditions at room temperature. The cell is composed of 16 DGEBA and 36 MeHHPA. Then the system was exposed to 1000 steps minimization to reach the minimum energy. Next the amorphous cells is equilibrated for 10 ps in the canonical ensemble (NVT) dynamics at 298K, with the integration time step of 1 fs. Another isothermal-isochoric ensemble (NPT) dynamics at 298 K and 1 atm last for 10ps were performed on the amorphous cells to reach an equilibrium.

![Atomic Model](image)

**Figure 3** Atomic model

(a) E51 epoxy  (b) Carbon fiber

(c) the CF/epoxy interfacial model in dry condition  (c) the CF/epoxy interfacial model in water ingress condition
**Creation of covalent bonds**

Once does each structure reach an equilibrium condition, the distances between pairs of reactive atoms are measured. Covalent bonds will be formed between suitable atoms (those within cross linking cut-off distance, here 4Å-10Å were chosen). In order to relieve the stress forced in the system, a smart minimization task with 1000 iterations was performed. After that, the system was exposed to 10 ps high temperature canonical (NVT) dynamics at the temperature of 500K with each step of 1fs. This process gives enough kinetic energy to the molecules and enhances the possibility of reacting sites to be posed in the reaction cut-off distance. This cross-linking process has been repeated several times until no reactive atoms are identified.

**Post-equilibration**

After the cross-linking process is completed, the cell is treated with a relaxation process by exposed to 10 ps temperature canonical (NVT) dynamics at the temperature of 500K, 430K, 360K and 298K. Here an epoxy model with 83.56% cross-link containing 1573 atoms in the box with the dimension of 27×27×27 Å³ (see Figure 3.a) were obtained.

**INTERFACIAL MODEL**

Carbon fiber cell was simplified to be several paralleled graphene sheets with the initial density of 1.76g/cm³ at the dimensions of 89×90×15 Å³ (see Figure 3.b). To start the simulations, the epoxy was placed paralleled to the carbon fiber surface (see in Figure 3). The epoxy and carbon fiber were put in a periodical orthorhombic box with the same lateral dimensions as the fiber sheet, making the sheet effectively infinite in size. Then the simulation configurations were relaxed by sequentially performing 100ps canonical (NVT) at 298K, 100ps isothermal-isochoric ensemble (NPT) dynamics at 298 K and 1atm, 100ps canonical (NVT) at 298K. After the process, the E51 epoxy molecules were spontaneously adsorbed to the carbon fiber surface (see in Figure 4(a)). This molecular dynamics simulation was performed using LAMMPS simulation package, with a basic time step of 1fs, and with forcefield CVFF.

To assess the molecular adhesion of the epoxy to carbon fiber, the potential of mean force (PMF) pertaining to the desorption process was calculated by Metadynamics (Laio and Gervasio 2008) using PLUMED plug-in package (Bonomi, Branduardi et al. 2009). In the metadynamics simulation, a Gaussian hill energy was added to the system every 100 steps, with a basic time-step of 1fs, with the height of 0.05KJ/mol, and the width of 0.35.

For a compound material, interfacial adhesion in the presence of water is critical. Thereafter, water molecules were put into this interfacial system to study the water effects on the interface bonding (see in Figure 4(b)). Water molecules were represented using the simple point charge (SPC) model of Berendsen (Berendsen, Postma et al. 1981). The simulation configurations were relaxed by sequentially performing 100ps canonical (NVT) at 298K, 100ps isothermal-isochoric ensemble (NPT) dynamics at 298 K and 1atm, 100ps canonical (NVT) at 298K. After the process, the E51 epoxy molecules still adsorbed to the carbon fiber surface (see in Figure 4(b)). Next, the same rule of Metadynamics simulation was performed on this interfacial system.

![Figure 4: The interface model](image-url)
RESULTS AND DISCUSSIONS

The results of the experiment and simulation are presented in this section, mainly focus on the effect of water in the bonding performance of FRP material.

Interfacial shear strength of E51 epoxy/ carbon fiber

Figure 5 presents the experimental results of the interfacial shear strength (IFSS) between the single carbon fiber and epoxy droplet with the microbonding pull-out method. These E51 epoxy/carbon fiber samples were immersed in water for 0, 7, 30, 60 and 90 days, respectively. As shown, a remarkably decrease in the interfacial shear strength of E51 epoxy/carbon fiber under moisture condition can be found. The IFSS of the E51 epoxy/ carbon fiber sample under dry condition is 139Mpa, which is 1.98 times of the sample under the condition of 90 days immersed in water, whose IFSS reduced to 70Mpa. The IFSS of the samples decreased rapidly after 7 days immersion in water. Then with the increase of immersion days from 7 days to 90 days, the IFSS decrease still remarkable, but slowly.

![Figure 5 The interfacial shear strength of E51 epoxy/carbon fiber as a function of water immersion days.](image)

Small molecules of water penetrate into the interface by diffusion and filtering through voids and cracks of the resin or by capillary migration along the fibers. The water then forms a weak hydrogen bond with E51 epoxy molecules (Wang, Huang et al. 2015).

In order to clarify the effect of water in the bonding performances of the epoxy/carbon fiber from microscopic scale, MD simulations are performed and the influence of water molecules are illustrated in the next section.

Molecular Adhesion

Here the molecular adhesion was simulated by atomic model in order to enlighten the effect of water on the interfacial bonding. The E51 epoxy/Carbon fiber interface model under the dry condition and wet condition were built respectively. The later condition is achieved by adding a number of water molecules into the model. As shown in Figure 4, after the system reached the equilibrium, under the dry condition, the E51-epoxy molecule is attached to the surface of carbon fibers, the distance between the center mass of epoxy molecules and the surface of carbon fibers in vertical direction is around 5 Å. In the wet condition, however, the distance between the center mass of E51 epoxy and the surface of carbon fibers in vertical direction is around 6.6 Å. The epoxy molecules are slightly detached from the fiber surface as the water molecules entered the area between E51 epoxy molecules and carbon fiber molecules and formed hydrogen bonds with E51 epoxy molecules (it has been calculated that some water molecules is within the distance of 3.5 Å from E51 epoxy molecules).

In the detachment simulation using metadynamics method, E51 epoxy molecules were pulled away from the surface of carbon fibers, the potential of mean force (PMF) of the E51 epoxy/ Carbon fiber interface in the process were calculated, and the free energy profiles of metadynamics simulation of the interface in dry and wet condition are constructed and plotted in Figure 6. Metadynamics is a powerful algorithm that can be used for both reconstructing the free energy and accelerating rare events in the systems described by complex Hamiltonians, at
the classical or at the quantum level (Laio and Gervasio 2008). In the algorithm the normal evolution of the system is biased by a history-dependent potential constructed as a sum of Gaussians centered along the distance between the E51 epoxy molecule and carbon fiber sheets in vertical direction. The sum of Gaussians is exploited for reconstructing iteratively an estimator of the free energy and forcing the system to escape from local minima (the adhesion state). Here the metadynamics method was used to calculate the free energy need for the system to change form adhesion state to detach state by summing the energy ejected into the system incessantly. Figure 6 (a-b) show the free energy profile of the interface model under different metadynamics simulation duration time. As show in Figure 6(a), 100ps simulation time are enough for the E51 epoxy to change from the energy minimum state--adhesion state (see in Figure 7(a)) to energy higher state-- detach state (see in Figure 7 (d)) in dry condition. With the simulation time increase, no more energy is added to the free energy profile for the change of states. When the metadynamics simulation time was 50ps or 80ps, the E51 epoxy was partly detached from the carbon fiber sheets (see in Figure 7(b-c)). In moisture condition, 50ps simulation time are enough for the E51 epoxy to change from the energy minimum state--adhesion state (see in Figure 7(e)) to energy higher state-- detach state(see in Figure 7 (h)). With the simulation time increase to 100ps, no more energy is added to the free energy profile for the change of states. When the metadynamics simulation time was 20ps or 30ps, the E51 epoxy was partly detached from the carbon fiber sheets (see in Figure 7(e-f)).

![Free energy profile](image1)

![Free energy profile](image2)

(c) The free energy profile of the interface in dry and water ingress condition

Figure 6 The free energy profile of the E51 epoxy/carbon fiber interface according to their vertical distance

The interfacial molecular adhesion can be estimated by calculating the free energy difference between the adsorbed state where the free energy was in the lowest value and the detached state where the curves have levels off. As shown, the binding free energy of CF/epoxy interface is around 43KJ/mol in dry condition and 17KJ/mol in water ingress condition.

In the adhesion state, the contact area between E51 epoxy molecules and carbon fiber sheets is around 3595Å² in dry condition and 2942 Å² in water ingress condition. Here we can calculate the surface energy by equation (1). \( S_0 \) is the contact area, \( E_b \) is the binding free energy. In dry condition, the surface energy is around 1.9mJ/mol. In moisture condition, the surface energy is around 0.96mJ/mol, with 49.7% reduction. Water molecules account for a significant part of the total work of adhesion of E51-epoxy/Carbon fiber interface by interaction with molecules of the interface. In the long-term application of FRP, small molecules of water would penetrate into the interface.
by diffusion and filtering through voids and cracks of the resin or by capillary migration along the fibers, thus the degradation of interface adhesion can’t be neglected.

\[ \gamma_s = \frac{E_b}{S_0} \]  

Figure 7 E51 epoxy molecules in different attach state from carbon fiber sheets during metadynamics simulation:  
(a) – (d) in dry condition; (e) – (h) in water ingress condition

As shown in Figure 8, carbon fiber is hydrophobic, with few water molecules permeated into its body. In our model, water molecules mainly interact with E51 epoxy molecules, increasing the chain movement of E51 epoxy molecules, making E51 epoxy molecules need less free energy to escape from the adhesive state with carbon fibers. In addition, water molecules would enter the area between carbon fibers and E51 epoxy molecules, forming hydrogen bonds with E51 epoxy molecules and decreasing the adhesion between E51 epoxy molecules and carbon fibers. Those two factors may account for the distance between the center mass of epoxy molecules and the surface of carbon fibers in vertical direction to change from 5.0 Å to 6.6 Å in stable adhesive states after changing from dry condition to wet condition. Thus lead to the decrease of Van der Waals’ force, which is in inverse proportion to distance. The binding free energy of E51 epoxy/carbon fibers is corresponding decrease in wet condition. Water molecules play an important role in the decrease of FRP interfacial bonding that can’t be neglected and is a main factor for the FRP debonding failure.
CONCLUSIONS

The interfacial mechanical behavior of E51 epoxy/Carbon fiber interface in dry and moisture conditions has been investigated using the microbonding pull-out test and molecular dynamics simulation. The simulation matched the experimental results well in showing the water ingress leads to remarkable degradation of interfacial bonding. The experiment shows that the interfacial shear strength of E51 epoxy/Carbon fiber interface could decrease to 59% after 90 days immersed in water. The adhesion of E51 epoxy carbon fiber decreased with the increase of duration of water immersion. The MD simulation shows the free energy for the E51 epoxy to debond from carbon fiber surface decreased to 51% of the free energy in the moisture condition. It is shown that water molecules account for a significant part of the total work of adhesion of E51-epoxy/Carbon fiber interface by interaction with molecules of the interface. In this way, the MD simulation gives us a qualified way to assess CF/epoxy interfacial adhesion by calculated the decrease of free energy and could enhance our understanding of failure mechanism in FRP.

As shown, the water ingress led to remarkable deterioration of CF/epoxy interfacial adhesion. There is a need to take the water effect into account during the design of FRP. Many applications of FRP are used in moisture environment and require FRP to work well for over 50 years. During the process, small molecules of water would penetrate into the interface by diffusion and filtering through voids and cracks of the resin or by capillary migration along the fibers, thus the degradation of interface adhesion can’t be neglected. The present study provides insights into the fiber-resin bonding mechanisms, and reveals the effect of water ingress on the bonding. The study is expected to be helpful for both the development of durable FRPs, and to predict the service life of a FRP subjected to hydrothermal aging accurately.

ABSTRACT

Freeze-thaw (FT) cycling is one of the primary concerns for the application of fiber reinforced polymer (FRP) in cold regions. Existing studies have shown different levels of degradation on the mechanical behaviour of carbon FRP (CFRP) or glass FRP (GFRP) laminates and FRP-to-FRP adhesively-bonded joints after subjected to FT environment. This paper presents the FT durability test results of the basalt FRP (BFRP) and its adhesively-bonded single-lap joints. Standard FRP tensile coupons and FRP-to-FRP single-lap joints were prepared and tested before and after subjected to FT cycles. Micro-structure observations were also conducted to compare the fracture sections of the BFRP laminate with CFRP and GFRP laminates before and after FT exposure. Test results indicated excellent FT resistance for both BFRP laminate and its adhesively bonded single-lap joint. FT durability mechanism of BFRP composites and BFRP-to-BFRP adhesively bonded single-lap joint was discussed based on the experimental observations.

KEYWORDS

BFRP, freeze-thaw cycling, durability, single-lap joint.

INTRODUCTION

Fiber-reinforced polymer (FRP) has been successfully applied in a wide range of infrastructures because of their unique properties for strengthening or reinforcing of structures. The increasing use of FRP presents many challenges to researchers and engineers. One of these challenges is to understand the performance of FRP in harsh environments (Hollaway 2010). Freeze–thaw (FT) cycling is the primary types of environmental stress that seriously weaken the durability of concrete structures in cold regions (Sun et al. 2002). When subjected to FT cycling, thermal incompatibility of the constituent materials and the moisture environment may decrease the mechanical properties of FRP. Wet lay-up FRP laminates are common used in the field of strengthening of concrete structures. Existing studies have shown different levels of degradation on the tensile behaviour of carbon FRP (CFRP) or glass FRP (GFRP) laminates (Karbhari 2007, Li et al. 2012, Shi et al. 2014). Higher residual tensile strength in CFRP laminate has been observed than that in GFRP laminate after exposure to FT cycles.

The behaviour of adhesively-bonded joint is one of the critical issues in the FRP strengthened concrete structures especially for the FRP confined concrete columns. Service loads are transferred between fiber sheets within the area of FRP-to-FRP adhesive-bonded joint. Till now many studies have focused on this field and many analytical models have been developed for the prediction of the bond capacity of different adhesive-bonded joints under static loads and normal environments (e.g. Her 1999, Parvathy 2003, Li et al. 2009). However, the study on the FT durability of FRP-to-FRP adhesively-bonded joint is very sparse. Lopez-Anido et al. (2004) tested the FT resistance of prefabricated E-GFRP adhesive bonds and found substantial reduction on the lap shear strength after exposure to 20 FT cycles. However, little attention is given to the FT durability of wet lay-up FRP-to-FRP adhesive bond. As an emerging environmentally friendly material, basalt FRP (BFRP) has been shown to have superior advantages in structural retrofitting, seismic strengthening and serving as new structural components (Wu et al. 2012, Wang et al. 2013). Till now, very limited information is available on the durability of BFRP and BFRP-to-BFRP adhesively-bonded joint in FT environments.

This paper introduces the durability study of BFRP laminate and BFRP-to-BFRP adhesively-bonded single-lap joints subjected to FT cycling. Standard FRP tensile coupons and FRP-to-FRP single-lap joints were prepared and
tested before and after subjected to FT cycles. Micro-structure observations were also conducted to further understand the FT resistance of BFRP and compare that with GFRP and CFRP. FT durability mechanism of BFRP and BFRP-to-BFRP adhesively bonded single-lap joint was also discussed based on the test results.

EXPERIMENTAL PROGRAM

Test coupons

To make BFRP tensile coupons, one layer of unidirectional basalt fiber sheet was completely impregnated with epoxy resin using a wet hand lay-up procedure. The nominal thickness of the basalt fiber sheet is 0.156mm. After the solidification of the epoxy resin, BFRP coupons were cut and prepared according to the GB/T-3354 (1999), as shown in Figure 1 (a). The FT durability test of corresponding epoxy resin was also conducted to reflect the degradation mechanism. Epoxy resin tensile and tensile shear test coupons were prepared according to the GB/T-2567 (2008), as shown in Figure 1 (b) and (c). BFRP-to-BFRP adhesively-bonded single-lap shear coupons were prepared based on the reference to the previous studies (Parvathy 2003, Li et al. 2009) with one layer of basalt fiber sheet bonded to the same other one, as show in Figure 1 (d). The overlap length (OL) used in the tests is 100 and 120mm for the two groups of BFRP-to-BFRP test coupons. All of the test coupons were cured for a minimum of one week at ambient temperature prior to testing.

![Figure 1 Test coupons in this study: (a) BFRP laminate; (b) Epoxy resin (tensile coupon); and (c) Epoxy resin (shear coupon); (d) BFRP-to-BFRP single-lap joint (Units in mm)](image)

Test procedures

The test coupons were soaked in water in rubber boxes and subjected to up to 200 accelerated FT cycles. The freezing and thawing condition were conducted at 3-4 hours per cycle, in accordance with the rapid FT method in the Chinese national standard GB/T 50082-2009. The temperature fluctuation is ranged from +8°C to -17°C during FT tests. After being subjected to scheduled FT cycles, each coupon was positioned in a 30kN tension testing machine for the tensile tests. The axial deformation of BFRP and epoxy resin tensile coupons was recorded using an extensometer with a gauge length of 50 mm. The tensile force was measured by a load sensor inside the testing equipment. The loading was controlled by displacement at a rate of 1.0 mm/min. The values of the load and the axial deformation were recorded at one-second intervals.

TEST RESULTS AND DISCUSSIONS

Test results of BFRP laminate and epoxy resin

Table 1 summarizes the mechanical properties of the BFRP laminate and epoxy resin at room temperature. Each value in the table is the average of 6 identical coupons, and the standard deviation is also given after the symbol “±”. The tensile properties of the BFRP laminate are calculated based on the nominal thickness (i.e., without considering the thickness of the resin matrix).

Figure 2 illustrates the variation in the residual mechanical properties of the BFRP laminate and the corresponding epoxy resin with respect to the exposure FT cycles. To simplify the analysis and facilitate comparison of the results after FT exposure, the test results were expressed by normalized values with respect to the control test results. The error bars in the figure represent the coefficient of variation (CV) of the test data. The tensile strength of the BFRP laminate decreased slightly at first 50 cycles, then increased up to 150 cycles, and finally decreased slightly. There was almost no reduction in the residual tensile strength of the BFRP laminate after 200 FT cycles. In contrast, nearly 20% degradation was observed on the tensile strength of epoxy resin after 100 and 200 FT cycles. The FT cycling did not diminish the elastic modulus of the BFRP laminate and the epoxy resin. A maximum increase in the elastic modulus of approximately 10% was observed for BFRP, indicating that FT cycling can contribute brittleness to the BFRP laminate. The rupture elongation of the BFRP laminate and the epoxy resin decreased as the number of FT cycles increased. After 200 cycles, the rupture elongation of BFRP laminate is around 90% of the control ones, which is mainly due to the increased brittleness introduced by FT cycling. Figure 2 (d) shows that the shear strength of the epoxy resin decreased steadily as the number of FT cycles increased. Up to 100 cycles, there was no significant difference in the degradation rate in comparison to that of the tensile strength of the epoxy resin. At a higher number of cycles, the normalized values of the tensile shear strength were much lower than the corresponding tensile strength values. The above analysis indicates that although the epoxy resin matrix was damaged, the tensile properties of BFRP laminate were almost not influenced by the FT cycling.

Figure 3 compares the micro-structure on the fracture sections of the BFRP laminate before and after FT exposure by scanning electron microscope (SEM) observations. Masses of matrix fragments can be found on the surface of basalt fibers after tensile fracture, as shown in Figure 3 (a), indicating good bonding condition between resin matrix and fibers for the control BFRP coupons. In comparison, relative lesser matrix fragment was observed on basalt fiber surface, as shown in Figure 3 (b). This is mainly due to the bond degradation of epoxy resin after FT cycling. To further study the effect of fiber types and epoxy resin degradation on the durability of FRP composites, the 200 FT cycles exposed CFRP and GFRP laminates were also conducted through the SEM observation testing. Obvious debonding phenomenon can be found between carbon or glass fibers and resin matrix, as shown in Figure 3 (c) and (d), indicating that the fiber-matrix bond performance was damaged by FT cycling in some levels. In comparison, the fraction section of BFRP laminate did not shown this kind of clear debonding between fiber and matrix.
Test results of BFRP-to-BFRP single-lap joints

Figure 4 shows the typical failure mode of the BFRP-to-BFRP single-lap joint. Debonding delamination between the two layers of basalt fiber sheets within the overlap section of the test coupons can be observed for all of the tested single-lap coupons in this study.

Figure 5 shows the normalized results of the apparent shear strength of BFRP-to-BFRP single-lap joints after subjected to different FT cycles. The apparent shear strength ($S$) of the single-lap joint is determined by dividing the peak load, $P$, by the overlap area, $A_L$. In which, $A_L$ is calculated by multiplying the measured coupon width, $b$, by the overlap length, $O_L$. Two groups of the test coupons, B-100 and B-120, with $O_L=100\text{mm}$ and $120\text{mm}$ were carried out to study the effect of overlap length on the FT durability of BFRP-to-BFRP adhesive bond capacity. The average value of $S$ is $2.92\text{MPa}$ and $2.41\text{MPa}$ for the test coupons B-100 and B-120, respectively. As can be observed from Figure 5, the apparent shear strength almost did not degrade with the increased FT cycles for both
B-100 and B-120 test coupons. After 200 FT cycles, the normalized average value of $S$ is 1.01 and 1.11 for B-100 and B-120, respectively. B-120 coupons retained higher shear strength than B-100 coupons, indicating that the longer overlap length can result in better FT resistance for the bond performance of BFRP-to-BFRP adhesive-bonded joints. Overall, BFRP-to-BFRP adhesive-bonded joints behave satisfactory durability in FT cycling environment.

**Discussions of the FT durability mechanism**

**BFRP laminates**

Two major effects occur when FRP composites are exposed to FT environments: thermal incompatibility and degradation of the constituent materials, including their interfaces (Green 2007). The first effect is related to the different thermal characteristics of the constituents of FRP composites. A decrease in temperature would cause the fibers and resin to contract, resulting in the formation of residual stresses at the resin matrix-fiber interface, due to the differences in the coefficients of thermal expansion (CTE) and the elastic modulus between the two materials. Basalt fibers have closer CTE to the epoxy resin than the carbon or glass fibers. Hence, better bonding performance between the basalt fibers and matrix after FT cycling can be achieved. This can be confirmed by the SEM analysis as discussed previously (Figure 3). The other major effect is the degradation of the constituent materials and their interfaces as a result of FT exposure, especially in the presence of moisture. Exposure to cold temperatures and FT cycles generally results in an increase in the elastic modulus and embrittlement of a resin matrix but a decrease in damage tolerance, contributing to the increase in the elastic modulus and the decrease in the tensile strength and rupture elongation of the FRP composites. According to previous studies (Karbhari 2007, Shi et al. 2014), the tensile strength of FRP composites is sensitive to the bond between fiber and resin matrix. As a result, good bond performance of the basalt fiber-matrix interface can lead to satisfactory durability of BFRP laminate in FT cycling environment.

**BFRP-to-BFRP adhesive-bonded joints**

The FT durability of prefabricated FRP-to-FRP adhesive bonds is mainly determined by the FT resistance of bonding adhesives. As the shear strength of epoxy resin decreases significantly with FT cycles, substantial reduction on the lap shear strength can be found on the prefabricated FRP-to-FRP adhesive-bonded joints (Lopez-Anido et al. 2004). For the condition of wet lay-up FRP-to-FRP adhesive-bonded joints, the adhesive layer between the two fiber sheets is very thin. The debonding of fiber and matrix within the area of overlap length controls the joint failure. As a result, good bond performance for the basalt fiber-matrix interface can also lead to a good resistance to the FT cycling for BFRP-to-BFRP adhesive-bonded joints.

**CONCLUSIONS**

Based on the results of the experimental studies and the discussions presented in this study, the following conclusions can be drawn:

1. FT cycling has a negligible effect on the tensile properties of BFRP laminate, while significant degradation of the mechanical properties of epoxy resin was observed after FT exposure.
2. FT cycling did not degrade the apparent shear strength of BFRP-to-BFRP adhesively-bonded single-lap joints. Longer overlap length can result in better BFRP-to-BFRP bond FT resistance.
3. Good bond performance of the basalt fiber-matrix interface is the main reason for the satisfactory FT resistance of both BFRP laminate and BFRP-to-BFRP adhesively-bonded single-lap joint presented in this study.

ABSTRACT

The performance of CFRP used in RC structures reinforcement resides in the ability of the adhesive bond to effectively transfer the load from the concrete substrate to the CFRP and also to maintain this behaviour through the structure service life.

The current study focused on the influence of the concrete alkaline chemical nature on the epoxy network properties. Thus, the ageing of epoxy resins from 2 different types of CFRP reinforcement has been studied after thermo-oxidative exposure and alkaline solution immersion. Both chemical and mechanical properties evolutions have been characterized.

The epoxy network oxidation kinetic was compared between thermo-oxidative atmosphere and alkaline concrete environment. The influence of water intake, alkaline degradation reactions or hydrolysis on the epoxy network mechanical properties was investigated.

Based on these experimental results and the identified chemical ageing mechanisms, a Polymer Ageing Prediction numerical tool was evaluated.

KEYWORDS

FRP, epoxy ageing, thermo oxidative, alkaline, adhesive bond, concrete.

INTRODUCTION

Carbon Fiber Reinforced Polymers have been commonly used worldwide for the strengthening and repair of civil structures for decades now. If the technique effectiveness has been clearly demonstrated and is now accepted by all decision makers in the construction sector, a major concern is the durability of the repairs. Indeed, the long-term mechanical behaviour of concrete/composite adhesively bonded interfaces exposed to mechanical and environmental ageing mechanisms throughout the life cycle of the structure has not yet been fully demonstrated. Over the last decade, several authors have reported that environmental conditions may indeed affect the integrity of both the interfacial bonds (substrate/polymer interactions) and the polymer material itself (adhesive joint in the case of bonded composite plates).

Accelerated conditions such as freeze-thaw/dry-heat cycles, immersion in salt solutions or exposure to humid environments were found to be detrimental to the adhesive bond properties (Karbhari et al 2007, Grace & Singh 2005, Benzarti et al. 2011). Also, the few available literature on field service study of CFRP strengthening indicated significative evolution of interfacial failure mode and defects propagation (Allen 2011, Benzarti et al 2009). The current study focused on the influence of the concrete alkaline chemical nature on the epoxy adhesive bond properties. Thus, the ageing of epoxy resins from 2 different types of CFRP reinforcement has been studied after thermo-oxidative exposure and alkaline solution immersion.

EXPERIMENTAL APPROACH

Materials

Two commercial epoxy resin were studied, and will be referred to as EPX A and EPX B. EPX A. The EPX A is commercially sold as an adhesive used as a wet-lay up applied solution of Carbon Fiber/Epoxy resin composite on concrete. The EPX B is used as an adhesive for pultruded CFRP plates glued on concrete. Table 1 shows that the
two selected epoxy resins are fairly different in composition and stiffness. The micrographs presented in the Figure 1 confirms these differences, displaying the EPX B high coarse fillers content.

**Accelerated ageing conditions**

The goal of this study was to compare the ageing mechanism between a classic thermo-oxydative environment and the alkaline reactive medium in contact with concrete. Thus, two accelerated ageing set-up were utilized:

- Thermo-oxydative conditions: aging in ventilated stoves at 70°C, 90°C and 110°C for up to 6000h,
- Cementitious conditions: immersion in a saturated lime solution at 40°C, 60°C and 80°C for up to 6000h.

**Characterization**

The vitrous transition temperature was determined using a NETZSCH DMA 242 device. Infra-red analysis was performed with a BRUKER FTIR microscope allowing one measurement every 128 µm. Tensile testing was performed according to ISO 527 with a INSTRON 8872 dynamometer on ISO 527 H2 dumbbells samples.

**RESULTS AND DISCUSSIONS**

**Influence of thermo-oxydative ageing**

The vitrous transition temperature Tg of the EPX A reference decreases at first until 500-1000h of accelerated ageing before increasing for longer times as shown in Figure 2. Concerning the EPX B, the Tg quickly increases and stabilizes. Both resins’ Tg decreases for the longest ageing durations. The lowering of Tg can be explained by crosslink openings whereas the increase is probably due to both post-curing and additional cross-kinking even though additional characterisation is needed in so far as only one sample per ageing step was tested. Previous studies also showed a competition between crosslink bond cleavage and additional crosslinking in epoxy thermo-oxydative ageing mechanisms (Zahra et al. 2014).
The chemical functions evolution through ageing was studied with FT-IR microscopy. The thermo-oxidative ageing mechanism of epoxy resin is already well documented and it has been shown that the carbonyl species concentrations are representative of the oxidation progression. Figure 3 shows both EPX A and EPX B 1710 cm⁻¹ carbonyl peak absorbance as a function of depth and ageing duration. All spectra were normalized with the 1608 cm⁻¹ peak absorbance attributed to aromatic cycles which are known not to be impacted by oxidation mechanisms (Zahra et al. 2014).

Figure 2 Evolution of T<sub>g</sub> as a function of thermo-oxidative ageing duration

The carbonyl peak absorbance being proportional to carbonyl species concentration and thus to resin degradation through oxidative ageing, the Figure 3 a) shows a oxygen diffusion limited mechanism as the area closest to the sample surface are the most rapidly oxidized. Also the progressive increase through ageing time is clearly visible. Not presented in this paper, the influence of ageing temperature on the carbonyl production kinetic was observed. The oxidized layer thickness is estimated at about 1 mm. Unfortunately, the EPX B high fillers proportion impeaches a good spectra resolution, and is not fully exploitable. Still, the increase of carbonyl concentration is also visible for the EPX B resin.

Tensile mechanical properties characterization results for EPX A showed a tensile modulus decrease for the lowest ageing temperature of 70°C until 2000h. From 2000h to 4000h the tensile modulus started to increase before dropping between 4000h and 6000h. For higher ageing temperatures, the tensile modulus increased until 4000h before dropping for further ageing duration. Elongation at break did not display any clear tendencies other than a
general increase for the lowest ageing temperature and a decrease for the highest ageing temperature. The tensile modulus increase can be explained by additional crosslink bond formation. Incidentally a tensile modulus decrease could be linked to crosslink or backbone bonds cleavage. As both modulus increase and decrease occurs alternatively depending on the ageing temperature or duration, a competition between both bond formation and cleavage is likely explain the mechanical behavior of the EPX A epoxy resin through thermo-oxydative ageing. This hypothesis is backed with the Tg evolution results depicted before.

Concerning the EPX B resin, the tensile modulus showed a small decrease through ageing time for all temperatures. The elongation at break decreased rapidly before stabilizing at about half the pristine state value. The lower amplitude of the influence of thermo-oxidative ageing on the EPX B resin might be caused by the high concentration of fillers (>80%) in said resin. Incidentally, the elongation at break decrease is probably linked to filler/matrix chemical bond degradation through thermal ageing.

![Figure 4 Mechanical properties after tensile testing after thermo-oxidative ageing](image)

**Influence of cementitious environment ageing**

The diffusion coefficient of cementitious water through both EPX and EPX B epoxy network were determined (Table 2) using a Fickian model (Equation 1).

\[
D(T) = A e^{-\frac{E_a}{RT}}
\]  

(1)
Table 2 Cementitious water diffusion parameters

</tbody>
</table>

The results show that diffusion kinetics of cementitious water are much faster in EPX A resin than EPX B resin. This can be explained by the high fillers content of EPX B compared to EPX A.

Cementitious environment aging led to a fast drop of $T_g$ for EPX A and EPX B at 80°C. For longer ageing times, both EPX A and EPX B samples displayed a decrease in $T_g$.

Figure 5 Evolution of $T_g$ as a function of cementitious environment ageing duration

Figure 6 FT-IR microscopy showing the evolution of 1710 cm⁻¹ carbonyl and 3350 cm⁻¹ hydroxyl characteristic peaks as a function of sample depth and cementitious water ageing duration at 80°C
In addition to carbonyl species, hydroxyl groups hypothetically produced by hydrolysis reaction (Zhang et al. 2012) were monitored with FT-IR microscopy. The infra-red peak associated to hydroxyl groups is located around 3350 cm\(^{-1}\). The results presented by the Figure 6 show hydroxyl group concentration increase through ageing time for the EPX A sample, meaning that hydrolysis mechanisms do take place. Also, as opposed to thermo-oxidative mechanism, cementitious water induced chemical modifications seems homogeneous in the sample thickness. The carbonyl groups, however, tend to disappear with ageing duration, although the typical color change is witnessed on the aged samples. A potential explanation is a lixiviation phenomenon of carbonyl species by the cementitious water. The EPX B sample was not characterized because of the filler induced poor signal quality, as seen previously.

Tensile mechanical properties characterization results for both EPX A and EPX B after cementitious water aging showed a steep tensile modulus drop in the first 200h of aging (Figure 7). The elongation at break for EPX A also rose quickly. This tendency can be explained by the water intake, acting as a plasticizer in the resin epoxy network. EPX A tensile modulus later increased until 3000h of ageing, whereas the elongation at break decreased slightly. This can be understood as additional crosslinking of the epoxy network, in a similar way as in thermo-oxidative environment. EPX B tensile modulus stays stable after the initial drop, whereas the elongation at break continues to rise. This can be explained by the high filler content of this resin, leading to matrix/fillers interface debonding phenomenon unrelated to the matrix alone chemical modifications.

Ageing mechanism model

In order to simulate the ageing mechanisms of polymer networks, a numerical tool has been elaborated (Zahra 2012) and will not be detailed in this paper. Although the model has been validated in 1D virtual polymer networks, the O\(_2\) diffusion is still not fully implemented. However, first simulations show promising results as the oxidation...
layer is well reproduced. The Figure 8 shows the carbonyle concentration [CO] as function of sample depth and thermo-oxidative ageing duration à 110°C. The future work includes parameterization of the model according to the experimental results proposed in this work in terms of ageing kinetics, water intake as a function of temperature and time.

![Figure 8 Numerical simulation of carbonyle concentration through 110°C thermo-oxidative ageing in a model polymer](image)

**CONCLUSIONS**

This experimental study showed that both epoxy resins underwent oxygen diffusion limited oxidation in thermo-oxidative atmosphere leading to a maximal tensile properties decrease. The cementitious water ageing induced oxidation and hydrolysis mechanisms, although in lower proportion than the thermo-oxidative conditions showed. Hence, the mechanical properties evolutions are predominately caused by the water intake, acting as a plasticizer in the epoxy network. Cementitious water intake diffusion kinetics was determined. Tensile modulus values dropped up to 5 times after only 200h immersion, while elongation at break drastically increased. The studied resins being used as civil structures strengthening, both thermo-oxidative and cementitious environment ageing are to be taken into account, as this work’s conclusions showed the great influence of both ageing environment on the resins mechanical properties. The plasticizer effect of both external source and cement water cannot be overseen when considering the composite creep behavior, as shown in other studies (Houhou 2014). The homemade numerical model, enriched with this study results, will be of great help in lifetime prediction of such strengthening systems.

ABSTRACT

The use of externally-bonded fibre-reinforced polymer (FRP) composites to strengthen and repair existing concrete structures is an established technology. In this technology, organic adhesives (epoxy and other resins) are widely applied, since they have been proven to be excellent bonding agents between the FRP plates or sheets and the substrate materials (i.e. concrete, metal, wood) under common operation conditions and room temperatures. However, the poor temperature-resistance performance of epoxy is an obstacle for the application of FRP in civil buildings, such as residences, hospitals and commercial centres, which usually have a certain period of time of fire resistance requirements. The cementitious bonding agent is supposed to be a practical alternative of organic adhesives to solve this shortage. This paper therefore presents the performance at elevated temperatures of cement-based carbon fibre-reinforced composite to strengthen concrete structures. More specifically, a series of single-shear FRP-to-concrete joints using mortar as bonding agent were tested at steady state for temperatures ranging from approximately 20 to 700℃. The failure modes and the ultimate capacities at elevated temperatures were recorded. The bond strength of FRP-to-concrete joints at such high temperatures was compared with that at room temperature.

FRP, elevated temperatures, concrete structures, mortar, high-temperature behaviour.

INTRODUCTION

In current CFRP strengthening systems, the bond agents used as the matrix and also used as bond adhesive between the FRP composites and the substrate materials (i.e. concrete, metal and wood), are usually epoxies. Present-day epoxy resin products all basically consist of two components that react with each other forming a hard, inert material. One part consists of an epoxy resin and the other part is the epoxy curing agent, sometimes called hardener. The epoxies, as organic matter, degrade with increased temperature. Such degradation commences before the glass transition temperature, \( T_g \), is reached and subsequently the reductions of the bond properties occur. Normally, the \( T_g \) can lie in the range of 50 to 90℃ for commercially available products used in civil infrastructure applications (Foster et al. 2008). However, such temperatures can be easily exceeded when there are fires in buildings of residences, hospitals and commercial centres. Thus, the poor temperature performance of epoxy has been an obstacle for the applications of FRP in civil buildings, which usually have a certain period of time of fire resistance requirements.

Most recently, a cost effective way has been attempted to solve the fire-resistance shortage of the current FRP technology, in which a cement-based bonding agent is proposed as a practical alternative to organic adhesives. The called cement-based bonding agent is the common constructional material, mortar, which is one component, adds polymer reinforced powder material mixed with water. In addition to higher fire resistance and lower cost, it also has several advantages over the epoxy resins including no harmful toxicity to human body, better thermal compatibility with the concrete substrate and good operability at low temperatures (Hashemi et al.; 2008; Blanksvård et al. 2009). Of the limited research undertaken to date on cement-based FRP strengthened concrete structures, full scale beams and columns tests (Hashemi et al.; 2008; Blanksvård et al. 2009; Wiberg 2003; Täljsten et al. 2007; Wu et al. 2010; Badanoiu et al. 2003) have been conducted. These test results have shown that the sufficient mechanical bond properties for load transfer could be obtained using mortar. Such testing, however, has only considered the behaviour of the entire strengthened member or joints strengthened by cement-based FRP systems at room temperatures and not at elevated temperatures.
This paper reports the results of a series of single shear tests on the fundamental behaviour of FRP-to-concrete joints using mortar as a bonding agent at temperatures ranging from room temperature (approximately 22°C) up to high temperatures which may be expected in a fire (i.e. 700°C). It is important to note here, there are many types of commercial modified cements available, which will affect the test results more or less. Such study, however, is outside the scope of this paper. The cement-based bonding agents in this paper were prepared by just using most common commercially cement-based materials, superfine cement (SFC). By using a set of universal testing machines, the test specimens were heated to a specified temperature and then the tensile test carried out. The behaviour of the test specimens are reported as well as the failure modes.

EXPERIMENTAL INVESTIGATION

Test Set-up, Instrumentation and Loading

Figure 1 shows the overall view of test set-up. To restrain the displacement of the concrete block, a steel holding frame for the single-shear pull tests was fabricated and mounted inside a MTS 810 universal testing machine. Prior to fastening the bolts of this steel frame, the concrete block was positioned by adjusting the front baffle plate, which placed the FRP plate in a uniform line with the tensile force applied by the testing machine. The heating device used was an MTS Model 653 high temperature furnace with a maximum temperature of 1400°C. One side of the furnace which has internal thermocouples inside was used in this study. The temperatures were controlled by an MTS 409.83 temperature controller. The positions of the furnace and the FRP plate are shown in Figure 2 and maintained consistently for all 24 joints. The external thermocouples were put in the furnace and contacted the surface temperature of FRP plates, the readings of which were considered as the real temperatures of the specimens in this paper.

In the testing procedure, after a specimen was fixed, the temperature was raised to the desired temperature and then held constant for a target period of 30 or 90 minutes to allow the mortar or epoxy to undergo physical and chemical changes. During these stages, the free end of the FRP plate was unrestrained in order to enable the thermal expansion. After the holding time had been reached, the top jaws of the MTS were closed and then the tensile loads were applied on the specimens (while still under the influence of temperature) to failure.
Materials

Superfine cement (SFC) was used to make the mortar in this study. SFC has a mean particle size of 3.1\(\mu\)m as compared to 12.4\(\mu\)m for ordinary Portland cement (OPC). Table 1 presents the mixing ratios of the evaluated mortars in the laboratory test. In the mixing ratio, as superplasticizer (SP) was added to each mortar in order to disperse the cement grains and reduce agglomeration. The SP used was a polycarboxylate ether-based polymer having a molecular structure characterized by a main chain attached with side chains (ASTM C 109/C 109M, 2007). The silica fume (imported from Norway) was used as another addition to change the microstructure of the mortar and decrease the porosity of the transition zone. Table 2 presents overview of the mechanical properties of the evaluated mortars in the tests. The test method for the compressive strength of the mortars used 50 mm cube specimens according to ASTM C109/C109M-07, meanwhile, the elastic modulus was found according to ASTM C 469-94. The flexural strength was found according to ASTM C 348-02.

The commercial concrete was adopted and poured in one batch for all of the concrete prisms. All these samples were kept in a controlled environment over ten months, then prepared for bonding the FRP plate and tested in two and a half months. Concrete material property tests were conducted before starting the single-shear tests. The resulting properties were cube compressive strengths of 46.3 MPa; the other material properties of concrete block are also listed in Table 2.

The joints were divided into 4 groups (G1-G4), namely (i) G1 Room temperature Groups, (ii) G2 Time Groups, (iii) G3SFC Groups, and (iv) G4 Epoxy Groups. The materials, holding times and testing temperatures of each group are summarized in Table 3. The first group is the room temperature which is no holding temperature process in testing. The next two groups of joints G2 and G3 used the mortar as bond agent, whereas G4 used epoxy as bond agent. The holding time of the joints in G2 and G3 had the target holding time of 30 and 90 minutes, respectively.

Experimental results

A detailed description of the performance and failure modes of all test specimens is presented in this section. The behaviour of bond agent using mortar at room temperature and elevated temperatures was compared with the epoxy. A summary of the strength, testing temperature and failure modes of all specimen results contained in Table 3.

### Room temperature

The average ultimate loads of three types of FRP joints (using SFC and epoxy as bond agents) are 9.48 and 15.34 kN, respectively. The ultimate capacities of the joints using SFC as bond agents were around two-thirds of the joints using epoxy as the bonding agent. The joints of the epoxy failed in an explosive way by debonding of the concrete at the interface with the adhesive, leaving 1-2 mm of concrete attached to the CFRP plate and adhesive. This type of failure mode was shown widely by previous tests. Main failure modes of SFC were delamination between the fibers of plate. The reason for this is mainly because the mortar of SFC can not fully penetrate the fabric effectively. The quality of the bond capacity using mortar as the bonding agent is affected more vulnerably.
by manual operations than epoxy. It should be noted that the aim of this study is not to investigate the behaviour of the FRP at room temperature. Therefore, subsequent studies at room temperature which address extensive parameters such as bond length, FRP width, epoxy etc., are qualitative.

The effect of holding time

The results of Group G2 tests show that the ultimate strengths and failure modes for the specimens were almost the same as compared to the corresponding specimens in Group G3. Such results are shown in Tables 3. The reason for this behaviour was that the cementitious material was static under such elevated temperatures and holding time did not affect the ultimate load of these single shear joints.

Behaviour and failure modes at elevated temperatures

A brief description of all failure modes encountered in all tests is provided in Table 3 with selected typical photos of failed joints presented in Figure 3. The reduction factor of the ultimate strength at temperature $T$ to the ultimate strength at room temperature ($P_{u,T}/P_{u,normal}$) obtained from the steady state tests at different temperatures is plotted in Figure 4.

When the temperature rose to around $150\,^\circ C$, the test joints of epoxy series experienced a significant drop in strength compared with the room temperature strength. From the Figure 4, though the mortar has a weaker bond properties compared with the epoxy at room temperature, this superiority will not exist for the epoxy after around $150\,^\circ C$. At $150\,^\circ C$, the ultimate load of the mortar series was obvious higher than the ultimate load of the epoxy series.

For epoxy series, the reduction tendency of the ultimate strength was very obvious at selected levels of temperature. Referring to the joints tested at room temperature, the reduction of the ultimate strength was 0.72 at $130\,^\circ C$, 0.54 at $150\,^\circ C$ and 0.44 (the mean value) at $200\,^\circ C$. Three different types of failure modes were found in the tests (see Table 3). At $22\,^\circ C$, failure occurred in the concrete, leaving about 1-2 mm of concrete attached to the unbounded CFRP plates. At higher temperatures ($130\,^\circ C$ and $150\,^\circ C$) debonding occurred in the adhesive, leaving about 1 mm of epoxy attached to the unbounded CFRP plates. At $200\,^\circ C$, debonding occurred in the adhesive and FRP plate.
interface, leaving hardly any epoxy attached to the CFRP plate. For both failure modes debonding occurred in a rather explosive way.

From the Figure 4, it can be seen that before 600°C, the ultimate loads of the joints using mortar as the bonding agent showed no obvious reduction at elevated temperatures. The ultimate load of joint M-700-90-1 and M-600-90-1 was 0.39 and 0.69 of ultimate loads at room temperature, respectively.

**Conclusions**

A description of the test set-up and results of a series of single-shear FRP-to-concrete joints using mortar as the bonding agent at elevated temperatures has been presented in this paper. The temperatures ranged from approximately 20 to 700℃. In the tests results, the failure modes of cement-based joints are more complex and more diversified, which could be caused by operation uncertainties flexibilities. However, there were no obvious reductions on the bond strength of FRP-to-concrete joints at such high temperatures compared with the room temperature. This work demonstrated that using mortar as bonding agent was a good approach to provide sufficient fire endurance for the externally-bonded FRP systems. Further research will be needed to establish the long-term effectiveness of the cement-based joints and the effectiveness of additives, which could increase the bond strength of the joint without changing its mineral based characteristics.

ABSTRACT

Many cyclic models for FRP (fibre reinforcement polymer) confined concrete have been developed based on the post-peak strain hardening type of stress-strain curves. However, the investigation of experiment conducted by authors recently indicated that the confinement level and unconfined concrete strength have a more pronounced effect on the strain softening type of stress-strain curve, including the unloading path and reloading path, compared with the strain hardening type of curves. By considering the influence of strain softening, more accurate expressions for the key shape factors of the cyclic curve regarding reloading stiffness, tangent unloading stiffness at zero stress, and plastic strain are proposed. These new expressions can be easily incorporated into the cyclic stress-strain model previously developed by authors for more accurate predictions especially when strain softening type of curve occurs. Good agreement between the predictions of the model with the test results represents the capability and accuracy of the proposed model.

KEYWORDS

Concrete, FRP, confinement, cyclic load, strain softening, stress-strain model.

INTRODUCTION

Many stress-strain models have been developed for FRP-confined concrete under cyclic loading in the existing literature. Shao et al. (2006) firstly developed a cyclic stress-strain model for FRP-confined concrete on basis of their test results. Lam and Teng (2009) questioned the accuracy of Shao’s model due to insufficient database and proposed an algebraic expression to model the cyclic response of FRP confined concrete. Wang et al. (2011, 2012) proposed two cyclic stress-strain models for FRP-confined reinforced concrete (RC) columns, one for square cross-sections and the other for circular cross sections based on their tests on large columns. Hany et al. (2015) conducted experimental tests and proposed a unified cyclic stress-strain model by adjusting the coefficients of the monotonic stress-strain model proposed by Lam and Teng (2013) as the envelope model, and adopted the same form of unloading model proposed by Wang et al. (2012). The authors also proposed a cyclic stress-strain model with a simple form and better accuracy of prediction (Li and Wu 2015).

Among these existing cyclic stress-strain models, only Hany et al.’s (2015) claimed that their model has the capacity to account for the post-peak softening behaviour for FRP-confined concrete cylinder. But, all the strain-softening test results collected by Hany et al. (2015) were obtained from non-circular columns in which the softening effect was caused by the shape of the column cross-section. No softening type of response has been obtained for columns with a circular cross-section and sufficiently low confinement. On the other hand, except the authors’ model (Li and Wu 2015), the other existing models do not take into account all the important factors. For example, in the residual plastic strain model which is an important parameter for unloading and reloading paths, the only factor considered is the unloading strain. Further two other important factors, the confinement and concrete strength, have not been taken into account. The author recently carried out a series of experiments for filling the test gap and reported some impartment findings (Li and Wu 2016). On basis of the authors’ test results, the above issues are properly addressed, and in this paper, a cyclic stress-strain model for FRP-confined concrete with both post peak strain-hardening and strain-softening is proposed with good accuracy.
TEST DATABASE

The proposed cyclic model in this paper was derived from the authors’ test result (Li and Wu 2016) consisting of strain-softening curves and others work (Ilki and Kumbasar 2002, Lam, Teng et al. 2006, Ozbakkaloglu and Akin 2011, Abbasnia, Ahmadi et al. 2012, Abbasnia, Hosseinpour et al. 2012, Wang, Wang et al. 2012, Hany, Hantouche et al. 2015) that mainly show strain hardening post peak behaviour. The model covers all important parameters in a unified manner, in terms of unconfined concrete strength, confinement rigidity, aspect ratio, corner radius etc.

PROPOSED MODEL

The full stress-strain model for concrete under cyclic compression is comprised of three main elements: envelope curve, unloading path and reloading path, as shown in Figure 1. The main parameters controlling the shape of these curves have been discussed above. According to the test results in authors’ recent study (Li and Wu 2016), the proposed cyclic model for FRP-confined concrete adaptable for both the post-peak strain-hardening and strain-softening range is proposed as follows.

Envelope model

Wei and Wu’s monotonic stress-strain model (Wei and Wu 2012) is employed herein to model the envelope curve. This model having a unified form for both post-peak strain-hardening and strain-softening is applicable to different shapes of cross-sections, which is given following:

\[
\begin{align*}
    f_c &= E_c \varepsilon_c + \frac{f_o - E_o \varepsilon_o}{\varepsilon_o^2} \varepsilon_c^2, \quad 0 \leq \varepsilon_c \leq \varepsilon_o \\
    f_c &= f_o + E_o (\varepsilon_o - \varepsilon_c), \quad \varepsilon_o \leq \varepsilon_c \leq \varepsilon_{co}
\end{align*}
\]

where, \(E_c\) and \(E_o\) are the first of second slope of monotonic response (Figure 1), respectively. \(f_o\) and \(\varepsilon_o\) are the transitional stress and corresponding strain, respectively. The details of the other parameters in Eq. (1) were provided by original paper (Wei and Wu 2012). However, by a regression analysis of the current test database, it is noted that Wei and Wu’s model (2012) underestimated the confinement effectiveness because only square and rectangular cross section were collected for modelling softening behaviour. Therefore, the coefficient of \(f_l/f_{co}\) in ultimate stress \((f_{cu})\) model is modified to 0.66 in this study, instead of 0.73, and it is determined by the following equation:

\[
\frac{f_{cu}}{f_{co}} = 0.5 + 2.7 \left( \frac{2r}{b} \right)^{0.4} \left( \frac{f_l}{f_{co}} \right)^{0.63} \left( \frac{h}{b} \right)^{-1}
\]

where \(f_{co}\) is concrete grade, \(2r/b\) is the corner radius, \(h/b\) is the aspect ratio. \(f_l\) is the confinement pressure at the fibre rapture point.
Unloading model

The proposed unloading model applied the same mathematical form, as adopted in the work of previous developed by authors (Li and Wu 2015). The nonlinear expressions (Eq. 3) of the unloading curve, describes well the shape of the unloading behaviour for FRP-confined concrete specimens having a post peak strain softening response. The details of the unloading model can be found in the original paper (Li and Wu 2015).

\[
f_r = E_{um,0} \left( \frac{\varepsilon_r}{\varepsilon_{pl}} \right)^m \left( \varepsilon_r - \varepsilon_{pl} \right)
\]

where \(\varepsilon_r\) is the plastic strain, and \(E_{um,0}\) is the tangent unloading stiffness at the plastic strain point. \(m\) is the shape factor that can be obtained by substituted unloading point (\(f_{um}\) and \(\varepsilon_{um}\)) into Eq. 3. The influence of the key parameters on the \(E_{um,0}\) has been shown in Figure 2, and the \(E_{um,0}\) decreases with the increase of unloading strain. In particular, this trend is more pronounced for specimens featuring a post peak softening behaviour such as C60P0.3C, C50P0.3C, and C50P0C. This observation reveals that the process of concrete damage and material softening is accelerated by the presence of strain softening.

By regression analysis of these test data, a new expression for the predicting parameter \(E_{um,0}\), based on the same mathematic expression with that proposed by authors (Li and Wu 2015), is developed as follows:

\[
E_{um,0} = 0.194 \left( \frac{f_{um}}{f_{30}} \right)^{0.276} \rho^{-0.015} \left( \frac{\varepsilon_{um}}{\varepsilon_{cop}} \right)^{-1.126}
\]

where \(f_{30}\) is the unconfined concrete strength of C30, and \(\varepsilon_{cop}\) is the axial strain at the compressive strength of unconfined concrete. \(\rho\) is the confinement stiffness ratio.

Reloading model

The proposed reloading model (Eq. 5) also adopted the same mathematical form with Li and Wu’s model (Li and Wu 2015), which was originally developed based on Richard and Abbott’s (1975) four parameters function. This expression could model the nonlinear transition zone between two approximately linear parts. Moreover, it also has the ability to predict the descending second part of reloading curve.

\[
f_r = \frac{(E_r - E_2)(\varepsilon_r - \varepsilon_{pl})}{f_r}\left(1 + (\frac{(E_r - E_2)(\varepsilon_r - \varepsilon_{pl})}{f_r})^{n}\right)^{-\frac{1}{n}}
\]

where \(E_r\) is the reloading stiffness, \(f_r\) is the reloading reference stress shown in Figure 1, and \(n\) is the transition parameter. According to the test results (Li and Wu 2016), it can be observed that parameter \(f_r\) displays a dropping trend with the negative \(E_2\). Hence, in the study, \(f_r\) was presented into two separate formulae according to the sign of \(E_2\), as show in Eq. 6. In which the first part was proposed for strain-hardening, and the second part was obtained from the regression analysis of strain-softening curves.
\[ \frac{f_{re}}{f_{co}} = 0.067 \frac{e_{un}}{e_{co}} + 0.733 \rho^{0.1} \quad E_2 \geq 0 \]
\[ \frac{f_{re}}{f_{co}} = -0.084 \frac{e_{un}}{e_{co}} + 1.536 \rho^{-0.122} \quad E_2 \geq 0 \]

Figure 3 shows the parameter effect on reloading stiffness \( E_{re} \), and it is clear that \( E_{re} \) is also highly dependent on unconfined concrete strength and confinement level for FRP-confined concrete specimens. Similar trends as those for \( E_{un} \) can be observed. It is noted that the rate of degradation is faster for concrete specimens with lower confinement (0.3-ply and 0.5-ply) compared with those with higher confinement (1-ply). This decrease trend is more pronounced for specimens featuring a post peak softening behavior. According to these discussion and regression analysis, the \( E_{re} \) expression is given following:

\[ \frac{E_{re}}{E_c} = \left( \frac{f_{re}}{f_{so}} \right)^{0.032} (\varepsilon)^{-0.409} - 0.317 \rho^{-0.064} \]

\[ \varepsilon = \begin{cases} \frac{e_{un}}{e_{co}}, & \text{when } e_{un} / e_{co} \leq 10 \\ 10, & \text{when } e_{un} / e_{co} > 10 \end{cases} \]

The performance of Eqs. 6 and 7 is shown in Figures 4 and 5, respectively.

The value of \( n \) is not as sensitive as other parameters. By combining the current test data and existing database, the model of \( n \) proposed herein is the same as the existing model developed by the authors (Li and Wu 2015):

\[ n = 2.61 \left( \frac{e_{un}}{e_{co}} \right) + 4.88 \]
Plastic strain model

Figure 6 shows that unconfined concrete strength and confinement rigidity are factors affecting the relationship between residual plastic strain and unloading strain, especially the effects caused by CFRP confinement level are more profound for specimens with a strain-softening behaviour. Through data analyses, the following model is obtained:
Concrete under Cyclic Loading

It can be seen from the figure that the proposed model matches both strain hardening and softening test results very well and hence performs very well.

EVALUATION OF PROPOSED MODEL

Figure 7 shows comparisons between predictions of the overall proposed model and the current test results. The unloading strains and reloading strains of the model curves match the test points and all other parts of the theoretical curves are predictions of the proposed model. It can be seen from the figure that the proposed model matches both strain hardening and softening test results very well and hence performs very well.

CONCLUSIONS

A complete cyclic compression stress-strain model was proposed by combining the envelope stress-strain model with the unloading and reloading path model. It is capable of predicting the ascending and descending post peak stress-strain response. For the FRP-confined concrete cylinders, the concrete strength and confinement stiffness ratio were found to influence the shape of the unloading curve, reloading curve and plastic strain. These effects are more profound for specimens exhibiting a post peak strain softening behaviour. Good agreement between the predictions of the model with the test results of this paper represents the capability and accuracy of the proposed model.

ABSTRACT

Fibre-reinforced polymer (FRP) has been extensively used in the retrofit of concrete structure, especially for concrete columns. FRP provides uniform passive confinement for circular columns under axial compression while for non-circular columns and columns under compression with eccentricity, the confinement is non-uniform. True-triaxial experiment is essential to obtain the mechanical properties of concrete under non-uniform confinement. In this paper, the triaxial behaviour of concrete cubes under uniform passive confinement was studied using a new triaxial setup. The results were compared with those of FRP-confined concrete cylinders which have same strength and lateral stiffness ratio. End-friction influence on both fresh concrete cubes and passively confined cubes was analysed. The axial stress-strain behaviour of cubes was modelled including the friction effect. Then the curves of cubes with and without friction effect were compared with those of cylinders. At last, the lateral strain-axial strain curves of cubes and cylinders were analysed. It comes to conclusion that, excluding the friction effect, the stress-strain curve of cubes fit well with that of cylinders. Further, the new testing equipment is ready to provide non-uniform passive confinement for concrete cubes, which can assist the numerical modelling of FRP-confined elliptical or rectangular columns for the sake of engineering practice.

KEYWORDS

Concrete, friction effect, true-triaxial compression, uniform passive confinement.

INTRODUCTION

It is well known that by providing lateral confinement for concrete elements the ultimate axial compressive strength increases considerably. That’s the mechanism of fibre-reinforced polymer (FRP) confined concrete. FRP provides passive confinement, which due to the elongation imposed on it because of expansion of concrete, induces confinement for column. For circular columns, it is commonly accepted that the passive confinement is uniform while for non-circular columns and columns under eccentric compression, the passive confinement is non-uniform. The corresponding mechanical behaviour of concrete is usually studied by wrapping FRP jacket around concrete cylinders (e.g. Xiao and Wu 2003). Then the stress-strain relationship is established based on the experimental results (e.g. Lam and Teng 2003), in which the lateral strain in the middle and average axial strain along the height are commonly adopted as the lateral and axial strain in the constitutive model. Through digital measurement, it can detect the non-uniform strain field in longitudinal direction (Figure 1). The non-uniform deformation can be attributed to the end-friction effect on the column. The additional confinement will exist at 1/3 of the height at each end zone (Figure 1a). Strictly speaking, the recorded stress-strain curves still reflect the structural behavior rather than the material mechanism. Therefore, it needs a more efficient testing method to study the mechanism of concrete under passive confinement. A novel triaxial equipment has been invented by the authors (Jiang et al. 2015) to provide passive confinement for concrete cubes. Regarding the true-triaxial testing, the specimens have different dimension to the standard cylinder. The friction effect of cubes, regarding the stress boundary condition at loading end, needs to be clarified to obtain the inherent mechanical properties of concrete.

209
EXPERIMENTAL PROGRAM

The adopted new triaxial equipment consists of two parts, the vertical loading part and the passive loading part. It was tailored for 100mmx100mmx100mm cubes. The vertical force is applied with the universal testing machine. The passive loading apparatus is composed by the steel box and GFRP bars. The details about the apparatus can be found in Jiang et al. (2015). When the cube is subjected to vertical force, its lateral deformation will initiate the elongation of bars which will generate confinement pressure linearly proportional to the expansion of concrete. To reduce friction on the cube surface, layers of PTFE with an intermediate layer of grease were placed between each surface of the cube and the steel loading plate.

In the experiment, concrete cubes were divided into three groups. Their 28-day strengths were 25.4MPa, 36MPa and 44MPa, respectively. For each group of concrete specimens, uniform passive confinement was provided with four different loading schemes, evaluated by lateral stiffness ratio $\rho=d(f_{f(c)})/d\delta$. This was achieved by using GFRP bars of four different diameters. Table 1 listed the details of specimens. Specimen ID for cubes shows four different loading schemes, evaluated by lateral stiffness ratio $\rho$. The deformation and load data were collected through loading. The measurement scheme is detailed in Jiang et al. (2015).

STRESS-STRAIN BEHAVIOR OF CONCRETE CUBE UNDER PASSIVE CONFINEMENT

The specimens under biaxial uniform confinement were characterized by bi-linear strain-hardening (Figures 2a-2c), which have the same pattern as FRP-confined cylinders. Similarly, the second linear slope decreased when $\rho$ was decreased (from D-D to A-A). The stress-strain curve can be expressed by the piece-wise curve (Eq.1), composed by a parabolic curve followed by a linear curve, as proposed by Lam and Teng (2003) for FRP-confined cylinders. The intersection point $(\varepsilon_0, f_0)$ is termed as the transition state point. The stress-strain curve bifurcates at the transition state point where the passive confinement takes effect.

$$
\sigma_\varepsilon = \begin{cases} 
E_\varepsilon \varepsilon_0 - \frac{(E_\varepsilon - E_0)^2}{4f_0} & (0 \leq \varepsilon_0 \leq \varepsilon_0) \\

$$

(1a,b,c)

where $E_\varepsilon$ is the Young’s modulus, $E_0$ is the slope of second line; $f_0$ is the intersection of second line with the stress axis; $E_2$ and $f_0$ are regressed from the test data.
FRICTION EFFECT ON MECHANICAL PROPERTIES OF PASSIVELY CONFINED CONCRETE CUBE

Due to different Poisson’s ratios between the steel loading plate and the concrete, the non-consistence in expansion between two materials generates the friction between the two surfaces under axial compression. The end friction is the major reason for the variance in concrete specimens with different slender ratio. In order to obtain the inherent characteristic of material, end friction reduction is the basic approach to eliminate the friction effect.

End Friction Reduction for Fresh Concrete Cube

With respect to the dimension of cube, the end-friction can be equivalent to lateral confinement exerted along overall height (Figure 3a). The additional restraint in the specimen end was expected to increase the concrete strength. To eliminate the end-restrain effect, the friction-reduction pad has been commonly adopted in triaxial testing (Van Mier et al. 1997). Herein PTFE laminate (0.05 mm/ply) was adopted to investigate the appropriate number of layers which ranged from 1 to 3. For those with more than one-ply PTFE laminate, the specimens were divided into two groups: with or without grease. The properties of the specimens are detailed in Table 2, together with their test results.

With the increase of the PTFE ply number, the concrete showed a substantial reduction of its peak strength (Figure 3b). In other words, the increase of PTFE layers can achieve smaller friction coefficient between two surfaces. The reduction percentage remained constant when the layer number was larger than two, while the side-wedge peeling could still be observed and the end friction still existed. With additional grease between the laminate layers, the pads of the 2- and 3-ply PTFE laminate can have smaller friction coefficient to slide. The peak strength further decreased to half of the cube strength without a friction-reduction pad. The failure pattern was characterized by

splitting cracking. Accordingly, specimen a2B and a3B were regarded as free of end restrain. By comparison, those with end friction effect experience lateral confinement (Figure 3a) and exhibit similar phenomenon to the cube under constant confinement. The confinement pressure can be derived by introducing the failure criterion function from Wang et al. (1987), and deemed as the equivalent confinement, \( f_{lt} \) (Table 2). It can be found that the direct attachment between steel plate and concrete can exert lateral confinement pressure equivalent to as much as 20% of the true peak strength. Accordingly, the 2-ply PTFE with an intermediate layer of grease was adopted as the friction-reduction pad for the following triaxial compression tests.

**End Friction Reduction for Passively Confined Concrete Cube**

With additional lateral passive confinement, the cube has two major features different from fresh cube, that is, the delayed dilation and continuous increase in axial loading bearing. As reported in Van Mier et al. (1997), the Teflon friction reduction pad has stick-slip behavior. The free of friction force will be stabilized after certain sliding. In practice, the free of restrain will be fully generated at post-peak for fresh concrete due to fast development in lateral expansion. For passively confined cube, the severe lateral dilation is restrained by progressive confinement, which will postpone the state of free of restrain. Moreover, the larger axial loading forces the grease to be squeezed out of Teflon pad. It can be observed that the oil spots scattered on the loading surface of tested specimen which reflects the uneven contact surface. The micro-cracking on loading surface may rough the pad under high level of compression, which will increase the friction coefficient between interlayer sliding.

The axial stress at transition point \( (\epsilon_{lt}, f_{lt}) \) is adopted as the reference point to evaluate the additional restraint caused by end friction. Since concrete experienced minor damage before it reaches the transition state, it can consider non-path dependence between passive and active confinement (Xiong et al. 2016). By introducing the failure criterion function obtained from traditional triaxial tests (Wang et al. 1987), the lateral confinement \( f_{lt} \) required to achieve \( f_{lt} \) is obtained. The resulting values of \( f_{lt} \) for current specimens exhibit much larger than the lateral confinement \( f_{lt} \) exerted by the lateral loading apparatus corresponding to the transition point (Figure 4). The difference in the experiment is attributed to the additional restraint because of end friction. The effect of end friction is related to fresh concrete strength.

Previous research has been done on 150mm×300mm concrete cylinders (Jiang and Teng 2007; Wu and Jiang 2013). To exclude the effect from unconfined concrete strength and confinement stiffness, the compared cylinder specimens were selected based on the same value of concrete strength \( f_{c0} \) and lateral stiffness ratio \( \rho \) (Table 3). Herein, the end friction effect on the stress is excluded from the testing results. Axial stress at transition point \( f_{lt} \) is substituted with the axial stress \( f_{lt} \) calculated from triaxial failure criterion function setting the lateral confinement as \( f_{lt} \). Then the curves of cubes with and without friction effect are compared with those of cylinders in the same group in Figure 5. Figure 6 illustrates the comparison of lateral strain vs. axial strain curves. As can be seen, the axial stress-strain curves have close match between cylinders and cubes, but with minor variation without clear trend. The same phenomenon can be observed in lateral strain vs. axial strain curves. However, it
can be found the axial strain in cube has the same difference trend at the same axial stress and lateral strain, to compare with cylinder. That demonstrates that the axial strain detected in the cube reflect the localized value in the cylinder. And since the axial strain data scatters along the longitudinal direction (Bisby and Take 2009, Figure 1b), it also results in the comparison having no clear trend.

Figure 5 Comparison of axial stress-axial strain curves between cylinders and cubes

Figure 6 Comparison of lateral strain-axial strain curves between cylinders and cubes
CONCLUSIONS

In this paper, the mechanism of concrete under passive confinement was studied with triaxial experiment on concrete cubes using a new triaxial equipment. The friction effect of cubes was clarified to obtain the inherent mechanical properties of concrete. Conclusions have been drawn as follows:
(a) Axial stress-axial strain curve of cubes under biaxial uniform confinement were characterized by bi-linear strain-hardening, which have the same pattern as cylinders. The second linear slope decreased when lateral stiffness ratio was decreased. The stress-strain curve was expressed by the piece-wise curve, composed by a parabolic curve followed by a linear curve.
(b) End friction is the major reason for the variance in concrete cubes and cylinders. For fresh concrete cube, with increase of PTFE ply number, concrete showed a substantial reduction of its peak strength. With grease between 2-ply PTFE laminate, the peak strength decreased to half of the cube strength without a friction-reduction pad. The direct attachment between steel plate and concrete can exert lateral confinement pressure equivalent to as much as 20% of the true peak strength.
(c) End friction effect on passively confined concrete was quantified. It results additional confinement which is related to the unconfined concrete strength. When friction effect on axial stress is excluded from original testing data, the axial stress-axial strain curves of cubes have minor difference to those of cylinders. The corrected cubic results reflect the localized condition in FRP confined cylinders.

ABSTRACT

A novel equipment is introduced which is able to conduct tri-axial and bi-axial passive confined tests on concrete cubes. Lateral stiffness ratio is provided by which the level of confinement can be adjusted for each lateral direction. An experimental set-up is proposed which is used for calibration of the measurement system in lateral directions. The friction between loading platens and concrete has been released so that the test results are validated in comparison to typical circular FRP confined columns. Comparison of preliminary tests with finite element results reveals that the proposed experiment is able to verify the accuracy of models which are developed for three-dimensional modelling of non-uniform FRP confined concrete columns.

KEYWORDS

FRP, tri-axial, bi-axial, load path dependent, concrete cube, dilation properties, passive confinement.

INTRODUCTION

Fiber reinforced polymers (FRPs) are used to enhance the strength and ductility of concrete columns. Numerous empirical and semi-analytical models have been developed for FRP confined concrete columns (Jiang and Teng 2007; Wei and Wu 2012). Also, plasticity based material models are used with finite element methods (FEM) to capture the strength and deformational behavior of such structures (Karabinis et al. 2008; Yu et al. 2010a; Yu et al. 2010b). For FEM, users need to adjust the parameters of constitutive material models. This adjustment is done by using tri-axial concrete tests (Jiang and Wu 2014; Rousakis et al. 2007; Teng et al. 2015). All existing tri-axial concrete cube tests are for active confinement. Concrete is load path dependent material and recently it was shown that behavior of concrete under passive confinement is different from that in active confinement (Lim and Ozbakkaloglu 2014; Ozbakkaloglu et al. 2016). Also, the lateral deformations of concrete in tri-axial tests are required for calibration of material models. Existing active concrete cube tests can hardly get the lateral deformations after peak stress.

For addressing the above issues, this study introduces a tri-axial testing equipment for conducting multi-axial passive confined tests on concrete cubes. The confinement level in each lateral direction is adjustable so that different non-uniform passive confinement i.e. tri-axial and bi-axial tests can be conducted. The preliminary results for monotonic tests are illustrated. Finally, FEM is used by concrete damage-plasticity material model (Yu et al. 2010b) to compare experiments with numerical results. The proposed test is able to verify the accuracy of models which are developed for three-dimensional modeling of FRP confined concrete columns.

EQUIPMENT DESIGN

The second author (Jiang and Wu 2014) for the first time proposed the design of tri-axial passive testing equipment as shown in Figure 1. A concrete cube is confined by metal plates and in lateral directions clamped elastic bars are used to imitate the passive confinements. The axial force is applied in the direction normal to the paper and concrete expands in lateral directions so that lateral confinements are activated. This idea for the first time could be implemented at Tongji University (Jiang et al. 2015) by means of FRP bars. However, as shown in Figure 1b the clamping system is very large due to the problem of threading FRP bars. In present study as shown in Figure 1a, Aluminium bars are adopted for elastic bars and standard steel nuts are used for clamping. Also, Aluminium is used for confining plates to minimize the weight of plates. The size of the concrete cube is 150 by 150 mm.

In typical FRP confined columns the lateral stiffness ratio \( \rho \) is a function of FRP stiffness \( E_{frp} \), FRP thickness \( t_{frp} \), unconfined concrete strength \( f_{cu} \) and diameter of column \( D \) (Jiang and Wu 2012):
\[ \rho = \frac{2E_{\text{bar}}A_{\text{bar}}}{Df_{\text{co}}} \]  

(1)

(a) Proposed design  
(b) First implementation (Jiang et al. 2015)

Figure 1 Equipment design

In present equipment by using equilibrium and compatibility between concrete cube and confining plates, the following lateral stiffness ratio is obtained as a function of elastic bar stiffness \( E_b \), length of bars \( L_b \), cross-sectional area of bars \( A_b \) and cross-sectional area of concrete \( A_c \):

\[ \rho = \frac{4E_b}{f_{\text{co}}} \left( \frac{A_b}{A_c} \right) \left( \frac{L_c}{L_b} \right) \]  

(2)

The coefficient of four is for having four bars in each lateral direction. Therefore in each lateral direction by equating Eqs. (1) and (2) the thickness and length of elastic bars are calculated.

CALIBRATION

In real tests, Linear Variable Differential Transducers (LVDTs) are used to capture lateral displacements. In Figure 2, a couple of confining plates is shown. Two LVDTs named as LVDT-S are located at sides, the same as real test measurement system to measure concrete lateral deformations. However, the confining plates will bend due to concrete expansion. The designed plates should be rigid enough in order to capture correct lateral displacement of the concrete cube. Plates are designed and their flexural rigidity is checked by FEM modelling. Finally, a calibration procedure is designed as in Figure 2. A hydraulic jack is located between the plates. All system is located on a surface covered with greasy Teflon in order to let the plates move freely. Figure 2 shows the top view. The length of jack plus other components located between plates is almost equal to the length of the concrete cube. The hydraulic jack pushes the plates while they are clamped with Aluminum bars (shown with dashed lines). The displacements are measured through the couple of LVDT-S at sides as well as by the couple of LVDT-C at center. The overall measurement at the central LVDTs should be equal to that for the side LVDTs. If this condition is not met then the rigidity of plates should be increased e.g. by changing the thickness of plates.

In real tests, the lateral displacement measured by the couple of LVDT-S is not equal to concrete lateral deformations. It includes extra deformations related to other components i.e. Teflon and confining plates. To measure the extra deformations, as shown in Figure 2, another type of calibration is conducted. This time, the couple of LVDT-M, the couple of LVDT-S and strain gauges are used for measurements. The geometry and stiffness of steel cubes are known. Therefore, lateral pressure is calculated by means of strain gauges. Also, the value measured by the couple of LVDT-M is subtracted from that measured by LVDT-S to calculate extra part of measured lateral displacements. As a result, the extra lateral displacement is obtained as a function of lateral pressure. Such a calibration test should be repeated for all type of elastic bar diameters which are used in real tests. Calibration in the axial direction is referred to Mohammadi and Wu (2016) for the sake of brevity.
VALIDATION

When the level of confinements in lateral directions are equal, then the cube test is the same as a typical circular FRP confined column. However, the friction between the concrete cube and loading platens should be released. Trial tests of Mohammadi and Wu (2016) revealed that three layers of Teflon sheets should be used at top and bottom faces of the concrete cube and a single Teflon layer is needed for other faces to release the friction properly. Adopted Teflon thickness is 0.05 mm. The final validation test is shown in Figure 3 in which cylindrical column tests are compared to present tests for one ply CFRP confinement. The thickness and stiffness of FRP are 0.165 mm and 245 GPa respectively.

RESULTS

Preliminary monotonic tests are depicted in Figure 4 in which the major confinement level is one ply of CFRP (thickness per ply=0.165 mm, stiffness=245 GPa). The minor confinement level is changing with half and zero plies of CFRP. The thickness and length of Aluminium bars are calculated by equating Eqs.(1) and (2). Evidently, stress-strain of a non-uniform confined cube is similar to a circular FRP confined column. But the ultimate strength
decreases when the minor level of confinement is decreased. Also, each lateral direction dilates with a constant different rate. However, the bi-axial stress-strain behaviour of concrete is totally different and the confined direction does not dilate after peak strength. This type of behaviour may happen in non-uniform FRP confined columns near the side of cross sections, especially in rectangular confined columns.

![Diagram](image-url)

**Figure 4** Tri-axial and bi-axial passive confined compression tests \( f_{c'} = 25.63 \text{MPa} \) (a) 1 Plies-1 Plies CFRP (b) 1 Plies-0.5 Plies CFRP (c) 1 Plies-0 Plies CFRP (d) 0.5 Plies-0 Plies CFRP

**DISCUSSION**

In modelling of non-uniform FRP confined columns e.g. square columns the elements near the rounded corners sustain uniform confinement. Also, the elements at sides of the cross section may sustain bi-axial or triaxial state of stress. The present experiments can provide the experimental data for verification of models which are developed for three-dimensional modelling of FRP confined concrete columns. A proper constitutive material model should be able to capture the stress-strain behaviour as well as dilation behaviour of bi-axial and tri-axial passive confined cube tests. Besides this, the material model should be able to capture the global strength and deformation of a non-uniform FRP confined columns. In this regard, for three-dimensional modelling of FRP confined columns the advanced model developed by Yu et al. (2010b) which is able to model the behaviour of non-uniform FRP confined columns is adopted. That model utilizes analysis oriented model of Teng et al. (2007) to calibrate the Concrete Damage-Plasticity Model developed by Lubliner et al. (1989) and implemented in ABAQUS. The accuracy of that model has been clarified by FRP confined columns and here the present experiment provides the only way for verifying the accuracy of that model (and any other model) for capturing the behaviour of concrete elements under non-uniform passive confinements.

To this aim, the concrete material is modelled with Concrete Damage Plasticity the same as Yu et al. (2010) model. However, the required analysis oriented model is replaced with the model of Jiang and Teng (2007) which is superior for capturing the softening behaviour compared to the old model. A single concrete element is modelled and the passive confinement is applied on each face. The results are shown in Figure 5. As shown in Figure 5a-b whenever the dilation behaviour is captured successfully then the stress-strain is captured very close to experiments.
However, as shown in Figure 5c, FEM cannot capture the dilation properties successful enough for softening cases then the strength behaviour is not captured very well.

Figure 5 Comparison of tests with concrete damage plasticity developed by Yu et al. (2010) : (a) 1 Plies-1 Plies CFRP (b) 1 Plies-0.5 Plies CFRP (c) 1 Plies-0 Plies CFRP (d) 0.5 Plies-0 Plies CFRP

The present test method is able to provide the experimental data for verification as well as modification of material models which are developed for three-dimensional modelling of non-uniform FRP confined columns. Establishing a proper dilation properties such as the one proposed by Teng et al. (2007) is essential for developing analysis oriented models and for developing calibration procedures of plasticity based material models. In this regard, for dilation properties of non-uniform confined columns, the lateral strain captured around the perimeter of columns is variable and dependent on how to attach strain gauges on the surface of the column (Wang and Wu 2008). The present test uses LVDTs for capturing the dilation under non-uniform passive confinement. The proposed measurement system can provide accurate dilation properties.

CONCLUSION

A new multi-axial testing equipment was introduced which is able to conduct biaxial and tri-axial passive confined compression tests. The calibration procedure for lateral strain measurement system was elaborated. Therefore the system can be replicated by others. The friction on concrete cube faces could be released. Typical FRP confined concrete columns were used to validate the stress-strain and the dilation properties captured by presented equipment. Comparison of tests with FEM results shows that the present tests can provide a simple way for verifying the accuracy of any material model developed for three-dimensional modelling of FRP confined concrete columns.

ABSTRACT
Reinforced concrete structures have good fire resistance due to the inherited properties of concrete. Depending on the intensity and duration of fire, concrete properties deteriorate at different rates. Several researchers have documented the compressive properties of fire damaged concrete. Carbon fiber reinforced polymer (CFRP) composites have been successfully used for strengthening of circular column. Transverse wrapping of circular column could enhance confinement, shear resistance, enhance flexural ductility, and increase axial strength. CFRP wrapping increases the both axial strength and ductility of circular concrete columns, including the columns with low concrete compressive strength damaged by fire. This paper presents analytical investigation into the axial strength of fire damaged concrete columns strengthened with transverse CFRP wrapping. The results in this research suggest that CFRP wrapping should increase the axial strength of fire damaged circular concrete columns.

KEYWORDS
Axial strength, circular concrete column, fire damaged concrete, CFRP wrapping.

INTRODUCTION
Fire damage is one of the leading causes of structural damage around the world. With increasing population densities and larger buildings being built, it is safe to say that concrete structural-fires will be occurring at an increasing rate in the future unless methods to stop them are implemented.

The changes that occur to fire damaged concrete structures depend on the temperature level achieved, exposure time, and the cooling conditions. Concrete is a versatile material and when properly specified, is comparatively fire proof compared to most building materials because of its non-flammability and thermal insulation properties. However, severe temperatures and prolonged exposure to a high temperature fire results in reduction in both the compressive and tensile strength of concrete. The thermal changes cause the aggregate in the concrete to breakdown by means of cracking, which will lead to phenomenon called disaggregation. This is when the bond between the concrete paste and the aggregate is lost. Other phenomenon’s that occur to concrete when exposed to fire is explosive spalling, sloughing off, fine cracks, and wide cracks. Most fine cracks are confined to the surface where wide cracks near supports may mean a loss of anchorage or yielding of reinforcement bars. A number of changes will occur when concrete is exposed to high temperatures and they are all dependent on the temperature of the fire at that time. Concrete strength is affected by the variation of temperature, rate of heating, duration of heating, imposed load, type and size of aggregate, percentage of cement paste, and the water cement ratio. High temperatures will result in concrete compressive and tensile strength reduction, disaggregation, spalling, and cracking.

Carbon fiber reinforced polymer (CFRP) composites have been used for structural strengthening in the United States for almost 25 years. During this period, acceptance of CFRP composites as a mainstream construction material has grown, and so has the number of completed FRP strengthening projects. As a result, the use of CFRP for strengthening and rehabilitation is gaining more popularity among design professionals over conventional strengthening techniques.

CFRP strengthening of fire damaged concrete structures can involve complex evaluation, design, and detailing processes, requiring a good understanding of the existing structural conditions along with the materials used to repair the structure prior to CFRP installation. In the past few decades, research has demonstrated that for a compression member, the use of CFRP wrapping can result in an increase in load-carrying capacity and ductility.
In terms of the repair of post-heated concrete members, only a few studies have considered the use of CFRP fabrics for subsequent strengthening (Saafi and Romine, 2002, Cleary et al., 2003, Bisby et al., 2011, Yaqub and Bailey, 2011, Al-Kamaki and Al-Mahaidi, 2013). To date, several testing has been undertaken on RC-loaded columns by using electrical furnaces. However, these studies didn’t cover the analytical investigation of fire damaged concrete structures repaired with CFRP wrapping.

ANALYTICAL INVESTIGATIONS

Effects of elevated temperatures on the concrete properties

Concrete is regarded as a heat resistance material compared with other materials because of the low thermal conductivity of concrete at high temperatures. The thermal properties of concrete are highly dependent on the type of aggregate in the concrete. The certain aspects of concrete is affected by different aggregate types when exposed to high temperatures. These high temperatures caused by fire may create internal shear stresses due to the differences in thermal properties between the cement paste and the aggregates. Several concrete properties like the compressive strength of concrete at high temperatures varies according to the type of aggregate, cement to aggregate ration, and the degree of loading, among some other factors.

The temperature level achieved, exposure time, and the cooling conditions together controls the changes that occur to concrete. Concrete is a versatile material and when properly specified, is practically considered “fire proof” compared to most building materials because of its non-flammability and thermal insulation properties. However, severe temperatures and prolonged exposure to a high temperature fire will definitely results in decreases in both the compressive and tensile strength in concrete. The thermal changes results the aggregate in the concrete to breakdown by means of cracking, which will lead to phenomenon called disaggregation. This is when the bond between the concrete paste and the aggregate is lost. Other phenomenon like explosive spalling, sloughing off, fine cracks, and wide cracks will occur to concrete when exposed to high temperature. Most fine cracks are confined to the surface where wide cracks near supports may mean a loss of anchorage or yielding of reinforcement bars. These cracks are very import when examining a member after exposed to fire. A professional must be able to understand and evaluate what the concrete member experienced throughout fire based on visual examinations let alone the tests taken.

A series of changes will occur when concrete is exposed to high temperatures. These changes are dependent on the temperature of the fire at that time. Concrete strength is affected by the variation of temperature, rate of heating, duration of heating, imposed load, type and size of aggregate, percentage of cement paste, and the water cement ratio. High temperatures will lead to the reduction of concrete compressive and tensile strength, disaggregation, spalling, and cracking.

Concrete remaining strength after fire

The remaining strength of concrete after fire damage cannot be decided by simply ways of evaluation or calculation. Normally, when concrete rises above 100°C, moisture is driven out and the cement paste will begin to dehydrate. The aggregate particles will start to expand generating large internal strains. Micro cracking may begin, however, the integrity of the concrete is not really affected. When the temperatures exceed 300 °C, compressive strength will be threatened. Tensile strength is reduced immediately and continues to decrease as temperatures increase. Above 350 °C, some aggregates will dehydrate and begin to break off, particularly flint gravels. Some aggregates can withstand much higher temperatures such as crushed granite. As temperature increases other phase transformation occurs such as successive dissociation of calcium hydroxide and calcium carbonate. This may happen before the melting point of 1200 °C. A temperature line has been made to help better understand what a reinforced concrete member will generally go through as a fire increases in temperature throughout the burning phase (Figure 1). The concrete color will change throughout the rise in temperature and usually depends on aggregate type.

Because concrete has such great thermal properties, concrete itself is considered as a shield against the high temperatures. Generally, a cross section of concrete column with various temperature gradients throughout has areas of varying strength due to those temperature gradients. Each of these differential areas of the cross section contributes strength to the overall strength of the column. For ease of design and analysis, several conservative methods have been proposed to deal with temperature variations across the concrete section. The 500°C isotherm method and the 400/600°C isotherm method are two of those methods.
The first method called 500°C isotherm method considers that any portion of the cross section above 500°C has zero strength while only the part of section below 500°C contributes strength. Another method, the 400/600°C isotherm method uses two ways instead of one to predict the strength of the column. The method assumes that concrete sections below 400°C acquire 90% strength, those between 400°C and 600°C acquire 70% strength, and sections above 600°C have no contribution at all.

These are all approximate estimation methods because the actual strength of concrete decreases continuously from ambient temperature. Figure 2 shows the compressive strength of siliceous aggregate concrete. The compressive strength started decrease from about 100°C and the remaining strength decreased to about 20% of its original strength when the temperature reached about 700°C. The isotherm methods try to approximate the strength curve while still allowing for ease of calculations. The red line in Figure 2 is the strength assumption of the 500°C isotherm line, and the blue line is the strength assumption of the 400/600°C isotherm method. Each of these methods assumes that the cross-section remains intact throughout the entire heating and cooling process (Buchanan, 2002) (Society of Fire Protection Engineers, 2008).

Figure 3 below shows how a concrete column with diameter of 24in. will resist a typical fire that lasts for 2 hours. It also shows the strength of the same column in percentages after 2 hours. Based on the temperatures, the
remaining strength of the column would most likely be efficient enough to support the load that it was designed for. (Lie, T. T. (1992))

Figure 3 Concrete resistance to fire (Lie, T. T. (1992))

A reduction coefficient should be considered when measuring the remaining strength of the fire-damaged concrete after the cooling. The reduction coefficient is quite different according to different temperature and is also affected by the different cooling methods and type of the concrete. Table 1 shows the result of one experiment applied by W. Kong fan. It shows the performance of concrete cooled down from high temperature.

The Method of Applying CFRP to Concrete Column

Material Property

Table 2 below shows the properties of the CFRP materials used in this investigation.

| Thickness per layer t<sub>f</sub> | 0.0113in. |
| Rupture strain ε<sub>fu</sub> | 0.0167in./in. |
| Modulus of elasticity E<sub>f</sub> | 33000ksi |

Calculation of the strength gained from CFRP wrapping

CFRP systems can be used to enhance the axial compression strength of a concrete member by providing confinement with a CFRP jacket. Confining a concrete member is accomplished by orienting the fibers transverse to the longitudinal axis of the member. In this orientation, the transverse or hoop fibers are similar to conventional spiral or tie reinforcing steel. Any contribution of longitudinally aligned fibers to the axial compression strength of a concrete member should be neglected. (ACI.2R_08). In this study, Lie, T. T. (1992)’s evaluation method combined with the reduction coefficient was adopted, which calculates the remaining strength of concrete column by dividing its cross section into several layers as shown in Figure 4. Different diameter and type of concrete and different condition of fire may lead to quite different result. We just take the temperature to be around 500°C and other conditions to be mentioned above to see the result. Assume the diameter of the column to be 100 cm x 100 cm.
The axial compressive strength of a non-slender, normal weight concrete member confined with an FRP jacket can be calculated using the confined concrete strength. The maximum confined concrete compressive strength \( f_{cc}' \) can be calculated from ACI.2R_08.

\[
f_{cc}' = \psi_f 3.3 K_a f_l + f_c'
\]

where
- \( f_c' \) (the peak concrete strengths for unconfined)
- \( \psi_f \) (an additional reduction factor) = 0.95
- \( K_a \) (shape factor) = 1
- \( f_c' \) (the effective strain level in the FRP at failure) = \( K e_{fu} = 0.586 e_{fu} \)
- \( n \) (the number of piles)
- \( f_l \) (the maximum confinement pressure) = \( \frac{2E_f t_f e_f}{D} \)

According to the remaining strength of the concrete column after the fire damage mentioned above, the concrete compression strength could be calculated, as presented in Table 3.

CONCLUSIONS

CFRP can be utilized as strengthening technique for increasing the axial load carrying capacity of fire damaged circular reinforced concrete columns. The axial compressive strength of fire damaged concrete increases significantly by warping with CFRP composites. The amount of strength gained from CFRP can be calculated according to the ACI.2R_08. The amount and warping method of CFRP for certain RC columns damaged by fire depends on the column type and condition. Further study and experiments are needed for assessing the remaining strength of the CFRP strengthened fire-damaged concrete structures.

ABSTRACT

The enhancement of the axial strength of plain concrete columns wrapped with fibre-reinforced polymer (FRP) fabrics has been extensively investigated, both analytically and experimentally. Respective research on reinforced concrete (RC) columns strengthened with FRP is significantly more limited. This paper deals with axially loaded RC columns fully wrapped with carbon and glass FRP, with circular, square, and rectangular cross-section. A simple design model is proposed and described in detail, which has resulted from a combination of Eurocode provisions in such a way that the predictions are good and also safe. Furthermore, three models from the literature, selected among others because of their good agreement with experimental data, are also presented and some of their aspects are discussed. All models are applied to 95 specimens tested in the literature. The criteria for selecting the models presented here were their simplicity in application, combined with their accuracy in predicting the strength of test data available in the literature.

KEYWORDS

FRP, RC column, reinforcement, models, axial strength.

INTRODUCTION

Available design models that calculate the ultimate strength of reinforced concrete (RC) columns strengthened with fiber-reinforced polymer (FRP) fabrics are based on a variety of approaches. The models propose, in general, a procedure that takes into account the lateral confining contribution of both factors: steel stirrups and FRP. They differ, though, in the approach they adopt to calculate this contribution. The lateral confinement pressure because of steel confinement is usually taken into account by the Mander et al. (1988) model, by calculating the effectiveness in confinement according to the layout of stirrups in height and in the plane of the cross-section (CEN 2004a; Wang and Hsu 2007; Pellegrino and Modena 2010; Rousakis and Karabinis 2008; Galal et al. 2005; Illiki et al. 2008), or by a different procedure (Tastani et al. 2006), or not taken at all into account (Esfahani and Kianoush 2005). The lateral confinement pressure of FRP is calculated usually by the well-known formula yielding of stress equilibrium in the cross-section (Mirmiran and Shahawy, 1997), or by empirical equations (Rousakis and Karabinis 2008). A basic parameter that leads to different results is the value of rupture strain of the FRP used to calculate the maximum lateral pressure offered by the FRP (for which the value of 60% of the ultimate tensile strain determined by the direct tension tests was proposed by Lam and Teng, 2003). Furthermore, in case of rectangular cross-sections, different empirical factors are introduced in each model in order to account for the reduced confinement provided (Pellegrino and Modena 2010). Finally, the models differ considerably in the way they calculate the ultimate confined concrete strength from the lateral pressure. Attempts have been made also to take into account the negative effect of buckling of the longitudinal steel bars (Pellegrino and Modena 2010; Bai et al. 2012; Tastani et al. 2006) which may lead to premature failure. This paper presents four models, among a number of models considered elsewhere (Paparizos 2016; Miliokas 2016), that were found to lead to the best predictions of an experimental database of 95 specimens from the literature. In detail is presented only the model proposed, which has resulted from a combination of Eurocode provisions in such a way that the predictions are good and also safe. From the three other models presented only particular issues are discussed, while all the details may be found in the original publications.

PRESENTATION OF SOME ASPECTS OF THE MODELS CONSIDERED

Eurocodes do not explicitly describe how to estimate the ultimate axial capacity of FRP-confined RC columns, although EN1998-3 offers equations to separately calculate the confinement effect of steel and FRP. Furthermore, alternative procedures are offered to calculate the lateral confinement pressure due to FRP. Therefore, the model presented in this paper is the result of the combination of provisions in EN1998-3 (CEN 2005), EN1998-1 (CEN 2004a) and EN1992-1-1 (CEN 2004b). This calculation procedure has been found to lead to good and safe predictions (Figure 1a, Table 2) and will be presented in detail in the following. The stress-strain relation of confined concrete compressive strength, \( f_{ck} \), in relation to the effective lateral compressive strength, \( \sigma_2 \), and the characteristic compressive concrete strength of concrete at 28 days, \( f_{ck} \), is calculated according to Eqs 1a and 1b from EN1992-1-1 (CEN 2004b):

\[
\begin{align*}
    f_{ck,a} &= f_{ck}(1.0 + 5.0\sigma_2 / f_{ck}) & \text{for } \sigma_2 \leq 0.05 f_{ck} \\
    f_{ck,a} &= f_{ck}(1.125 + 2.5\sigma_2 / f_{ck}) & \text{for } \sigma_2 > 0.05 f_{ck}
\end{align*}
\]

The confinement pressure applied by the FRP sheet is calculated from Eq. 2:

\[
f_{f,frp} = 2E_f \varepsilon_{ju} / D
\]

where \( E_f \) is the FRP elastic modulus, \( \varepsilon_{ju} \) is the ultimate strain of FRP, \( t_f \) is the total thickness of the FRP jacket, and \( D \) is the diameter in case of a circular cross-section, or the larger cross-section width in case of rectangular cross-sections. It is noted that EN1998-3 (CEN 2005) specifies that \( \varepsilon_{ju} \) is “the adopted FRP jacket ultimate strain, which is lower than the ultimate strain of FRP \( \varepsilon_{ju} \) ”, setting elsewhere 0.015 the limit strain for CFRP. However, since no effectiveness factor is explicitly mentioned in the code, the model has been applied in this work using the ultimate strain for the FRP materials. To account for the increased axial strength this assumption would result, the contribution of longitudinal reinforcement is not included in calculating the ultimate axial strength. It is noted that the lateral strains measured on the FRP jacket in column tests, have shown considerable variation along the same cross-section (Pellegrino and Modena 2010 and Wang et al. 2012). Therefore, it is difficult to decide which value of the FRP rupture strain is more representative to adopt for the calculation of the confining lateral pressure at the ultimate load. The values of the in-situ jacket rupture strains adopted in the various models vary, e.g. Lam and Teng (2003) assume \( \varepsilon_{ju} = 0.586 \varepsilon_{ju} \), while Illiki et al. (2008) assumed \( \varepsilon_{ju} = 0.85 \varepsilon_{ju} \), both studies for carbon FRP jackets. Both models in these two papers show very good correlation with the experimental results.

The confinement pressure due to steel stirrups, \( f_{s,sl} \) is proposed to be calculated by Eq. 3 (among different alternatives supplied in EN1998-3 (CEN 2005):

\[
f_{s,sl} = a \rho_{sx} f_{yw}
\]

where \( f_{yw} \) the stirrup yield strength (in MPa), \( \rho_{sx} = A_{sx} / b_h s \) =ratio of transverse steel parallel to the direction x of loading, with \( s \) the stirrup spacing, and \( a \) being the confinement effectiveness factor, calculated according to Eqs 4a, 4b and 5, for circular and rectangular cross-sections, respectively (EN1998-1, CEN 2004a):

\[
\begin{align*}
    a &= (1 - s / 2d_h) & \text{circular cross-section with spiral hoops} \\
    a &= (1 - s / 2d_h)^2 & \text{circular cross-section with circular hoops} \\
    a &= (1 - 6h_i b_h / b_h) / (1 - s / 2d_h) & \text{rectangular cross-section}
\end{align*}
\]

where \( d_h \) is the diameter of the confined circular core (to the centreline of hoops), \( h_i \) and \( b_h \) are the depth and width, respectively, of the confined rectangular core (to the centreline of hoops), \( s \) is the spacing of hoops, and \( b_h \) is the distance between consecutive longitudinal bars, engaged by a tie or a stirrup.

The confined concrete strength, \( f_{ck,a} \), is calculated according to Eqs 1a and 1b, by calculating the total lateral confinement pressure due to both FRP (Eq. 2) and stirrups (Eq. 3):

\[
\sigma_2 = f_{f,frp} + f_{s,sl}
\]

Pellegrino and Modena model (2010)

The model is applicable to columns with and without steel, for all types of cross-sections. It has been calibrated against a vast number of specimens with and without steel reinforcement and takes explicitly into account a number of parameters that other models do not consider. The authors propose the use of an empirical formula to calculate the coefficient of efficiency, \( k_e \), of the FRP, i.e. to calculate the actual tensile FRP-rupture strain, \( \varepsilon_{ju} \) from the ultimate strain of FRP \( \varepsilon_{ju} \), \( \varepsilon_{ju} = k_e \varepsilon_{ju} \). For RC elements \( k_e \) considers the effect of FRP stiffness on restraining
steel buckling, is calculated according to Eq. 7, and depends on parameter \( C \) that expresses the ratio of mechanical steel percentage \( (E_{y,\text{long}} \cdot \rho_{y,\text{long}}) \) to the mechanical FRP percentage \( (E_f \cdot \rho_f) \), where \( E_{y,\text{long}} \) and \( \rho_{y,\text{long}} \) are the elastic modulus of the longitudinal steel reinforcement and the longitudinal steel ratio, respectively, \( E_f \) is the elastic modulus of FRP and \( \rho_f = 4t_f / D \) for circular- and \( \rho_f = 2t_f (b + h) / bh \) for rectangular cross-sections, with \( D, b, h \) the geometric dimensions of the cross-section.

\[
k_u = \gamma = \frac{E_{y,\text{long}} \cdot \rho_{y,\text{long}}}{E_f \rho_f} \leq 0.8
\]

where \( \gamma = 0.7 \) for CFRP and \( \gamma = 1.5 \) for GFRP fabric.

**Rousakis and Karabinis model (2008)**

The model is applicable to circular and square cross-sections. Formulas are offered (from regression analysis) to calculate the confined strength due to FRP. \( f_{cc,\text{FRP}} \) in which tensile FRP-rapture strain \( \varepsilon_{ju} \) is not needed: Eqs 8 and 9, for round and square cross-sections, respectively. The total confined strength of the element is calculated as sum of the independent contribution of FRP, of stirrups and of longitudinal reinforcement.

\[
f_{cc,\text{FRP}} / f_{co} = \left( \rho_f E_f / f_{co} \right) \left( 0.4142 E_f \cdot 10^{-6} / E_{yu} + 0.0248 \right) + 1
\]

\[
f_{cc,\text{FRP}} / f_{co} = 2 \left( \rho_f E_f / f_{co} \right) \left( 0.4142 E_f \cdot 10^{-6} / E_{yu} + 0.0248 \right) / (2r/b) + 1
\]

where \( \rho_f = 4t_f / D \), and \( D, b \) and \( r \) are the diameter, external dimension of square section, and the corner radius, respectively.

**Ilki et al. model (2008)**

Applicable to CFRP-confined RC elements, this model calculates the confined concrete strength as sum of the enhancement due to (a) CFRP (Eq. 10), (b) internal transverse reinforcement (ITR, Eq. 11) and (c) the unconfined concrete strength of the RC specimen, assumed to be 85% of the standard cylinder strength at the time of testing if the strength of the same unconfined specimen is not available.

\[
f_{cc,\text{FRP}} = f_{co} + 2.54 f_{I,\text{FRP}}
\]

\[
f_{cc,\text{ITR}} = f_{co} + 4.54 f_{I,\text{ITR}}
\]

where \( f_{I,\text{FRP}} \) the effective lateral confinement stress, calculated according to Wang and Restrepo (2001) for CFRP, and a \( f_{I,\text{ITR}} \) the lateral stress for ITR confinement, according to Mander et al (1998). Tensile rupture CFRP strain is assumed to be 85% of the ultimate strain \( \varepsilon_{fu} \).

**COMPARISON WITH EXPERIMENTAL RESULTS**

The data used to evaluate the predictive capacity of the models consist of 95 specimens, with circular, square, and rectangular cross-sections. The specimens considered had, in general, steel reinforcement and were wrapped with FRP fabric extending to the whole height of the column: thirteen specimens with glass FRP fabric (GFRP), and the rest with carbon FRP fabric (CFRP). The test data is taken from the following publications: Bai et al. (2012), Bourmas et al. (2007), Carey and Harries (2005), Chaalal and Shahawy (2000), Chastre and Silva (2010), Cole and Belbari (2001), De Luca et al. (2011), De Paula and Da Silva (2002), Esfahani and Kianoush (2005), Feng et al. (2002), Harajli et al. (2006), Ilki et al. (2008), Li et al. (2003), Matthys et al. (2006), Rodriguez and Silva (2001), Roussakis and Karabinis (2008), Tastani et al. (2006), Wang and Hsu (2008), and Wang et al. (2012). The range of the test parameters in the database included are grouped in Table 1. It is noted that the range of the test parameters provided is purely indicative, since only the precise values of all parameters used in each specimen may be representative of the actual behavior of the specimen.

In Figures 1a, 1b and 2a, 2b, the axial strength from the test (“experimental”) is compared to the respective value predicted by each design model considered (“model”). All values are expressed in MPa. In the model of Rousakis and Karabinis (2008) the specimens with rectangular cross-section are not included (22 specimens), and in the model of Ilki et al. (2010) the specimens with GFRP are not included (13 specimens), because of the limitation of applicability of the models. It is noted that the strengths of materials were entered in the models without reduction factors, since they were obtained experimentally. Values below the diagonal are unsafe predictions, given that the model estimates higher capacity than the one that was observed in the test. However, the application of safety
factors used for design would result in that certain unsafe predictions would be on the safe side. The main objective of the comparison, however, is to determine which model tends to better predict the ultimate axial strength for the range of the test parameters considered.

(a) Model according to Eurocodes
(b) Model of Pellegrino and Modena (2010)

Figure 1 Axial strength predictions for the whole data base

Table 2 offers statistical indices for the models presented. All models predict well the experimental database. The model based on Eurocodes results in the best correlation coefficient and \( R^2 \)-value, but lower average predicted-to-test axial strength ratio among the models considered. In general the predictions of this model are on the safe side, hence the lower average predicted-to-test axial strength ratio. Given the fact, though, that it is a code-model, as such, it should provide increased safety. Therefore, the Eurocode model is recommended for use in design because it combines a uniform and simple approach for all types of cross-sections and FRP materials, and describes well the influence of the various design parameters.
CONCLUSIONS

The proposed model is based on Eurocode provisions and makes the simplistic assumptions that a) the FRP strain at failure is assumed to be the one provided by the manufacturer from flat coupon tests, and b) the longitudinal reinforcement is not disregarded in the calculation of the axial strength, in order to counterbalance for the overestimation of the axial strength because of the increased rupture strain of the FRP. The predictions of all the models presented have shown good agreement with the experimental results of the test database used in this study. However, the proposed model is recommended for use not only because of its slight superiority over the other models concerning its predictive capacity to accurately describe the behaviour of all design parameters, but mainly owing to its simplicity of application and uniform approach to all types of cross-sections and FRP materials.

REFERENCES

ABSTRACT

Fiber Reinforced Polymer (FRP) can be used as an excellent material for structural retrofitting to against seismic or impact loads and has been applied widely in the past 20 years to confine reinforced concrete column. Due to concentrated stress at the corners of square or rectangular columns which significantly influences FRP confinement, various modification methods which modifying the column cross sections have been investigated recently. This paper aims to provide an overview of the recent investigations on confining concrete columns with non-circular cross section using various modified cross section methods. The characteristic of FRP in confining existing columns in bridges and buildings was summarized first in the paper, followed by the assessment of performance of circular and non-circular columns confined by FRP. Investigations on modifying column cross section from square or rectangular to circular or elliptical sections before being wrapped with FRP layers using different techniques are reviewed in details. The review revealed that modifying the column cross section using grouting material with prefabricated FRP is an effective way to reach desired effectiveness of FRP confinement in strengthening existing columns.

INTRODUCTION

Many structures had built before the modern code of design, so it cannot withstand severe seismic activities. It is anticipated that, if no treatment for these buildings is taken, a one third of them will be threatened to fail over the next four decades due to seismic loading (Promis & Ferrier 2012). The demand to strengthen seismic resistance of concrete columns can be achieved in one of three ways: improve strength, improve ductility, or improve both ductility and strength. However, the type of structures is the criterion for choosing the strengthening method. Often, the method of improving ductility is considered as the favorite method to dissipate the energy of seismic activity (Promis & Ferrier 2012). Confining concrete structure by high strength materials externally can enhance many properties significantly such as ductility, energy dissipation as well as concrete strength. To date, the performance of many structural elements has been enhanced at different aspects by using FRP for its superior strength and high resistance against corrosion (Teng & Lam 2004; Gu et al 2010).

Confining concrete elements might include wrapping the existing concrete by FRP as a retrofitting layer or encapsulating a new pre-fabricated system (Mirmiran & Shahawy 1997). Using FRP to rehabilitate columns has many advantages, however these advantages could be less valuable and effective when it was used to repair a square or rectangular column. The tests that have been reported in the literature have established that the corner radius significantly affects the confinement effectiveness (Wang and Wu 2008). FRP external sheet can enhance the ductility and strength of concrete columns with circular cross section due to the uniform distribution of pressure that is exerted surrounding the column. Whereas, FRP confining layer cannot provide a notable confinement on the straight face on rectangular or square column, the effectiveness depends on the curvature of the corners. FRP wrapping can provide significant advantages only when column cross section shape is changed to elliptical or circular shape. In the last decades, a large amount of investigations have been conducted on circular columns confined by FRP. However, the investigations on FRP confined square or rectangular columns were much less. In square column, the confinement effectiveness is less than that of circular column due to the non-uniform distribution of confinement to concrete. Some investigations reported that there was no confinement at sharp corners, others researchers mentioned that a certain degree of confinement was provided by a jacket with sharp corners (Mirmiran 1998; Wang & Wu 2008).
A study presented by Mirmiran (1998) revealed that cross section of column had direct effects on the confinement performance. As external FRP layers had to be bonded on a column surface, they must be bent. The bending affects the efficiency of FRP laminates, the effectiveness of confinement of column depends on the corner curvature (Yang et al. 2001). Confining effectiveness for circular column is more than their square counter parts due to the concentration stress at the corner (Mirmiran 1998; Mostofinejad & Ilia 2014). Al-Salloum (2007) revealed that FRP confinement efficiency and performance were absolutely related to the curvature radius of column edges which may cause premature failure of FRP rapture at the sharp edges. He also found that the failure of square column started at the sharp edges that the stress was concentrated. On this basis, investigators have studied the effect of column cross section on the efficiency of the FRP confinement. This study presents a review of the effectiveness of various cross section modification methods when the columns were strengthened with FRP wrapping or jacketing.

THE EFFECT OF EDGE CURVATURE ON COLUMN CONFINEMENT

An experimental investigation was presented by Al-Salloum (2007) on the effects of curvature on the strength of confined square columns. The investigation included testing columns with a wide range of corner radius in addition to circular column to compare the performance. The results revealed that the circular specimens presented the best efficiency. The poorest performance was the column with 5mm edges radius. As the cross section of column changed from circular to square shape, the ultimate strength decreased because of the non-uniform stress distribution. The effect of corner radius on CFRP confinement efficiency was also investigated by Wang & Wu (2008). The effect of CFRP thickness, concrete strength and corner radius was studied specially for polygonal columns as shown in Figure 1. The results indicated that corner radius is of great importance in relation to the level of confinement. The strength gain of confined concrete columns was in direct linear relationship to the corner radius ratio regardless of the confinement level and concrete strength. The results also revealed that, the confinement effectiveness was insufficient to enhance the columns strength before the peak load. On the other hand, a higher level of confinement does not correlate with the higher ductility; in contrast, it reduced the ductility of the column in some cases.

CONFINEMENT TECHNIQUES FOR COLUMNS WITH NON-CIRCULAR CROSS-SECTION

It was clear that the corner radius had a significant effect of the effectiveness of column confinement, different types of techniques were then developed by various researchers to modify the cross section of column before wrapping with FRP to avoid stress concentration on sharp edges. The most effective techniques are discussed and compared in the following sections:

Rounding the Sharp Edges of Columns

Rounding the sharp edges of columns has been considered as a conventional technique to enhance the performance of FRP confinement in the last decade (He et al. 2013; Yaqub and Bailey 2012; Wu & Wei 2010). This technique can help to reduce the punching and concentration of FRP sheet at the sharp corners. Yaqub and Bailey (2012) investigated confining square concrete column by a single layer of carbon or glass FRP under seismic load after rounding the corners to be an arc with the radius of 25mm as shown in Figure 2. An experimental investigation comprising large scale of five damaged columns with various damage patterns was conducted by He et al. (2013) to assess the effectiveness of using carbon FRP for confining these columns. To prepare the damaged columns for CFRP installation, the loose concrete layer was removed and substituted by accelerated pastes. The sharp corners of the columns were rounded with the radius of about 25 mm by using a hand grinder. Yaqub and Bailey (2012) and Teng and Lam (2002) mentioned that the effectiveness of FRP confinement gradually increased with an increment in the radius of edges. Choosing 25 mm radius is more suitable with using hand grinder as recommended by these researchers. With increasing the edges radius, the stress distribution becomes more uniform, and this would improve the column strength and ductility. However, as the radius was limited by the presence of internal steel reinforcement to a small value, the confinement effect was also limited (Teng and Lam, 2002). The efficiency
of FRP confinement of square columns with round corners is still significantly lower than circular columns (Al-Salloum, 2007).

Figure 2 Rounding edges (Yaqub and Bailey 2012)  
Figure 3 Circularization and CFRP (Pham et al. 2013)

FRP Wrapping and Shape Modification

The idea of column shape modification was explored by Priestley et al. (1994) for seismic retrofit of bridge columns using steel jackets, with the gap between the column and the steel jacket filled with concrete (Teng and Lam 2002). More research has been carried in recent years of using FRP (Alsayed et al. 2014; Hadi et al. 2013 and Pham et al. 2013) where, rectangular/square column was modified to an elliptical or circular cross section by adding concrete or mortar before wrapping FRP confinement.

Shape modification with circularization

Circularization technique has been commonly used for shape modification of column with a square cross section. Pham et al. (2013) used concrete strength ranging from 40 MPa to 100 MPa to change a square cross section of 150x150 mm to a circular shape before the column was wrapped by CFRP as shown in Figure 3. The concrete cover and CFRP layer behaved as a composite material under concentric and eccentric compressive load and flexural load. Normal concrete with design compressive strength of 40 MPa was used to cast the specimens (core). Unidirectional CFRP, with the width of 75mm, was used for confinement. In order to create a circular segment with the chord of 150 mm (the same length as square column side), sections made of cork were used and added to the rectangular mould to create the required shape. The segments, after 28 days of casting, were removed and bonded to the columns using adhesive after cleaning the columns and the segments. Four circular covers were bonded onto the column side to change the cross section from square to circular. The specimens were then confined in three layers of separate rings of CFRP with the overlap of 100mm. Different types of load, such as concentric, eccentric, and flexural load were considered to study the behavior of modified square columns.

The results revealed that, the un-strengthened columns failed by dedonding of concrete cover and buckling of the main reinforcement at the mid height of the column for concentric load. In contrast, brittle failure was observed with crushing of concrete covers and rupture of CFRP for confined columns (Figure 4). For eccentric force, cracks were observed on the tensile sides between two strips placed at the mid height of the column. The specimens also failed by the rupture of CFRP followed by compression failure in concrete. For flexural load, vertical cracks were observed in the mid span of specimens. The results also revealed that confined specimens presented high ductility with respect to reference group. The strength of the groups which strengthened in segment with 80 and 100 MPa concrete presented similar behavior as that of the columns strengthened in 40 MPa. The research indicated that the effect of segments compressive strength on the ductility of confined columns is negligible. The same technique was also used by Hadi et al. (2013). It was recommended that this method proved to be effective in increasing the ultimate load for the confined column.

The effectiveness of shape circularization was investigated by Hadi et al. (2013), where three techniques to confine square section column were compared. The first method (RF) was that the column’s corners were rounded to have 20 mm radius before wrapping the columns in three layers of carbon fiber. For comparison, the straight faces of the columns in the second method (CF) were combined with segments of circular section to change the shape of column to circular cross section before wrapping with three layers of CFRP. In the third one (CS) the same technique as that of the second method was considered but steel strips were used to warp the columns. The columns were left without confinement as reference columns (N). The testing results are shown in Figure 5.
The testing results indicated that Group CF (using shape circularization and CFRP wrapping) outperformed the other groups because of the significant reduction of stress concentration at the corners of square columns and using CFRP. Specimens of group CF showed the highest ultimate load capacity for all types of loading conditions followed by specimens of group CS (using shape circularization and steel strips). Under eccentric load condition, the specimens of group CF also showed the highest strength as compared to other groups and same result for flexural test. It was proved that the concept of shape circularization to be an effective process to increase the ultimate load capacity of the columns confined by CFRP. The efficiency of the circularization process was higher than that of rounding corners process.

**Shape modification with an elliptical section**

For columns with rectangular shape, modifying the column section into an elliptical section has been practiced. The compressive strength and stress–strain behavior of FRP-confined concrete in elliptical columns have been investigated (Teng and Lam 2002). The testing results indicated that for CFRP-wrapped specimens, the compressive strength was significantly affected by the major-to-minor axis length ratio a/b of the column section (Figure 6). The confining FRP becomes increasingly less effective as the section becomes more elliptical. However, substantial strength gains from FRP confinement can still be achieved even for strongly elliptical sections.

Large scale axial compression tests were performed on RC columns with and without CFRP confinement (Alsayed et al. 2014). The CFRP was wrapped on the column after modifying the rectangular section to an elliptical shape using normal cement mortar. Failure of strengthened column was due to the crushing of concrete and buckling of longitudinal rebars after yielding instead of the rupture of CFRP sheet which was reported in many studies. The bulging of column at mid-height and a simultaneous rapid decrease in the load carrying capacity of strengthened column was an indication that the actual failure was due to crushing of concrete and buckling of longitudinal steel (Alsayed et al. 2014).

Another effective technique to help reducing the stress concentration at column corners and increase the efficiency of FRP confinement has been investigated (Mahfouz et al. 2001). A "Sandwich Wrapping Confining System (SWCS)" for strengthening columns having a rectangular cross section was developed where two layers of FRP with incompressible pulp core were used to confine rectangular concrete columns using the normal epoxy wrapping method. It was found that the stiffness of the SWCS in the transverse direction of the element must be high enough to bring about the required confining pressures at relatively low transverse strains. SWCS has both axial and flexural stiffness in the transverse direction of the column, it effectively improved the properties of square and rectangular columns.
Shape Modification with Prefabricated FRP Composite Systems

Prefabricated FRP composite repair systems may be used both as the formwork for concrete casting to achieve shape modification and to provide the lateral confinement following the curing of the new filling materials (Teng and Lam 2002). Yan and Pantelides (2011) attempted using prefabricated FRP shell and expansive cement concrete to retrofit non-circular concrete columns. As expansion of the grout was restrained by FRP shell, the post-tensioning effect would generate an active confinement. The testing results indicated that columns strengthened by the non-bonded FRP jacket with expansive cement achieved a higher axial strength compared to columns strengthened with FRP wrapping method. The failure mode was due to facture of the FRP shell and cracking of the expansive cement (Figure 7) which indicated extensive participation of the FRP in confinement.

Herwig & Motavalli (2012) used unbonded GFRP and light weight concrete to confine square columns. The sides of the columns were mounted by light weight deviation concrete board before the GFRP confinement as shown in Figure 8. The results revealed that for the columns confined in 6 and 7 plies, the ultimate strength was about 46% and 32% higher than the un-confined column. It was found that the effectiveness of the confinement was determined by the accurate choice of board, unbonded spies and the wraps geometry and number. The method could be used for retrofitting existing columns as an economic technique to reach a desired ductility and high resistance against impact loading.

CONCLUSIONS

Enhancing the strength and ductility of columns are one of the important applications for FRP, which can be used as a prefabricated jacket or external wrapping on the column. The advantages of FRP reinforcement for concrete column have been studied through many investigations. FRP wrapping can effectively enhance the ductility and strength of concrete columns with circular cross section due to uniform distribution of the pressure. Whereas, FRP cannot provide a notable confinement on the straight face on rectangular or square columns. For such a case, FRP sheet can only provide significant advantages when the column cross section shape was modified to elliptical or circular shape. The research results indicated that the method of modifying column cross section before FRP wrap was more efficient than rounding the sharp edges of columns. Another method which uses prefabricated FRP composite as the formwork for concrete casting to achieve shape modification and to provide the lateral confinement following the curing of the new filling materials has been developed recently. Using prefabricated FRP with grouting materials could be considered as an effective way in enhancing column strength in existing buildings, however, the research in this area has been limited. It is important to focus on research in this area in the future to find out a suitable grouting material that can be used as part for the new FRP composite system.

ABSTRACT

Based on a series of tests on seven groups of CFRP confined large-scale square concrete columns with different corner radius, the basic mechanical properties were obtained. Test results demonstrate that the confined strength increases according to the corner radius increasing except for the specimens with sharp corner. All of the specimens failed due to CFRP rupture and the fracture location occurred in the chamfer region. So the phenomenon of the stress concentration can be observed obviously. The ultimate strains measured on the CFRP jackets are about 35% less than the ultimate strain tested by the coupon specimens, which is more serious than the smaller-scale specimens. Five existing confinement models are used to predict the ultimate compressive strength of test columns in the paper and the results present significant differences.

KEYWORDS

INTRODUCTION

Wrapping fiber reinforced polymer (FRP) is an effective method to improve the mechanical properties for concrete columns. The tensile forces of FRP jacket around the perimeter of the columns confine the lateral expansion of concrete and thereby enhance their deformability and axial capacity significantly. Some experimental research have been performed on FRP confined square or rectangular columns in the recent years (e.g., Mirmiran et al. 1998; Pessiki et al. 2001; Shehata et al. 2002; Rocca 2007; Wang and Wu 2008; Wang et al. 2012). Most of reported experiments has focused on the small-scale specimens, especially with the length less than 250 mm and height less than 600 mm. The research conducted by Pessiki et al. (2001) and Masia et al. (2004) has shown that the enhancement effect by CFRP confinement in strength and ductility observed for the small-scale square specimens should not be directly extrapolated to the real size columns. In order to address the knowledge gaps discussed above, this paper carried out a series of tests on CFRP confined large-scale square section columns. This study try to assess the influence of column cross-sectional size on the strength and deformation of CFRP confined square columns.

EXPERIMENTAL DESIGN

Specimen Design and Material Characteristics

The experimental program consisted of testing of 42 large-scale plain concrete columns under concentric axial load, three specimens in each group. Half of columns were confined by wrapped CFRP jackets and the rest served as control (unwrapped). All columns are square section with 300mm in side length b and 600mm in height. The specimens vary with a corner radius r of 0, 15, 30, 60, 90, 120 and 150mm according to the corner radius ratio rc, corner radius ratio and equal to 2r/b, of 0, 0.1, 0.2, 0.4, 0.6, 0.8 and 1.0. It means that the columns with square (sharp) section or circular section with rc equal to 0 or 1.0, respectively. From the rc point of view, this study can be good corresponded to the series tests on the small-scale specimens performed by Wang and Wu (2008), of which the cross section sizes are 150mm in side length and 300mm in height.

The specimens were prepared using a single mix design and cast in the laboratory, in which mix proportion of materials was selected as cement : water : sand : gravel = 1:0.56:1.90:3.10. The 28-day average compressive cylinder strength was 38.4MPa according to the ACI standard (2008a).
An unidirectional carbon fabric, with the nominal thickness of 0.167mm, and a two-part epoxy resin were selected for wrapping concrete columns. To determine the material properties of the CFRP, six flat coupons of 25mm width and 200mm length were test in accordance with ASTM D3039 to produce the tensile strength of 3587MPa, the elastic modulus of 236GPa and the elongation at rupture of 1.52%.

**Specimen Preparation**

A suit of high precision steel molds were custom-made, three identical molds for each corner radius. The concrete was poured into steel molds in three equal layers and vibrated by a vibration rod. Two days after casting, the specimens were removed from the formworks and cured in laboratory for 30 days.

The CFRP was wrapped in the hoop direction in a wet lay-up manner. Discontinuous three sheets were used to wrap a specimen, in which had a single lap 100mm in length for each layer. Those overlap regions were arranged near the middle of different sides in order to avoid the corners. The wrapped columns were stored in an indoor condition at least 4 weeks and tested at least 2 months after pouring of the concrete.

**Instrumentation and Test Procedure**

All tests were conducted using a YAW-10000 universal testing machine of 10000kN capacity, as shown in Figure 1. Axial deformation of specimens were measured with two linear variable displacement transducers (LVDTs) which were mounted onto the two steel frames that were spaced about half of the column height at the midheight region, as show in Figure 2. A certain amount of strain gauges of 10mm gauge length were bonded onto the outside surface of the wrap in the hoop direction at midheight section of each column.

All specimens were tested according to an automatic two-stage control mode. Columns were tested in a load controlled manner at a loading rate of about 5kN/s before 90% of the pre-estimated peak load reached. Then a displacement control was used at approximately 0.05mm/min until specimen’s failure.

**TEST RESULTS AND ANALYSIS**

**Failure Modes**

The typical failure modes of the test specimens are shown in Figure 3. The unconfined columns failed in a classic shear manner, a mainly diagonal crack crossing the specimen, as shown in Figure 3(a). All confined columns failed by tensile rupture of the CFRP jacket within the midheight region. Continuous cracking sound could be heard approaching failure followed by an explosive sound suddenly. CFRP rupture region varied from 190mm to 450mm along the height direction. For columns with a small corner radius \( r \leq 30 \text{mm} \), the breaking points always occurred near the center of the corner and the vertical profile of the cracks were virtually straight, as shown Figure 3(b)-3(d). For columns with a lager corner radius \( r \geq 60 \text{mm} \), the breaking points occurred near the center of the corner or the curvature changing point and the ruptures were rather jagged, as shown in Figure 3(e)-3(h). The exactly rupture locations of all columns except for circular section \( r = 150 \text{mm} \) were situated in the chamfered region. It suggested that the stress concentration caused by the corner have important effect on the failure of the CFRP jacket in the large-scale columns.
Stress-strain Behavior

The typical stress-strain curves for each group is presented in Figure 4, in which axial strain and lateral strain are defined as positive and negative, respectively. The compressive strength of all specimens are presented in Table 1.

Table 1 Compressive strengths of test

Test results from Table 2 and Figure 4 reveal that the confinement effectiveness of CFRP jackets are affected by corner radius $r$. The stress-strain curves of the specimens with small corner radius ($r \leq 30$mm) demonstrated postpeak softening behavior, whereas monotonically bilinear ascending responses presented for larger corner radius.
radius ($r \geq 60\text{mm}$). A turning point of the stress-strain curves for all confined columns can be found in Figure 4, which approaches the onset of the unconfined concrete strength. Similar stress-strain behaviors have also been presented in smaller square section columns (Wang and Wu, 2008).

Corner Radius Effect

Table 1 gives the result of enhancement ratio, $f_{cc}'/f_{co}'$, in which $f_{cc}'$ is the mean compressive strength of the CFRP confined columns and $f_{co}'$ is the compressive strength of the unconfined columns. The values of $f_{cc}'/f_{co}'$ increase from 1.05 to 2.20 as the section of confined columns changes from sharp corner to circle gradually. The five curves of $f_{cc}'/f_{co}'$ versus corner radius ratio $r_c$ are presented in Figure 5, included test results conducted by authors and Wang and Wu (2008). It can be seen that $f_{cc}'/f_{co}'$ raises with $r_c$ increasing and $f_{cc}'/f_{co}'$ is not showed significant improvement with sharp corner for all series tests. Compared with the curves of Wang and Wu (2008), the curve of this paper also discovery that the strength gain of the confined large-scale columns is almost proportional to the corner radius ratio even $r_c$ less than 0.2.

Rupture Strain of CFRP

The ultimate strain of CFRP jackets at failure are also listed in table 1. The strain values are average value of test data of the three identical specimens. Among them, $R_{\text{max}}$ is the ratio of the rupture values measured in large-scale columns and measured in flat coupons. From Table 1, the maximum of $R_{\text{max}}$ is 0.75. From all the statistical results of the specimens, the mean of rupture strains of CFRP jacket is less than 35% of the ultimate strain tested by material experiment. Compared with the data of Wang and Wu (2008), the maximum of $R_{\text{max}}$ in the group data is 0.88. and the mean of rupture strains of specimens decreases by 25% than the ultimate strain form the flat coupon test. It suggests that the confinement effect of FRP jacket deceases with the size of columns increase.

**COMPARISON OF THE TEST RESULTS WITH THEORETICAL MODEL**
Five existing confinement models, such as Mirmiran (1998), Lam and Teng (2003), Ilki (2004), Al-Salloum (2007) and Wu (2009), are used to predict the ultimate compressive strength of test columns in the paper. The comparative results between the theoretical predictions and tests are showed in Figure 6. According to the works of Ilki et al (2004), the hoop rupture strain of CFRP jacket was only taken as 70% of its ultimate tensile strain from the coupon test in the calculation models.

![Figure 6 Comparison between test results and existing models](image)

In the case of the small corner radius \( r_c \leq 0.2 \), the results predicted by Mirmiran (1998) and Wu’s (2009) strength model are good agreement with the test data. And other models are obviously overestimated the compressive strength of confined column. Under the condition of the larger corner radius \( r_c > 0.2 \), all models underestimate the compressive strength of the specimens and the prediction error increases significantly with the increase of \( r_c \).

CONCLUSIONS

1. Enhancement ratio \( f_{c'} / f_{c0} \) of the confined columns increases almost linearly with the increase of the corner radius ratio \( r_c \). Corner radius \( r \) has important influence on the mechanical properties of CFRP confined large-scale square column.
2. The exactly rupture locations of confined specimens are situated in the chamfered region. The measured ultimate strain of CFRP jackets is less than 35% of the ultimate strain tested by flat coupons. Compared with the test results from small size specimens, the confinement effect of FRP jacket deceases with the size of columns increase.
3. Five existing strength models of CFRP confined square column are used to predict the ultimate compressive strength of test columns. All models underestimate the compressive strength of the specimens and the prediction error increases significantly when corner radius ratio \( r_c \) is larger than 0.2.

ABSTRACT

This paper presents an experimental study on the effect of coarse aggregate size on the mechanical behavior of passively confined concrete. In total, 32 concrete cylinders with different aggregate sizes and thicknesses of fiber reinforced polymer (FRP) jacketing were tested under monotonic axial loading. From the test results, it is shown that the aggregate size does not affect behavior of unconfined concrete and the beginning stage of stress-strain curves of FRP confined concrete. However, in the transitional stage of stress-strain relationship of FRP-confined specimens, the concrete with larger aggregates has a higher stress. The second stiffness of stress-strain relationship is not affected by the aggregate size. Furthermore, at the ultimate stage, larger aggregates cut FRP to failure more easily and earlier. Hence, the ultimate strain has a decreasing trend with increasing aggregate size. Meanwhile, the ultimate strengths are similar for the specimens with different aggregate sizes because of the two aspects with increasing aggregate size: enhancing effect on stress in the transition stage and decreasing effect on strain in the ultimate stage.

KEYWORDS

FRP, concrete, confinement, aggregate size, stress-strain relationship.

INTRODUCTION

The strength and ductility of concrete can be significantly increased by confining with fiber reinforced polymer (FRP). Both the strength model and stress-strain behavior are widely studied with large scatters in the recent decades (Ozbakkaloglu et al. 2013; Cao et al. 2016). The enhancing effect on the concrete mechanism behavior is caused by the FRP lateral confinement activated by the dilation of concrete material. That is to say, the mechanical behavior of concrete material under triaxial stress condition plays a key role in the FRP confining. For the concrete material, the coarse aggregate takes more than 75% of volume of concrete, and can affect mechanical properties of concrete (Neville 1995). To individually study the effect of aggregate size on the behavior of FRP-confined concrete columns, this work studied specimens by different sizes of coarse aggregate with fixing both the specimen geometrical proportions and their scales.

EXPERIMENTAL PROGRAM

Test specimens consisted of 32 circular concrete cylinders in total. The variation factors included mixture proportion, aggregate size, and number of FRP sheet layer. Details of the specimens are given in Tables 1. All the specimens were tested under uniaxial compression at a fixed load rate with monotonic displacement control.

Design of specimens

The size of all the cylinder specimens were 150 mm in diameter and 300 mm in height, which is widely used in stress-strain modeling of FRP-confined concrete (Lam and Teng 2002; Wu and Wei 2010; Wu and Jiang 2013a). In order to investigate the factor of aggregate size independently, and to avoid the “wall effect” (Neville 1995) caused by concentration of smaller aggregates near the surface of cylinders, coarse aggregate with only one size was used in a particular specimen.. Aggregate size was the major variable of the tests and values of 5, 10 and 20
mm were adopted. Though 20 mm aggregate in the cylinder specimens may disproportionately large for the practical large columns, the 20 mm specimens were studied in this work for the academic purpose. Carbon FRP (CFRP) was used with the variation of layer number from one to three plies. Two different mix proportions of concrete for 10 mm aggregate size especially were used which aimed to 25 MPa and 40 MPa for concrete uniaxial compressive strength. Two specimens were tested for each design. The test results in the following sections showed a very small difference between the two identical specimens in the two different groups.

</table>

In Table 1, the two mix proportions are identified by the first letter A and B in the specimen ID; the second character of the specimen ID (d5, d10 or d20) denotes the coarse aggregate size of 5, 10 and 20 mm, respectively; and the third character of the specimen ID (p0, p1, p2 or p3) means the number of CFRP layers, where 0-ply is the unconfined concrete; the two identical specimens are separated into two different groups identified by the last number 1 or 2 in the specimen ID. For example, A-d10-p2-2 indicates the second identical specimen by mix proportion A, with 2-ply CFRP and 10 mm coarse aggregate.

A high tensile strength carbon fiber fabric known as TORAYCA Cloth, which has a nominal thickness of 0.167 mm, was used for jacketing. A two-part Sikadur-300 was used as saturant resin. Flat coupon tensile tests were
conducted to determine the material properties of the CFRP sheets. Mechanical properties of the CFRP laminate obtained from the coupon tests are 3922 MPa, 245 GPa and 1.6% in ultimate strength, tensile modulus and ultimate strain, respectively.

**Specimen preparation**

Mix A and B aimed to 25 MPa and 40 MPa respectively for the designed cylinder strength at 28 days. River sand was used as the fine aggregate. Crushed granite stones as coarse aggregate, which is a main parameter in this study, were sieved very carefully to divide three different sizes of aggregate, as shown in Figure 1(a). Coarse aggregates with a maximum size of 20 mm were sieved using a sieve level with \( 20 \times 20 \) mm\(^2\) square holes. The remaining aggregates on the 20 mm sieve level were used to cast the concrete with an aggregate size of 20 mm. Similarly, coarse aggregate with a maximum size of 10 mm and 10 mm sieve level were used to cast the concrete with an aggregate size of 10 mm. Then, the remaining stones were sieved continually to let them go through the sieve level of 6.3 mm and 5 mm, respectively. The stones left between such two levels, which indicated that their aggregate size was between 5 to 6.3 mm, were used to cast the concrete with an aggregate size of 5 mm. Therefore the exact average aggregate size should be \( (5+6.3)/2 = 5.65 \) mm. Both the fine and coarse aggregates were completely dried in an oven at 110°C for 24 hours to minimize the variation of water content. The concrete was mixed and cast in the laboratory. One day after casting, the specimens were removed from the molds and cured in a water tank at a constant temperature of 27°C for 28 days. Meanwhile, six cubes of \( 150 \times 150 \times 150 \) mm\(^3\) were prepared for each group and cured in the same manner as the cylinder specimens to monitor the development of concrete strength at different ages. At 28 days, the specimens were removed from the water and then ground with a grinding machine for getting a smooth contact surface.

The surface of specimens was cleaned with water and left to dry before FRP jacketing. The CFRP was wrapped around the specimens using the manual lay-up procedure, with the fibers oriented in the hoop direction. Each layer of CFRP has a single overlap of 150 mm in length. Details of the wrapping process can be found in Wu and Jiang (2013a). The wrapped specimens were kept in the laboratory air-conditioned environment at a temperature of 16°C for two weeks before testing.

![Aggregate sieving](image1)

![Test setup](image2)

**Figure 1** Compression test of specimens
Testing and instrumentation

The compression tests on FRP-confined concrete specimens were conducted using a 1600 kN MTS rock machine and a 2500 kN FORNEY testing machine, according to the load capacity of each specimen. Before testing, the calibrations of the load readings were conducted on the two testing machines. Two thick and flat steel plates were set at the top and bottom of the specimen and two linear variable differential transformers (LVDTs) were mounted on the left and right sides to obtain the axial deformation of specimen. Details are shown in Figure 1(b).

Digital image correlation (DIC) system that can capture continuous displacement and strain fields of the specimen surface during testing was used for strain measurement. DIC is very suitable for concrete testing and can provide much more accurate and reliable strain data than conventional electric strain gauges (Jiang et al. 2014; Wu and Jiang 2013b; Wu et al. 2015; Yu and Wu 2016). The instrumentation system includes two cameras and a computer used for storing and processing the captured image data. Two cameras were set in the front and behind the specimen in order to use DIC-2D system to measure the in-plane axial strain and displacement fields for the both sides. All the specimens were tested under a displacement control mode at a fixed rate of 0.3 mm/min.

FAILURE MODE

In the case of unconfined cylinder specimens, longitudinally splitting and shearing modes occurred randomly (Figure 2). The failure mode of FRP-confined columns was concrete crushing simultaneously after the CFRP rupture; no delamination of FRP at the overlapping zone was observed. Failure occurred suddenly at around mid-height, with an explosive sound. It can be seen that the aggregate size does not affect the failure mode for both unconfined and FRP-confined concrete columns.

EFFECT OF AGGREGATE SIZE ON THE BEHAVIOR OF UNCONFINED CONCRETE

In this study, for concrete with different aggregate sizes, the concrete mix proportion was fixed (mix A) to make the investigated factor more independent. Two different concrete mix proportions (mixes A and B) were adopted for one aggregate size (10 mm). The whole stress-strain curves for unconfined concrete were achieved in the tests as shown in Figure 3. In Figure 3(a), it can be observed that the elastic modulus (E) and strength (fcu) of concrete with the same mix proportion are quite similar. After the peak strength, the stress-strain curves of concrete with

![Figure 2 Failure mode of unconfined and confined concrete specimens](image)

![Figure 3 Strain-strain relationship of unconfined concrete](image)
smaller aggregates drop slower than that with larger aggregates. In Figure 3(b), the concrete with less water/cement ratio (mix B) shows a higher elastic modulus and strength, which is quite normal and common in concrete material.

EFFECT OF AGGREGATE SIZE ON THE BEHAVIOR OF FRP-CONFINED CONCRETE

The peak strength \((f_{cc})\) of both unconfined and FRP confined specimens, as well as the corresponding axial strain \((\varepsilon_{cc})\) are listed in Table 1. The concrete cylinder strength \((f_{co})\) and corresponding axial strain \((\varepsilon_{co})\) are obtained from the cylinder test data of the unconfined specimens. Typical stress-strain curves for all the specimens are plotted in Figure 4, where axial strain is achieved by DIC analysis.

\[\text{Figure 4 Effect of aggregate size on stress-strain curves}\]

The effect of aggregate size on the stress-strain relationship of FRP-confined concrete is investigated in this work. The stress-strain curves of confined concrete in this experimental program are drawn in Figure 4(a-c), with the individual FRP wrapping layers. Figure 4(d) enlarges the beginning part of Figure 4(a) to make the trend clearer. Subjected to adequate lateral confinement, all of the confined specimens have strain-hardening behavior.

At the beginning stage, the stress-strain relationships of specimens with various sizes of aggregates are the same. That is to say, the aggregate size does not change the initial stress-strain relationship. After the initial elastic stage, the concrete with larger aggregates has a higher stress from Figure 4. Furthermore, the second stiffness of stress strain curves is very similar for different kinds of concrete. However, the ultimate strain of confined concrete by larger aggregate size is smaller. This phenomenon is reasonable because the larger aggregates can cut the FRP more easily and earlier. Similar reasons and conclusions of decreasing on ultimate strain were conducted for higher strength concrete (Lim and Ozbakkaloglu 2013). Therefore, the ultimate strengths of confined concretes with different aggregate sizes are approximate according to the two opposite effect with increasing aggregate size: higher stress in transitional stress and lower ultimate strain.

CONCLUSIONS

An experimental investigation has been undertaken in this work to study the effect of aggregate size on the mechanical behavior of FRP confined concrete columns. The experimental program included loading tests of 32 column cylinders. After the analytical study, it can be concluded that the size effect by aggregate influences the mechanical behavior of FRP-confined concrete as:

1 For the unconfined concrete and the initial elastic stage of FRP-confined concrete, the aggregate size does not affect the mechanical behavior.
At and after the transitional stage of stress-strain relationship of FRP-confined concrete, the concrete by larger aggregates has a higher stress. The aggregate size has no effect on the second stiffness of stress-strain relationship.

In the ultimate stage, larger aggregates can cut the FRP to failure more easily and earlier. Hence, the ultimate strain has a decreasing trend with increasing aggregate size. The ultimate stresses are similar because of the two aspects: enhancing effect with increasing aggregate size in the transitional stage and decreasing effect with increasing aggregate size in the ultimate stage.

STRESS-STRAIN BEHAVIOUR OF FRP-CONFINED CONCRETE IN ECCENTRICALLY-LOADED CIRCULAR COLUMNS

G. Lin and J.G. Teng

The Hong Kong Polytechnic University, China. Email: cejgteng@polyu.edu.hk

ABSTRACT

Fibre-reinforced polymer (FRP) jacketing/wrapping has become a widely accepted technique for strengthening/retrofitting reinforced concrete (RC) columns. Although extensive research has been conducted on FRP-confined concrete columns under concentric compression, leading to many stress-strain models, the applicability of these concentric-loading (CL) stress-strain models in the analysis of columns under eccentric loading has not been properly clarified. This paper presents an in-depth investigation into this problem using an advanced three-dimensional (3D) finite element (FE) approach. The axial stress distributions and the stress-strain responses of FRP-confined concrete in circular columns under eccentric compression are examined using the FE results. It is shown that the stress-strain response of concrete varies greatly over the section and the direct use of a single CL stress-strain model for the entire section in the analysis of eccentrically-loaded columns may lead to significant errors, especially for the prediction of ultimate deformation/ductility. The paper also shows that a stress-strain model for the confined concrete at the extreme compression fibre of the section provides a relatively simple and much more accurate option for the analysis of eccentrically-loaded columns.

INTRODUCTION

Fiber-reinforced polymer (FRP) jacketing/wrapping has become a widely accepted technique for strengthening/retrofitting reinforced concrete (RC) columns (Teng et al. 2002; Hollaway and Teng 2008). To enable the safe and reliable design of FRP jackets, a large volume of research has been conducted on the behavior of FRP-confined concrete in these columns, leading to many uniaxial stress-strain models for FRP-confined concrete (Teng and Lam 2004). Most of these studies, however, have been focused on the behavior and modeling of FRP-confined concrete in columns subjected to concentric axial compression, where the concrete is subjected to (nominally) uniform confinement from the FRP jacket around the circumference. In reality, RC columns are rarely designed for concentric loading, and even when the intended loading is concentric, they are likely to be subjected to eccentric loading (i.e., combined compression and bending) as a result of unintended factors (e.g., accidental load eccentricity and geometric/material imperfections of the column).

Due to eccentric loading, a strain gradient (i.e., a linear strain variation) exists over the column section. A uniaxial stress-strain model established for FRP-confined concrete in columns under concentric loading [referred to as “concentric-loading (CL) stress-strain model” or simply “CL stress-strain model” hereafter] has generally been used in the analysis of RC columns under eccentric compression (e.g., Tao et al. 2004; Binici 2008; El Maaddawy 2008; Jiang 2008; Yuan et al. 2008; El Sayed and El Maaddawy 2011; Jiang and Teng 2012, 2013). The interest to find out whether a CL stress-strain model would work well for columns under eccentric loading and the need to quantify the effect of column slenderness have led to a number of experimental studies on FRP-confined concrete columns under eccentric loading (e.g., Fam et al. 2003; Li and Hadi 2003; Tao et al. 2004; Hadi 2006a, 2006b, 2007; Bisby and Ranger 2010; Hadi and Widiarsa 2012; Wu and Jiang 2013; Jiang et al. 2014). These experimental studies have shown that eccentrically-loaded columns exhibit some behavioral aspects that cannot be closely predicted using a CL stress-strain model. Based on the test results, several stress-strain models for FRP-confined concrete in columns under eccentric compression have been proposed (e.g., Fam et al. 2003; El Maaddawy 2009; Hu et al. 2011; Abdel Fattah 2012; Wu and Jiang 2013; Jiang et al. 2014). Such stress-strain models are generally eccentricity-dependent and are referred to as “eccentricity-dependent (EccD) stress-strain models” hereafter. A review of these stress-strain models has
shown that they predict significantly different or even opposite trends for the stress-strain behavior of FRP-confined concrete in columns under eccentric loading (Lin 2016). The lack of an in-depth investigation into the fundamental behavior of FRP-confined concrete in columns under eccentric loading due to the limitations of laboratory measurements is one of the main reasons for this controversy associated with the EccD stress-strain models.

This paper presents an improved understanding of the behavior of FRP-confined concrete (including axial stress distributions and stress-strain responses) in circular columns under eccentric compression based on results from an advanced three-dimensional (3D) finite element (FE) approach. The applicability of a CL stress-strain model for FRP-confined concrete in the analysis of columns under eccentric loading is given particular attention. The conclusions reached in this study will provide a solid basis for the development of a more rigorous and reliable EccD stress-strain model to enable more accurate predictions for FRP-confined RC columns under eccentric loading.

FE MODELING OF ECCENTRICALLY-LOADED COLUMNS

Lin and Teng (2016a) recently presented a 3D FE approach for modelling the behaviour of FRP-confined RC columns under eccentric loading and implemented it with ABAQUS (2011). In this approach, the whole column is considered in a 3D FE model (i.e., a full-height column model) although symmetry considerations should be taken advantage of to reduce the model size; for example, for a pin-ended column at both ends, only a quarter of the column need to be included in the FE model (Figure 1). The concrete, FRP jacket, and steel bars were represented respectively using 8-node solid elements (C3D8R), 4-node membrane elements (M3D4R), and 2-node truss elements (T3D2) available in ABAQUS (2011). Perfect bonding between the FRP jacket and the concrete was assumed, which was achieved by means of the “Tie Option” in ABAQUS (2011). The steel bars were also assumed to be perfectly bonded to the adjacent concrete using the “Embedded Option” in ABAQUS (2011) (Lin and Teng 2016a). The plastic-damage model developed by Yu et al. (2010a) with a small modification by Teng et al. (2015) was employed to model FRP-confined concrete. The FRP jacket was treated as an orthotropic linear-elastic-brittle material. For an FRP jacket with fibers only or mainly in the hoop direction of the column, the modulus of elasticity of the FRP jacket in the axial direction was assumed to have a very small value (e.g., 0.001 GPa). The FE approach has been shown to provide accurate predictions for many FRP-confined circular RC columns under eccentric loading (Lin and Teng 2016a).

Although a full-height column model is needed for the purpose of comparison with test results, such a model is not suitable for investigations into the effect of load eccentricity on the stress-strain behaviour of FRP-confined concrete. This is because the total actual eccentricity for a given section, which is equal to the sum of the initial eccentricity plus the additional eccentricity due to lateral deflections, varies with lateral deflections, which also means that the total actual eccentricity varies along the height of a deformed column. In order to isolate the total load eccentricity of a section as the only factor of variation, only a thin vertical slice of a column, representing the behaviour of a column section with a prescribed, constant load eccentricity, was modelled in the present study (Figure 2). The strain gradient (i.e., eccentric compression) was realized by imposing a monotonically increasing axial displacement that varies linearly across the column section to the nodes of the top surface of the slice model as shown in Figure 2. The nodes of the bottom surface of the slice model were restrained against displacements only in the vertical direction. Due to symmetry in geometry and loading, only half of the section needs to be included in the FE model (Figure 2). The location of the neutral axis (with a zero axial strain) was fixed during the loading process, which implies a varying combination of axial load and moment during the deformation process. By varying the location of the neutral axis, the stress-strain behaviour of FRP-confined

Figure 1 FE model for a typical column under eccentric compression

Figure 2 Slice model for a typical column under eccentric compression
CONFINEMENT MECHANISM UNDER ECCENTRIC LOADING

The results of the FE slice model for a typical FRP-confined circular concrete column are presented in this section. The column had a circular section with a diameter of 150 mm and was represented by a slice with a thickness of 5.0 mm. The nominal thickness, the elastic modulus, and the tensile rupture strain of the FRP jacket were 0.165 mm, 250 GPa, and 1.5%, respectively. The compressive strength of unconfined concrete was 30 MPa. Both the concrete and the FRP jacket had an element size of about 5.0 mm, chosen on the basis of a mesh convergence study (Lin and Teng 2016a). Diameter-to-compression depth ratios \( D/c \) ranging from 0.0 to 2.0 at an interval of 0.5 were examined (i.e., \( D/c = 0, 0.5, 1.0, 1.5 \) and 2.0). A \( D/c \) ratio equal to zero corresponds to concentric compression, and a larger \( D/c \) ratio represents a larger load eccentricity. The imposed displacement was monotonically increased until the hoop strain of the FRP jacket at the extreme compression fibre (ECF), \( \varepsilon_{h,c} \), reached the FRP tensile rupture strain \( \varepsilon_f \) (1.5%). This criterion was adopted based on the commonly accepted experimental observation that the recorded FRP rupture strain in an eccentrically-loaded column is close to the rupture strain from the standard FRP coupon tensile test (Lin and Teng 2016a).

Distributions of Axial Stresses

Figure 3 shows the axial stress distributions over the section with a \( D/c \) ratio of 1.5 when the hoop strain of the FRP jacket at the ECF, \( \varepsilon_{h,c} \), is at 0.1%, 0.5%, 1.0%, and 1.5%, respectively. The axial stresses are obviously non-uniform in the direction of bending (i.e., the X direction in Figure 3) due to the strain gradient, with the largest axial stress being at the ECF where the confinement from the FRP jacket is the highest. In the Y direction, the axial stresses are close to being uniform, which indicates that the axial stress distribution over the entire section can be well represented by the average axial stress distribution in the X direction only.

Average Axial Stress-Axial Strain Responses

Figure 4 shows the average axial stress-axial strain responses of concrete at nine selected locations evenly distributed in the X direction of the circular section. It can be seen that the axial stress-axial strain curves of concrete at locations 4 and 5, which are near the neutral axis, are well below the CL stress-strain curve even
though they are in the compression zone of the section. This is due to the stress state of combined compressive and tensile stresses in the section near the neutral axis, leading to a reduced axial stress compared to that under tri-axial compression (i.e., axial compression in combination with two equal lateral compressive stresses) (Lin and Teng 2016a). The CL stress-strain curve was obtained from the FE results for the section under concentric compression (i.e., $D/c = 0$), which is also identical to the stress-strain curve predicted by Jiang and Teng’s (2007) model for FRP-confined concrete that was used as a basis of the FE approach (Lin and Teng 2016a). The axial stress-axial strain curves of concrete near the ECF (at locations 6, 7, 8, and 9) generally feature a bilinear shape similar to the CL stress-strain curve. However, these axial stress-axial strain curves have a smaller slope for the linear second segment (referred to as the second-segment slope hereafter) but a larger ultimate axial stress and a larger ultimate axial strain than the CL stress-strain curve (Figure 4). The observation of a larger ultimate axial strain of concrete at the ECF of an eccentrically-loaded column than the ultimate axial strain of a corresponding concentrically-loaded column or that expected based on a CL stress-strain model has also been made in many experimental studies (i.e., the axial strain enhancement effect) (e.g., Scott et al. 1982; Fam et al. 2003; Bissy and Ranger 2010; Yu et al. 2010; Csuka and Kollár 2012; Wu and Jiang 2013). This is because the expansion of concrete over an eccentrically-loaded section is non-uniform with the concrete in the vicinity of the ECF having larger expansions due to larger axial strains there than the rest of the concrete. Therefore, the axial strain of concrete at the ECF in an eccentrically-loaded section to induce the same FRP hoop strain there needs to be larger than that for a concentrically-loaded section.

As the concrete at the ECF is subjected to the highest axial stress over the column section and has the greatest distance from the neutral axis, it is believed that its stress-strain response plays a key role in determining the response of the entire section. Figure 5 shows the stress-strain curves of concrete at the ECF of sections with different $D/c$ ratios from FE analysis. It is obvious that the second-segment slope decreases but the ultimate axial strain increases as the $D/c$ ratio increases, with the combined effect being a slight increase in the ultimate axial stress.

![Figure 4 Average stress-strain responses of concrete at different locations ($D/c = 1.5$)](image)

![Figure 5 Stress-strain curves of concrete at ECF of sections with different $D/c$ ratios](image)

![Figure 6 Axial load-curvature curves obtained with different stress-strain curves](image)

![Figure 7 Interaction diagrams obtained with different stress-strain curves](image)
EFFECT OF STRESS-STRAIN CURVE ON COLUMN RESPONSE

The above discussion indicates that the direct use of a CL stress-strain model in the analysis of columns under eccentric loading may lead to unreliable results. In order to clarify this effect, the responses of sections with different $D/c$ ratios were predicted using section analysis based on two different stress-strain curves: one is the CL stress-strain curve and the other is the stress-strain curve of the concrete at the ECF from FE analysis. In the section analysis, the section was divided into 50 layers in the direction of bending (i.e., in the X direction) and all concrete layers were assigned with the same stress-strain curve (Lin and Teng 2016a).

The axial load-section curvature curves for sections with different $D/c$ ratios from section analysis are compared with FE results in Figure 6. It can be seen that the predictions with the stress-strain curve of concrete at the ECF are much closer to the FE results than those with the CL stress-strain curve. The ultimate curvatures obtained using the CL stress-strain curve are generally much smaller than the FE results. It is worth noting that the axial load-section curvature curves from section analysis are not exactly the same as the FE curves, and this is due to errors caused by approximating the stress-strain responses of concrete over the whole section by that of a single stress-strain curve for the ECF in section analysis. The axial load-moment interaction diagrams from section analysis and that from FE analysis are compared in Figure 7. It can be seen that these diagrams are close to each other, indicating that the strain gradient effect on the stress-strain response has only a small bearing on the load-carrying capacity of sections under eccentric loading.

ECCENTRICITY-DEPENDENT STRESS-STRAIN MODEL

Based on the above observations, a stress-strain model for the concrete at the ECF instead of a CL stress-strain model should be developed for use in the section analysis of eccentrically-loaded FRP-confined concrete columns as a relatively simple option for reasonably accurate predictions, especially for the ultimate deformation/ductility. As clearly indicated in Figure 5, the second-segment slope of the stress-strain curve of concrete at the ECF decreases but the ultimate axial strain increases as the $D/c$ ratio increases. Based on these trends, an eccentricity-dependent (EccD) stress-strain model can be established by modifying a CL stress-strain model if the relationship between the two models can be established. A comprehensive parametric study using the aforementioned 3D FE slice model was conducted by the authors, with all the parameters that affect the responses of FRP-confined circular sections under eccentric compression being properly examined (Lin and Teng 2016b). The results of the parametric study allowed the relationship between the stress-strain behaviour of concrete at the ECF and the corresponding CL stress-strain model to be clarified over a wide range of section parameters, based on which an EccD stress-strain model was established (Lin and Teng 2016b). This EccD stress-strain model can be directly used in section analysis of eccentrically-loaded FRP-confined RC columns. The proposed EccD stress-strain model has been shown to provide much more accurate predictions for the test results of eccentrically-loaded FRP-confined circular RC columns than the corresponding CL stress-strain model (Lin and Teng 2016b).

CONCLUSIONS

This paper has presented an improved understanding of the behaviour of FRP-confined concrete in a circular section under eccentric compression obtained from a 3D FE investigation. The following conclusions can be drawn from the results and discussions presented in the paper:

1. The uniaxial stress-strain response of concrete varies greatly over the section and may differ greatly from a stress-strain model obtained from studies on FRP-confined concrete columns under concentric loading (CL stress-strain model);
2. In the vicinity of the extreme compression fibre (EFC) of the section, the concrete receives much stronger confinement than the concrete near the neural axis, and has a bilinear stress-strain curve similar to that of a CL stress-strain model;
3. The direct use of a CL stress-strain model in the section analysis of an eccentrically-loaded column may lead to significant errors, especially for the prediction of ultimate deformation/ductility;
4. A stress-strain model for the concrete at the ECF offers a good option as the stress-strain model for section analysis of such columns for reasonably accurate predictions;
5. As the $D/c$ ratio increases, the second-segment slope of the stress-strain curve of concrete at the ECF decreases but the ultimate axial strain increases. Based on these trends, a so-called eccentricity-dependent
(EccD) stress-strain model can be established for the analysis of eccentrically-loaded columns by modifying an existing CL stress-strain model.

ABSTRACT

Reusing concrete can not only save natural resources, but also develop the composites of recycled aggregate concrete (RAC), among which are the fibre-reinforced polymer (FRP) confined RAC columns. The experiment for relatively large scale (with a diameter of 300mm) of prefabricated basalt fibre-reinforced polymer (BFRP) tube confined RAC stub columns (BCRSs) were performed under cyclic axial compression. Three parameters, including the strength of RAC, the recycled coarse aggregate (RCA) replacement ratio and the loading rate, were set to study the mechanical properties of these composites. The curves of Load-displacement, the envelopes of stress-axial strain, the curves of stress-hoop strain were obtained. The residual strain and stress degradation were analyzed, and a modified effective confinement factor of BCRSs was proposed. The experimental results will be a good supplement for the data base of FRP confined concrete columns.

INTRODUCTION

As a form of construction garbage regeneration, recycled aggregate concrete (RAC) has been newly reused into construction (Rao et al. 2007; Silva et al. 2014) due to its social, environmental and economic significance. However, it generally restricted to non principal components with low load-bearing capacity because of its originally high bibulous rate, large porosity and low strength (Al-Bayati et al. 2016; Fan et al. 2016; Kovler and Roussel 2011). Existed researches have shown that the performance of concrete members can be significantly enhanced by external confinement using fiber-reinforced polymer (FRP) (Xiao et al. 2012; Yu et al. 2015), due to its superior material properties, such as high tensile strength to weight ratio and excellent corrosion resistance (Wei et al. 2009).

So far, numerous experimental studies have been conducted to investigate the mechanical properties of components confined with high-tensile-strength carbon fiber-reinforced polymer (CFRP) or high-ductility glass fiber-reinforced polymer (GFRP) (Wu and Wei 2010; Seffo and Hamcho 2012; Almusallam 2007), but very few have related to basalt fiber reinforced polymer (BFRP), which has high cost efficiency and promising application prospect (Ozbakkaloglu 2013). Moreover, most studies have limited to focus on FRP confined RAC columns under monotonic axial loading (Jiang et al. 2016; Chastre and Silva 2010). This paper presents an experiment performed on BFRP confined RAC stub columns (BCRSs) under cyclic axial compression, which may be essential to seismically active areas.

EXPERIMENT PROGRAM

8 specimens of BCRSs were tested under cyclic axial compression with a diameter of 300mm and a height of 600mm. Three parameters were included, which were recycled coarse aggregate (RCA) replacement rates (0%, 30%, 50%, 70% and 100%), the strength of RAC (C40 and C60) and the loading process (Type A and Type B). The specimens were listed in Table 1. Each specimen was prepared 3 cubes and 3 cylinders respectively to test the concrete strength.

Materials and Specimen Preparation
BFRP tubes were prefabricated with an inner diameter of 300mm and a thickness of (2.35±0.25)mm by 40% of basalt fibre spirals in 80°. All pipes used were divided from the same BFRP tube after cutting the length of 500mm at both sides. The ultimate tensile strength of BFRP tube was 690MPa and modulus of elasticity was 51.3 GPa according to the measurement at laboratory.

Two grades of core concrete strength was C40 and C60. The lower strength concrete mixture ratio was cement: water: fine aggregate: coarse aggregate = 225: 475:641:1057 with a water cement ratio of 0.47, while the other mixture ratio was cement: water: fine aggregate: coarse aggregate: water reducing agent = 214: 643: 395: 1058.5: 10.28 with a water-cement ratio of 0.35. The fine aggregate was natural river sand with a fineness modulus of 2.4. The RCA was produced in the manufacture from a served building for over twenty years. Its properties were listed in Table 2, as well as the natural coarse aggregate (NCA).

The BFRP tube was served as a template for concrete, which was cast in the laboratory. The RCA replacement rate is based on the volume of coarse aggregate.

Test Setup and Measurements

For each BCRS, two bi-directional strain gauges with a length of 20mm were installed at the mid-height spaced 90° around the outer surface of the BFRP tube, totally 8 strain gauges. 4 linear variable displacement transducers (LVDTs) with a range of 50mm were additionally used to obtain the axial deformation for the whole column. All test data, including the strains, loads and displacements, were recorded simultaneously by a data logger, TDS530 static measurement acquisition system. The test setup and instruments were shown in Figure 1.
All cyclic axial compression tests were carried out using an electric-fluid servo compression machine with a loading maximum of 10000kN. The whole loading was controlled by displacement. Two loading types (Type A and Type B) were both designed as mixed loading schemes. The type A with a loading rate of 0.36mm/min involves: (1) 1 single full unloading/reloading (load below 70kN) cycle at displacement value of 0.6mm; (2) 11 repeated full unloading/reloading cycles, whose unloading displacement value was 0.6mm larger than the former one; (3) 6 repeated full unloading/reloading cycles at the displacement value of 7.8mm (0.6mm×13); (4) up to the specimen fracture. The type B with a loading rate of 0.54mm/min involves: (1) 1 single full unloading/reloading cycle at displacement value of 0.6mm; (2) 11 repeated full unloading/reloading cycles, whose unloading displacement value was 1.2mm larger than the former one until the specimen fracture which appeared the bearing capacity of BCRSs dropped dramatically below 50% of the peak load.

RESULTS AND DISCUSSIONS

Failure Modes

Specimens after test were shown in Figure 2. The failure modes of BCRSs revealed an explosive rupture of BFRP jacket in the mid-height and a little above region, which were similar with that of FRP confined NAC members under monotonic axial compression. As to the BCRSs with low-strength RAC, the filamentous fracture of the outer tubes could be seem, following with concrete smashing, which had a certain predictability before destruction. However, for the BCRSs with high-strength RAC, the BFRP tubes were generally laminar tearing and concrete was splitting aslant without any predictability.

Bearing Capacity

The load-deformation curves for some specimens were shown in Figure 3. The main test results were summarized in Table 3, where the enhancing coefficient of bearing capacity defined as the ratio of BCRS strength to equivalent concrete strength from cylinders (Sabins and Mirza 1979). From the enhancing coefficient, it can be seen that the BFRP confinement improve the load-bearing capacity of low-strength RAC effectively by approximately 50%, even reaching 62% when RCA replacement ratio is 100%. However, the improvement of the BCRSs with high-strength concrete was less than 20%, which indicates that cyclic axial compression has obvious negative influence on the high-strength BCRSs.

The strength model of FRP confined concrete is defined by the following Eq. 1 (Teng, J.G, 2002).

\[
\frac{f}{f_{\text{c}}} = 1 + k \cdot \frac{f}{f_{\text{c}}}
\]

(1)
where $f_c$ and $f'_c$ are the compressive strength of confined concrete and unconfined concrete respectively; $k_1$ is the effective confinement factor; and $f_l$ is the lateral restraint stress, which is defined by Eq. 2 (Teng, J.G et al. 2002).

$$f_l = \frac{2f_{frp}d}{d}$$

where $f_{frp}$ and $t_{frp}$ are the hoop tensile strength and thickness of FRP respectively; and $d$ is the diameter of confined concrete.

It should be noted that the effective confinement factor can be applied for BCRSs under cyclic axial compression, and the value is suggested as 1.8 for the BCRSs with low-strength concrete, but no longer applicable for the BCRSs with high-strength concrete.

![Figure 3 Curves of load-deformation](image)

![Figure 4 Envelopes of stress-axial strain](image)

![Figure 5 Curves of residual strain-unloading strain](image)

**Envelopes of Stress-Strain**

The envelopes of stress $\sigma$–axial strain $\varepsilon_v$ were shown in Figure 4. The curves of the BCRSs with low-strength concrete have an obvious enhancing section, in which the bearing capacity and ductility are improved significantly. The RCA replacement rate has little effect on the mechanical properties of BCRSs. The load-bearing capacity and the deformation ability of BCRSs with RAC replacement ratios of 50% and 100% are both better than that with...
natural concrete. The BCRS with a rate of 30% is similar with the specimen with a rate of 70% in strength and ductility. Compared with the low-strength ones, the first section of the high-strength BFRSs’ curves has a larger slope, which drops slightly after reaching the second section whose slope is nearly zero. The ductility of high-strength BFRSs is not as good as that of low-strength ones. For higher cyclic loading speed, the load-bearing capacity of BFRSs decreases, but a slight increase in ductility.

Residual strain

The last loading has an accumulation effect on deformation for the next loading after the period of elasticity, thus there will be a residual strain, or permanent deformation, after unloading. The relationship of residual strain $\varepsilon_{re}$ and unloading strain $\varepsilon_{un}$ were shown in Figure 5. The relationship can be delivered through the linear function fitting, as Eq. 3, with an adjust determination coefficient of 0.98949.

$$\varepsilon_{re} = 0.72717 \varepsilon_{un} - 0.00115 \quad (3)$$

Hoop Strain

Two of the stress $\sigma$-hoop strain $\varepsilon_h$ curves were shown in Figure 6. The development of its relationship is the same as that of the stress and axial strain.

Stress degradation

The load-bearing capacity of specimens would be lower after reloading to the same displacement compared to last reloading, which is measured by stress degradation rate. The primary stress $\varphi_1$ is the ratio of stress $\sigma_{un,1}$ in the second reloading corresponding with the first unloading strain $\sigma_{un}$ to the first unloading stress. The $n^{th}$ stress degradation rate $\varphi_n$ is the ratio of stress $\sigma_{un,n}$ in the next reloading corresponding with the last unloading strain to the last unloading stress $\sigma_{un,n-1}$ in the last 6 repeated loading circle. The stress degradation was shown in Figure 7. In Figure 7a, the values of primary stress are ranged from 0.85 to 1. The primary stress decreases before the unloading strain approximately reaching to 0.004, after which develops steadily. However, the discretion is larger for the BCRSs with high-strength concrete, especially at a high loading rate. From Figure 7b, the value of $n^{th}$ stress degradation rate is ranged from 0.92 to 1, without large deviation among specimens.
CONCLUSIONS

A cyclic axial compression test was performed on BCRSs with different RCA replacement ratios, concrete strength and loading rates. The following test results could be concluded.

1. The low-strength BCRSs were shown the filamentous fracture of the outer tubes and concrete smashing, while the high-strength ones were presented BFRP tubes laminar tearing and concrete splitting aslant without any predictability.

2. BCRSs improve the load-bearing capacity of low strength concrete effectively by approximately 50%, while the improvement of high-strength BCRSs was less than 20%. The effective confinement factor can be applied for BCRSs under cyclic axial compression, and the value is suggested as 1.8 for the low-strength BCRSs.

3. The envelopes of stress-strain for the low-strength BCRSs has an obvious enhancing section. The RCA replacement ratio has little effect on the mechanical properties of BCRSs. The ductility of high-strength BFRSs is not as good as that of low-strength ones. For higher cyclic loading speed, the bearing capacity of BFRSs decreases, but a slight increase in ductility.

4. The relationship of residual strain and unloading strain can be delivered through the linear function fitting.

5. The primary stress degradation rate develops steadily after unloading strain approximately reaching to 0.004. The value of n° stress degradation rate is ranged from 0.92 to 1, without large deviation.

ABSTRACT
Confinement using Fibre-reinforced polymers (FRP) significantly improves both the strength and the ductility of reinforced concrete columns. Many analytical models for prediction of strength and ductility of the FRP-confined concrete can be found in the literature. However, most of these models were developed based on conventional deterministic approaches. In this study, a probabilistic approach for predicting the ultimate strength and strain of FRP-confined concrete is developed. Using probabilistic models for concrete and FRP materials and the Monte Carlo simulation technique, uncertainty in evaluating the ultimate strength and strain in FRP-confined concrete is investigated and lower percentile design models are suggested.

INTRODUCTION
RC columns serve an important role in the load-carrying capacity of concrete structures. Failure of a column, due to overloading or age deterioration, would lead to more catastrophic consequences than would the failure of other structural elements. Therefore, it is necessary to strengthen deteriorated or deficient RC columns to increase their load-carrying capacity, and to improve their ductility in order to better their performance against accidental and seismic loads. In the last decade or so, the retrofit of RC columns by wrapping them with FRP sheets has gained increasing interest in the engineering community (Binici 2008; Demers and Neale 1994; Ozcan et al. 2010; Saadatmanesh et al. 1994). The work of many researchers has indicated that FRP confinement (especially in the potential plastic hinge regions) can substantially enhance the axial compressive strength and ductility of RC columns (Binici 2008; Gu et al. 2012; Ozbakkaloglu and Saatcioglu 2006), and this is an important rehabilitation option to consider. The effectiveness of FRP confinement in increasing the strength and ductility is attributed to its ability to avoid or delay undesirable phenomena such as concrete crushing or longitudinal reinforcing bar buckling.

Accurate estimation of the ductility and strength of FRP-confined columns is necessary for a reliable retrofit strategy. Due to the inherent uncertainties in material properties and geometrical dimensions, structural strength and ductility exhibit variability, which needs to be statistically quantified. Furthermore, there is always uncertainty associated with the models used for predicting structural responses. Therefore, a reliable predictive model should result from a probabilistic procedure containing all the mentioned uncertainties. The probabilistic procedure for deriving predictive design models involves four important steps: (i) developing a best-fit predictive model; (ii) establishing a probabilistic model for the model error; (iii) establishing/collecting statistical models for the main random variables, such as material properties; and (iv) developing a probabilistic design model based on a specific confidence level. The probabilistic models can then be used to predict the axial/flexural strength and ductility of FRP-confined columns or to investigate the reliability of FRP-confined columns. In any development of design provisions for FRP-confined concrete members, probabilistic models for the ultimate strength and strain of FRP-confined concrete are essential. These models can directly be used for calculating the design values of the ultimate strength and strain of FRP-confined concrete. They can also be useful in any moment-curvature analysis aimed at predicting the design curvature ductility and flexural strength of columns. Most importantly, these models can be employed in reliability-based calibration of resistance reduction factors.
This paper presents a probabilistic procedure for evaluating the ultimate strength and strain of FRP-confined circular columns. A probabilistic procedure based on the Monte Carlo simulation is employed for establishing lower percentile design models for the ultimate strength and strain. The methodology presented here can be extended to columns with rectangular or square sections.

FORMULATION OF STRENGTH AND DUCTILITY MODELS

Mechanism of FRP confinement

Figure 1 illustrates the stress state of a circular concrete column wrapped with FRP. Using the force equilibrium and considering the linearity of FRP materials behaviour, the lateral (radial) confining pressure acting on the concrete core at the FRP jacket failure at the ultimate state, \( f_r \), is given by

\[
f_r = \frac{2\sigma_{fu} t_f}{D} = \frac{2E_f \varepsilon_{fu} t_f}{D}
\]

where \( \sigma_{fu} \) and \( t_f \) are the FRP ultimate strength and thickness of the FRP jacket, respectively, and \( D \) represents the diameter of the concrete cylinder. Variables \( E_f \) and \( \varepsilon_{fu} \) denote the Young's modulus and the ultimate radial strain of the FRP jacket. In Eq. 1, by assuming a perfect bond between the FRP jacket and the concrete core, the radial strain in the FRP membrane is equal to that of the concrete core.

![Figure 1 Stress diagrams in FRP-confined concrete](image)

The confining pressure around the concrete core increases proportionally with the FRP hoop strain, until the point when the whole system fails due to the failure of the FRP fibres. Thus, at the failure state, Eq. 1 can establish a relationship between the ultimate lateral pressure, \( f_r \), and the rupture strain of the FRP jacket, \( \varepsilon_{f,rup} \). The failure is characterised by the tensile fracture of the FRP jacket. However, it has been observed that, at failure, the tensile strength of the FRP wrap is different from the uniaxial tensile strength of the FRP (Lam and Teng 2003; Pessiki et al. 2001). To address the difference between the actual rupture strain and the ultimate strain of FRP material, by replacing the FRP ultimate tensile strain, \( \varepsilon_{fu} \), with the actual hoop rupture, \( \varepsilon_{f,rup} \), the actual confining pressure, which is here denoted as \( f_{r,rup} \), and can be seen in Eqs. 2a and 2b, is introduced.

\[
e_{f,rup} = k_e \varepsilon_{fu}
\]

\[
f_{r,rup} = \frac{2E_f \varepsilon_{f,rup} t_f}{D}
\]

Results from different tests show that the so-called FRP strain efficiency factor, \( k_e \), given by the ratio \( \varepsilon_{f,rup} / \varepsilon_{fu} \), varies for different types of FRP materials.

Another term that is usually used regarding FRP-confined concrete is the so-called “jacket lateral stiffness”, which is here denoted using the symbol \( E_j \). Using Eq. 1, and taking advantage of Hook’s law, Eqs. 3a and 3b result.

\[
f_r = \frac{2E_f \varepsilon_{fu} t_f}{D} = E_j \varepsilon_{fu}
\]

\[
E_j = \frac{2E_f t_f}{D}
\]

The jacket lateral stiffness (also called jacket lateral modulus) plays an important role in the derivation of expressions for the confined concrete dilation rate.
Strength model

In this study, a linear model is used to predict the ultimate strength of FRP-confined columns, $f'_{cc}$. The linear model used in this study follows the original form suggested by Richart et al. (1928), based on the well-established Mohr-Coulomb failure criterion. If a least-square regression analysis is used to fit the data to a line relating the axial and the lateral stresses, as is shown in Figure 2a, the slope of this line represents the confinement effectiveness coefficient, $k$. Eq. (4) shows this approach for finding this factor.

$$\frac{f'_{cc}}{f'} = 1 + k \frac{f'_{tu}}{f'_r} = 1 + k \frac{2k'\lambda_{tu}}{Df'_r}$$  \hspace{1cm} (4)

In Eq. (4), $f'_{cc}$ is the maximum strength of FRP-confined concrete. It should be noted that in the regression analysis that leads to the determination of $k$, the fitting line is forced to pass through the point representing the uniaxial test results of plain unconfined concrete. In the model proposed by Richart et al. (1928), a confinement effectiveness factor of 4.10 was suggested for actively confined concrete. For FRP-confined concrete, based on the model proposed by Lam and Teng (2003), this factor is 3.30. This model will be adopted in the probabilistic analysis presented in the next section.

Ductility model

In this study, a simplified model initially proposed by Tamuzs et al. (2006) and later used by Berthet et al. (2006) for predicting the ultimate strain of concrete, which can be seen in Figure 2b, is adopted. In this model, using a bilinear curve (as shown in Figure 2b), the dilation behaviour of FRP-confined concrete is approximated. The initial slope, which represents the elastic behaviour, is the Poisson ratio, while the second slope, which represents the post-cracking behaviour, is the asymptotic plastic dilation ratio. Berthet et al. (2005) showed that, for specimens experiencing strength enhancement, this bilinear representation is a reasonable approximation and it would considerably simplify the derivation of the ultimate strain of FRP-confined concrete. A recent study by Ozbakkaloglu et al. (2013) showed that predictive models based on this form of approximation are more accurate than other types of models. It has been reported that the asymptotic values of the dilation ratio and dilation rate, $\eta_u$ and $\mu_u$, are approximately equal (Tamuzs et al. 2006). Referring to Figure 2b, the ultimate strain of FRP-confined concrete, $\varepsilon_{cc}$, can be calculated as shown in Eq. 5.

$$\varepsilon_{cc} = 1.00 + \left( \frac{1}{\mu_u} \right) \left( \frac{\varepsilon_{f,upp} - \varepsilon_{c,0}}{\varepsilon_{c,0}} \right)$$  \hspace{1cm} (5)

The strain ratio in Eq. 5 can be considered as the strain enhancement or ductility. Since the dilation behaviour of confined concrete depends on the confinement level, as an indicator of volumetric dilation, the dilation rate, $\mu_u$, could reasonably be related to the properties of the FRP jacket and, in particular, to the jacket lateral stiffness. A model proposed by Baji et al. (2016), which can be seen in Eq. 6b, is adopted for calculating the ultimate dilation rate, $\mu_u$.

PROBABILISTIC APPROACH

According to the developed analytical models, the ultimate strength and strain enhancements are shown in Eqs. 6a and 6b. In comparison with the total ultimate strain, the elastic lateral strain i.e $\nu_0$ (see Eq. 6b) is negligible.
Therefore, in the ductility model, shown in Eq. 6b, it is ignored. As can be seen, the second terms of the both enhancement models are the products of different random variables.

\[
S = f'_{c} - 1.00 = \xi (3.30) \left( \frac{2k_{c} \sigma_{n}}{D'_{c}} \right) \tag{6a}
\]

\[
M = \frac{e_{c0}}{\xi_{c0}} - 1.00 = \xi \left( \frac{1}{5.1} \right) \left( \frac{k_{c} \sigma_{n}}{E_{r} e_{c0}} \right) \left( \frac{2E_{r} f'_{c}}{D'_{c}} \right)^{0.36} \tag{6b}
\]

where \( \xi \) represents the model error. The normalised strength enhancement \( (S) \) and strain enhancement \( (M) \), can be treated as random variables. Using a probabilistic study, statistics of these variables can be derived. Furthermore, the lower percentile values can be calibrated as design models. For developing these design models, probabilistic models for all the variables shown in Eqs. 6a and 6b are required. Typical probabilistic models taken from the current literature, shown in Table 1, will be used in this study. The nominal value for the FRP strain efficiency factor is taken from the ACI 440 (2008).

The lower percentile value of the ultimate strength and strain can be used for design and code calibration purposes. In comparison with the conventional deterministic models the lower percentile design models, such as models presented in this study, provide more consistent level of safety in the design procedure. The resistance predicted by a design model is lower than that of deterministic model, which is based on nominal values of the variables. In this research, a relationship between the nominal ultimate strength and strain enhancements and design values (based on lower percentile) of these variables is established. This relationship considers uncertainties in all the main random variables. Derivation of the ratio of lower percentile to nominal values based on the empirical cumulative probability density function of the strength or ductility enhancement is graphically shown in Figure 3. The subscripts \( p \) and \( n \) denote the lower percentile value and the nominal values, respectively. The Monte Carlo simulation technique (Melchers 1999) is used for finding the empirical cumulative probability density function of both the strength and strain enhancements.

The lower percentile value of the ultimate strength and strain can be used for design and code calibration purposes.

![Figure 3 Probabilistic lower percentile values i.e. design models](image_url)
RESULTS AND DISCUSSIONS

Following the solution provided in the previous section, the ratio of the $p^{th}$ percentile to the nominal value, of the strength and strain enhancement value can be calculated. The statistical models shown in Tables 1 can be used as an application example for the proposed model. Value of the lower percentile, $p$, is generally decided by code authorities and depends on the overall reliability analysis of the member as well. Generally, 5% and 10% are common in design practice. Based on the different lower percentile values ($p = 0.05, 0.10$ and $0.25$), variation of lower percentile to nominal ratio with respect to concrete compressive strength is shown in Figure 4.

Due to the dependence of statistical measures of concrete compressive strength on the concrete specified strength, the probabilistic model for the strength enhancement varies with change in the concrete compressive strength. Nevertheless, as shown in Figure 4, the variation is not considerable. For concrete compressive strengths above 30 MPa, the ratio of $S_{p=0.10} / S_n$ is about 0.60. Considering this ratio, the lower percentile strength model can be proposed as follows.

$$
\left[ \frac{f'_c}{f_{c0}} \right]_{p=0.10} = 1.00 + (0.60) \left[ \frac{2k \sigma_{sf \ell} \ell}{Df_c} \right]_{\text{Nominal}}
$$

(7)

Accuracy of the probabilistic-based model shown in Eq. 7 depends on the accuracy of the probabilistic models for the material properties of concrete and FRP and, more importantly, on the accuracy of the model error. Results for different $p$ values can be easily obtained using the established probabilistic procedure.

The strain enhancement or ductility variable ($\varepsilon_c / \varepsilon_{c0} - 1$) is a product of eight different random variables (shown in Eq. 6b). In comparison with the strength model, more random variables are involved in the strain model. The procedure used for deriving the strength enhancement model can be followed for obtaining the $p^{th}$ percentile value of the strain enhancement. The probabilistic models shown in Table 1 can again be used as a case study for calculating the statistics of the strain enhancement ratio and the $M_{p=0.10} / M_n$ ratio. Similar to the strength model, this ratio is nearly constant (about 0.45) for concrete compressive strengths of more than 30 MPa. Therefore, the $10^{th}$ percentile value model for the strain enhancement can be expressed as follows.

$$
\left[ \frac{\varepsilon_c}{\varepsilon_{c0}} \right]_{p=0.10} = 1.00 + (0.45) \left[ \frac{1}{5.1} \left( \frac{k \sigma_{sf \ell} \ell}{E_j \varepsilon_{c0}} \right)^{0.56} \right]_{\text{Nominal}}
$$

(8)

This model, along with the strength model shown in Eq. 7, can be used for the evaluations of the design strength and strain ductility.

CONCLUSIONS

Probabilistic investigation into the ultimate strength and strain of FRP-confined concrete was the main target of the current research. Analytical models for the ultimate strength and strain of FRP-confined concrete were taken from the available literature. Considering the variability in the model error, in the mechanical properties of concrete and FRP materials and using the Monte Carlo simulation technique, a probabilistic procedure for deriving design
models for the ultimate strength and strain was proposed. Design models based on a predefined lower percentile values were suggested.

ABSTRACT

This paper presents an experimental study on concrete filled tubular stub columns. The environment friendly seawater and sea sand concrete (SWSS) and high corrosion resistance materials (i.e., stainless steel (SS) and carbon or basalt fibre reinforced polymer (CFRP or BFRP)) were adopted to make the stub columns. An appropriate mixture was firstly developed for SWSSC and the material properties of SS, CFRP and BFRP were determined by tensile coupon test and disk-split test. A total of 12 SWSSC filled columns and 12 corresponding hollow sectional tubes were tested under axial compression. The structural behaviour of test specimens was discussed. Finally, current design methods were used to estimate the ultimate capacity of SWSSC filled SS, CFRP and BFRP tubular stub columns.

KEYWORDS

SWSSC, stainless steel, CFRP, BFRP, concrete-filled stub columns.

INTRODUCTION

Concrete filled tubes, which are composed of core concrete and outer tubes, have been widely applied in civil engineering, such as bridges, high rise buildings, and power transmission towers. As the core concrete is confined by the encasing tubes, the strength of the concrete can be considerably enhanced by the so called “confinement effect”. Past researches (Zhao et al. 2010) have indicated that the confinement effect provided by circular outer tube is much higher than that provided by square or rectangular tubes.

It is well known that the huge consumption of Portland concrete causes environment problems (e.g. CO₂ emission due to the highly energy intensive production of Portland cement) and exacerbate the resource shortage (e.g. fresh water, river sand). An attractive solution is to replace the Portland cement, fresh water and river sand by industry waste (e.g. slag), seawater and sea sand respectively. Some studies (Mohammed et al. 2004) conducted on concrete made of seawater and (or) sea sand have found insignificant difference in the mechanical properties of seawater and sea sand concrete (SWSSC) and ordinary Portland concrete. However, the chloride ion introduced by seawater and sea sand can cause serious corrosion problems, which should be carefully considered before the application of SWSSC into engineering practice.

Because of its high corrosion resistance, the stainless steel (SS) is regarded as one of the desirable materials to replace the carbon steel used in marine structures. Several studies (Lam and Gardner 2008, Uy et al. 2011) have been conducted on concrete filled SS tubular columns. Their studies indicate that concrete filled SS tubes display more ductile behaviour than concrete filled carbon steel tubes and the current design methods for composite columns are conservative. A major reason for this different structural behaviour is that the material properties of SS, which has a rounded stress-strain curve, is different from carbon steel.

Even though many studies have been conducted on concrete confined by FRP wraps (Ozbakkaloglu 2013, Teng et al. 2009), the experimental investigations on concrete filled fibre reinforced polymer (FRP) tubes are rather limited. The FRP tube can provide strength in both longitudinal and hoop directions and can be used as formwork in new constructions. The reported researches mainly focused on concrete filled glass fibre reinforced polymer (GFRP) tubes (Fam and Rizkalla 2001, Zhang et al. 2015, Li et al. 2016). There is a need to study concrete filled
This paper presents an experimental investigation on seawater and sea sand concrete (SWSSC) filled stainless steel, CFRP and BFRP tubular stub columns. Both SWSSC filled circular tubes and corresponding hollow sectional tubes were tested. The material properties of SS and FRP were also obtained by tensile coupon test and disk-split test. Finally, the ultimate capacity of SS, CFRP and BFRP filled tubes is predicted using the existing design methods.

EXPERIMENTAL INVESTIGATION

Specimens

A total of 12 SWSSC filled tubular stub columns and 12 corresponding hollow section columns were tested in the present study. The specimens were made of SWSSC, SS, CFRP and/or BFRP. Four different nominal diameters (50, 101, 114, 165 mm) of outer tubes were adopted and the nominal thickness of the tubes was 3 mm. In order to eliminate the influence of global buckling and end effect, the specimen length is 150 mm for tubes with nominal diameter of 50 mm and 400 mm for all the other tubes.

The dimensions of test specimens are summarized in Table 1, where the ultimate capacity ($N_t$) is also given. The label of specimen consists of tube material type ("S" for stainless steel, "C" for CFRP, "B" for BFRP), nominal diameter ("50", "101", "114", "165"), and cross-section configuration ("H" for hollow sectional tubes, "C" for SWSSC-filled tubes).

Material properties

The alkaline-activated slag-based concrete with seawater and sea sand was used in this research. A 1 m$^3$ SWSSC contained 360 kg slag, 190 kg seawater, 830 kg sea sand, 1130 kg coarse aggregate, 38.4 kg sodium meta-silicate, and 14.4 kg hydrated lime slurry. The 3% (percentage weight of slag) sodium meta-silicate activator was pre-blended with slag in the dry form before mixing. The hydrated lime slurry was used to improve the workability. More details of the SWSSC mixture can be found in Li et al. (2016).

Two batches of concrete were cast for specimens: batch 1 for SWSSC filled SS and CFRP tubes and batch 2 for SWSSC filled BFRP tubes. The concrete strength was obtained by standard cylinder test and the averaged 28-day strengths were 35.8 MPa for batch 1 and 32.8 MPa for batch 2. All the specimens and concrete cylinders were sealed with plastic film and stored at room temperature before testing.

The SS tubes are made of 316 grade austenitic stainless steel in accordance with AS/NZS4673 (2001). The material properties of stainless steel was obtained by tensile coupon test. Two coupons were cut from each size of tubes and the ends of coupons were flattened in order to be gripped by test machine. The tensile coupon test was
conducted in accordance with AS 1391 (2007) and the test results are summarized in Table 2, in which $f_{0.2}$ is 0.2% proof stress, $f_u$ is the ultimate stress for SS.

Both carbon fibre reinforced polymer (CFRP) and basalt fibre reinforced polymer (BFRP) were used in the present study. The FRP tubes were fabricated by the filament winding process with different fibre orientations. Based on the manufacturer data, 20%, 40%, and 40% fibres were in the angles of 15°, ±40° and ±75° with respect to longitudinal axis of tubes.

The longitudinal strength of FRP was obtained by the tensile coupon test. As the ends of coupons were not flat, two sets of grips made of aluminium were used to ensure that the test machine gripped the coupon tightly. The “disk-split”, similar to the test specified in ASTM D2290 (2012), was conducted on 20 mm wide FRP rings to evaluate the hoop strength. A detailed introduction of the test setup can be found in Li et al. (2016). Two coupons and two rings were tested for each size of FRP tubes and the averaged strengths in longitudinal and hoop directions are given in Table 2, in which $f_{ul}$ is longitudinal strength and $f_{uh}$ is hoop strength for FRP. As shown in Table 2, the hoop strength of FRP is much higher than the longitudinal strength and the strength of CFRP is higher than that of BFRP.

Test setup and instrumentation

For SWSSC filled tubes and SS hollow sections, the load was directly applied on the stub columns. End plates with annular slots were used for FRP hollow sections and the gap between the tube and slots was filled by thin steel strips (shims) in order to avoid the end failure. The loading rate for all the specimens is 1 mm/min with displacement control. For SWSSC filled specimens, cement paste was used to fill the gap caused by the shrinkage of concrete to make sure the load was simultaneously applied on the core concrete and outer tube.

Three linear variable displacement transducers (LDVTs) were equally placed around tested tubes and their averaged data were used to estimate the axial end shortening. Three longitudinal and three circumferential strain gauges were affixed to all columns at mid-height. All the loads, displacements and strains were automatically recorded by a data acquisition system. The test setup and instrumentation are similar to those described in Li et al. (2016).

Test results and discussions

The ultimate capacity ($N_u$), i.e., the maximum load the tube can resist, is presented in Table 1. The hollow stainless steel tubes failed by the plastic local buckling and yielding. The load-axial strain curves are shown in Figure 1, in which axial strain is the axial end shortening divided by specimen length. As shown in Figure 1, with the increase of diameter to thickness ratio ($D_o/t_o$), the axial strain corresponding to peak load and ductility decrease. Furthermore, the ultimate stress of the tube (i.e., ultimate capacity divided by cross-section area) to 0.2% proof stress ($f_{0.2}$) ratios are 1.90, 1.28, 1.21 and 1.14 for SS hollow sections with nominal diameter of 50 mm, 101 mm, 114 mm and 165 mm respectively.

The failure mode of CFRP and BFRP hollow tubes can be regarded as local buckling and crushing. As mentioned previously, the tube ends were restrained by end plates to avoid the end crushing. The sudden failure of all the hollow sections occurred near the end plates, which followed by a dramatic drop of the applied load. The load-axial strain curves are summarized in Figure 2, in which the post failure curves are not plotted. In general, the load-axial strain curves display a linear behaviour, and the ultimate axial strains for FRPs are much lower than those of SS hollow sections. It is also found that the hollow sections under compression cannot reach the longitudinal strength ($f_{ul}$) obtained in tensile coupon tests.
The failure mode of SWSSC filled SS tubes is an outward folding (Figure 3(a)) which is commonly observed for concrete filled steel tubes. The load-axial strain curves are plotted in Figure 4. A strain hardening response was observed for specimen S50-C due to the substantial confinement effect. For other specimens, there was no obvious load drop even though the specimens were under large deformation, which displayed great ductility. The test was terminated when the end shortening was close to the stroke of test machine, which was about 60 mm. The ultimate capacity \( N_t \) for SWSSC filled SS tubes is taken as the maximum load within the 5% axial strain and the \( N_t \) data are listed in Table 1. Similar definition of ultimate capacity is also adopted by Lam and Gardner (2008). A comparison between Figure 1 and Figure 4 indicates that the infilled concrete can delay the local buckling of SS tubes and the ductility is greatly improved.
The structural behaviour of SWSSC filled FRP tubes is different from that of SWSSC filled SS tubes. A bilinear response was observed for SWSSC filled FRP tubes (Figure 5). With the increase of applied load, FRP tubes firstly buckled in longitudinal direction with a slightly drop of applied load. However, the specimens can still sustain the load until the rupture of outer tube in hoop direction. Based on the test observation, the rupture of CFRP tubes was more sudden than that of BFRP tubes. For SWSSC filled CFRP tubes, after rupture, the applied load dropped to almost zero immediately (marked by “+” in Figure 5) and the inner concrete came out (Figure 3(b)). Nevertheless, the SWSSC filled BFRP tube still had residual strength after tube rupture and the failure is not as sudden as in the case of SWSSC filled CFRP tubes (Figure 3(c)).

As shown in Figures 4 and 5, the confinement effect is more obvious for SWSSC filled FRP tubes, but the SWSSC filled SS tubes have much higher ductility. The main reason is the different material properties of SS and FRP. The SS, with rounded stress-strain response, can provide passive confinement while the FRP, with linear stress-strain response, can provide active confinement.

PREDICTION OF ULTIMATE CAPACITY

SWSSC filled SS tubes

Currently, there are no design codes for concrete-filled stainless steel columns. A design method (DBJ13-51 2003) for concrete filled carbon steel tubes ($N_{DBJ}$) and the simple superposition method ($N_{sup}$) are adopted in the present study. The design formulas in DBJ13-51 are listed as Eqs 1 and 2:

$$N_{DBJ} = (1.14 + 1.02\xi_0) f_{cu} (A_s + A_c)$$ (1)

$$\xi_0 = A_s f_y / A_c f_{cu}$$ (2)

in which $\xi_0$ is confinement factor, $A_s$ is cross-section area of steel tube, $A_c$ is concrete area, $f_y$ is yield strength ($= f_{0.2}$ for SS), $f_{cu}$ is cubic concrete strength, which is 0.85$f'_c$. In the simple superposition method, the predicted capacity is the capacity summation of core concrete and outer tube.

A comparison between the test capacity and predicted capacity is shown in Table 3. It seems that both the simple superposition method and current design method are conservative. The main reasons are the confinement effect is ignored in simple superposition method and the strain hardening of SS is not considered in either of the two methods.

SWSSC filled CFRP and BFRP tubes

Researchers (Ozbakkaloglu 2013, Lam and Teng 2003) have proposed some design methods for concrete confined by FRP wraps (fibre oriented in hoop direction only). However, there is no method for concrete filled FRP tubes that contain fibres in both hoop and longitudinal directions. The method proposed by Lam and Teng (2003) for concrete confined by FRP wraps is adopted herein to estimate the ultimate capacity of concrete filled FRP tubes ($N_{wrap}$). $N_{wrap}$ can be calculated by the following equations (the longitudinal strength is ignored):

$$N_{wrap} = A_c (f'_c + 3.3 f_l)$$ (3)

$$f_l = 2 f_{uho} / D_o$$ (4)

in which $A_c$ is concrete area, $f'_c$ is concrete strength, $f_l$ is confining stress, $f_{uho}$ is hoop strength of FRP, $D_o$ is tube diameter and $t_o$ is tube thickness. The predicted capacity by this method is listed in Table 4, in which the prediction by the simpler superposition method ($N_{sup}$) is also listed.

274
As shown in Table 4, the simple superposition method is too conservative as the concrete strength can be significantly enhanced due to the confinement effect provided by FRP tubes. Lam and Teng’s method for concrete confined by FRP wraps is slightly conservative as the longitudinal strength of the FRP tube is ignored.

CONCLUSIONS

This paper presents an experimental study on seawater sea sand concrete (SWSSC) filled SS, CFRP and BFRP tubular stub columns under axial compression. Several conclusions can be made from current study: (1) the concrete strength enhancement caused by SS tubes is lower than that by CFRP and BFRP tubes, but the ductility of SWSSC filled SS tubes is much higher; (2) Current design method for concrete filled carbon steel tubes can be conservatively applied to SWSSC filled SS tubes; (3) The design method for concrete confined by FRP wraps can be applied to SWSSC filled CFRP and BFRP tubes. There is a need to develop more accurate design models. Research is being conducted on the durability of SWSSC-filled SS tubes and FRP tubes.

ACKNOWLEDGEMENT

The authors wish to acknowledge the financial support provided by the Australian Research Council (ARC) through an ARC Discovery Grant (DP160100739), and CST composites for suppling the GFRP tubes. The tests were conducted in the Civil Engineering Laboratory at Monash University. Thanks are also due to Mr. Long Goh, Mr. Saravanan Mani and Mr. Jeff Doddrell for their assistance. We thank Mr. Damian Carr of Bayside City Council for his permission to obtain seawater and sea sand from Brighton Beach in Melbourne.

ABSTRACT

It has been recently proved that the Lattice Discrete Particle Model (LDPM) is capable of accurately capturing the behavior of uniformly and non-uniformly confined concrete and, consequently, it can be considered a useful tool for the simulation of FRP confined concrete columns with different cross sections under compressive loading. The LDPM computational framework is implemented into a multi-purpose structural analysis program called MARS, which is based on an explicit dynamic algorithm scheme, advantageous in terms of convergence. However, decreasing the maximum stable time step with the highest natural frequency of the system, the computational time necessary to carry out simulations of quasi-static events, like the compression tests in the present study, might be highly demanding. In order to decrease the computational cost of the simulations, the Proper Orthogonal Decomposition (POD) as a model reduction technique has been explored for the application to the LDPM models of FRP confined columns and the relationship between efficiency gain and accuracy loss is discussed.

KEYWORDS

FRP, POD, LDPM, confinement, numerical model.

INTRODUCTION

Various numerical models have been explored in literature to reproduce the behavior of FRP-confined concrete columns and to capture the interaction between the axial strains and lateral expansion of concrete with the corresponding stress increase in the external jacket (e.g. Karabinis et al. 2008, Yu et al. 2010, Teng et al. 2015). Most of the macroscopic models available, though, have limitations related to the simplification in the constitutive laws for concrete softening response, so that the good agreement between experimental data and numerical models is often oriented to specific applications rather than generally valid (Wu, 2015). The mechanisms activated during the fracturing process of concrete are complex and not easy to be simulated with a simplified macroscopic mode: precise and accurate material dilatation properties during the micro cracking evolution and fracture propagations are crucial for capturing the post-peak response of FRP-confined concrete (Lam and Teng, 2003). For these reasons, a recently developed mesoscale model for concrete (Cusatis et al. 2011), called the Lattice Discrete Particle Model (LDPM) has been explored for simulations of FRP-confined response of concrete columns. After an improvement in the constitutive law in compression and the proper parameters calibration (Ceccato et al. 2015), the model can predict the behavior of FRP confined concrete and its sensitivity to the stiffness of the FRP wrapping and to the shape of the cross section.

The LDPM computational framework is implemented into the MARS code (Pelessone, 2015), which is a multi-purpose structural analysis program based on an object-oriented architecture. MARS performs structural analysis by an explicit dynamic algorithm based on a central difference scheme and is very effective in the management of the various computational entities (nodes, finite elements, loads, etc.) making possible the numerical simulation of very large systems. In addition, the explicit character of the computational scheme implemented in MARS makes it advantageous because is not affected by the convergence problems that implicit schemes often have in handling softening behavior. Explicit algorithms, however, are stable under conditions and require an accurate evaluation of the numerical stability of the numerical simulations. Decreasing the maximum time step with the highest natural frequency of the computational system, a prohibitive number of increments may be required for problems governed by low frequencies and, consequently, application of explicit dynamics to quasi-static events,
like the ones related to the present study, may become critical in terms of time analysis. The computational time necessary to carry out the simulations performed, in fact, turned out to be significantly demanding. Though, time steps much larger than the critical one would be sufficient to accurately describe the low-dynamic overall response and, in literature, different solutions have been investigated to artificially increase the speed of the process in simulations (e.g. Cocchetti et al. 2013, Gao et al. 2014, Chang, 2014). An interesting and promising approach can be found in the Proper Orthogonal Decomposition as a Model Reduction technique, which has now applications in different fields of engineering and physics (e.g. Behzad et al. 2014, Chen et al. 2014, Li et al. 2013). Dynamic systems can be projected onto subspaces containing the solution of the problem or a good approximation, so that a high-dimensional process is converted into a low-dimensional description of it.

**EXPLICIT INTEGRATION OF THE DYNAMICS EQUATIONS OF DISCRETE SYSTEMS**

**Full-Order Integration Algorithm for LDPM**

In this section, the algorithmic framework for the solution of the dynamics equation is presented for LDPM, and more generally for any discrete dynamic equilibrium problem solved through explicit integrators. The application of a reduced order method to this algorithm is discussed afterwards.

Let consider the motion governing equation in \( \mathbb{R}^n \), a domain which is discretized in space:

\[
\begin{align*}
\ddot{u} + (G \dot{u}) + f_{\text{int}}(u) &= f_{\text{ext}} \\
u(t_0) &= u^*, \quad \dot{u}(t_0) &= \dot{u}^*
\end{align*}
\]

(1)

defined \( \forall t \in [t_0, t_f] \) and where \( M \) is the mass matrix, \( u \) is the nodal displacement vector, \( f_{\text{int}} \) is the internal forces vector, \( f_{\text{ext}} \) is the external forces vector; \( u^* \) and \( \dot{u}^* \) denote the initial displacements and velocities. Neumann Boundary Conditions are applied in the space domain in the form \( \dot{u}_i = v_0 \forall X_i \in \mathcal{B} \subset \mathbb{R}^n \).

The system (1) can be discretized in time to be solved numerically, using the middle point rule as a time integrator (explicit algorithm):

\[
\begin{align*}
\ddot{u}^m &= M^{-1}(f_{\text{ext}}^m - f_{\text{int}}(u^m)) \\
\dot{u}^{m+1/2} &= \dot{u}^{m-1/2} + \dot{u}\Delta t \\
u^{m+1} &= u^m + u^{m+1/2} \Delta t
\end{align*}
\]

(2)

where \( \Delta t \) is the time step and \( m \in [1, n_{\text{steps}}], n_{\text{steps}} \in \mathbb{N}^* \) the number of the current time step. In elastic regime, the time step \( \Delta t \) must be subjected, because of stability conditions, to the constraint \( \Delta t < \frac{2}{\omega_{\text{max}}} \) where \( \omega_{\text{max}} \) represents the highest natural frequency of the computational system. Belytschko et al. (2000) showed that \( \omega_{\text{max}} < \max(\omega_i) \), where \( \max(\omega_i) \) are the natural frequencies of each element belonging to the mesh, so the stable time step can be computed solving the eigenvalue problem given by \( \det(K - \omega^2M) = 0 \) where \( K \) is the stiffness matrix and \( M \) is the mass matrix.

**Reduced-Order Integration Algorithm for LDPM through the Proper Orthogonal Decomposition**

*A brief introduction to POD*

Thanks to model reduction techniques such as POD, dynamical systems can be projected onto subspaces containing the solution of the problem, or a good approximation of it, so that a low-dimensional process can describe a high-dimensional problem accurately enough (Liang et al. 2001). The approximate solution can be sought in a low-order subspace, reducing the computational costs and storage requirements but still reproducing the main characteristic dynamics.

In particular, the POD technique allows to find the optimal orthogonal projection of a vector space \( \mathcal{V} \subset \mathbb{R}^n \), where the vectors of interest (the solution) take their value, onto a subspace \( \mathcal{S} \subset \mathbb{R}^k \) of dimension \( k < n \), containing the best approximation possible of \( \mathcal{V} \) in \( \mathbb{R}^k \).

Assuming that \( u \in \mathcal{V} \subset \mathbb{R}^n \) is the vector solution of the problem and \( \{\phi_i\}_{i=1}^n \) is a set of arbitrary orthonormal basis vectors spanning \( \mathcal{V} \), \( u \) can be written as a linear combination of the basis vectors through the coefficients \( d_i \):

\[
u = \sum_{i=1}^n d_i \phi_i = \Phi d
\]

(3)

where \( d = (d_1, d_2, ..., d_n) \) and \( \Phi = [\phi_1, \phi_2, ..., \phi_n] \).

POD finds the set of basis vectors, called the proper orthogonal modes, that can span a vector subspace of order \( k \) containing the most accurate approximation of the vector \( u, \sum_{i=1}^k d_i \phi_i (k \leq n) \).
Considering a finite dimensional system of $n$ state variables of interest (e.g., displacement) and capturing, at $m$ instants of time, a set of $n$ simultaneous measurements of these $n$ state variables, data can be arranged in an $n \times m$ matrix $U$. Each element $U_{ij}$ is the measurement of the $i$-th state variable taken at the $j$-th time instant. The final result of the data collection is assumed to be the $n \times m$ matrix $U$:

$$U = \begin{pmatrix}
  u_1(t_1) & \cdots & u_1(t_m) \\
  \vdots & \ddots & \vdots \\
  u_n(t_1) & \cdots & u_n(t_m)
\end{pmatrix} \tag{4}
$$

The Schmidt-Eckart-Young-Mirsky Theorem (Antoulas, 2005) shows the following statement:

- Let define the $n$-by-$n$ real symmetric matrix $C = UU^T$;
- Let denote by $\lambda_i$ the eigenvalues of $C$ and $\phi_i \in \mathbb{R}^n$, $i = 1, \ldots, n$ their associated eigenvectors such that $C\phi_i = \lambda_i\phi_i$, $i = 1, \ldots, n$;
- $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n \geq 0$

The subspace optimizing the orthogonal projection of fixed rank $k$ is the invariant subspace of $C$ associated with the eigenvalues $\lambda_1 \cdots \lambda_k$. The corresponding eigenvectors $\phi_1 \cdots \phi_k$, spanning the subspace, are called proper orthogonal modes and can be collected into a matrix $B_k = [\phi_1 \cdots \phi_k]$ such that $B_k^T B_k = I$. This subspace is evaluated so that it is able to capture the majority of the variation in the model solution, by sampling the variable of interest from the full model for each node at different time. These samples are called snapshots and, if they are representative enough, they can be used in an interpolation scheme to approximate the full model. Being the displacement the variable of interest, the following equivalence holds:

$$u \approx \hat{u}(k) = \sum_{i=1}^{k} d_i \phi_i = B_k d; \tag{5}
$$

**Reduced Order Algorithm: integration scheme and boundary conditions**

The equation of motion (1) can be projected onto $\mathbb{R}^k$ through $B_k$:

$$B_k^T \mathbf{M} B_k d + (B_k^T \mathbf{G} B_k d) + B_k^T f_{\text{int}} = B_k^T f_{\text{ext}} \tag{6}
$$

and integrated numerically with the middle point rule:

$$\begin{cases}
  \bar{d}^m = (B_k^T \mathbf{M} B_k)^{-1} (f_{\text{ext}}^m - f_{\text{int}}) \\
  d^{m+1/2} = d^{m-1/2} + \Delta t_r \bar{d}^m \\
  d^{m+1} = d^{m} + \Delta t_r \bar{d}^{m+1/2}
\end{cases} \tag{7}
$$

The unknowns are the coefficients $d_i$, $i = 1, k$, guaranteeing that the linear combination of $B_k$ columns is as close as possible to the real solution. In each time step, the full dimensional displacement $\tilde{u}$ and the corresponding velocity $\tilde{u}$ are evaluated, from the associated projected values, because the internal forces and the residual forces are computed in the full original domain. The main reason for this choice is to keep the reduced system algorithm as close as possible to the original one, preserving all the explicit algorithm features, necessary when dealing with highly non linear constitutive laws, and allowing an easy transition from one to the other in the snapshot collecting process. The new time step $\Delta t_r$ must be subjected to a different constrain, $\Delta t_r < t_{cr} = 2/\omega_k \text{max}$, leading to the following eigenvalue problem: $\text{det}(B_k^T \mathbf{K} B_k - \omega_k^2 B_k^T \mathbf{M} B_k) = 0$.

The Proper Orthogonal Modes, through which the reduced system is computed, will automatically satisfy any fixed boundary conditions in terms of displacements (or velocities) for construction. In fact, the matrix $U$ has a 'zero' row corresponding to any fixed degrees of freedom and this information will be transferred to the POD MODEs themselves and, consequently, to any object in the subspace they span. The non-zero BCs need to be re-applied in the reduced system, these data not being preserved by the modes. It is not easy however, to apply the BCs directly to the projected degrees of freedom in the reduced subspace, because this would lead to an overdetermined system. To elude the obstacle, the BCs are applied indirectly as equivalent external forces through the penalty method: $f_{\text{ext}} = K_p (u_p - u)$, where $f_{\text{ext}}$ is the penalty force equivalent to the BC, set around $10^3$ times the element stiffness, $u_p$ the penalty displacement, whose value comes from the BC, and $u$ is the current displacement of the node of interest. Due to instability issues, the node mass $M_i$ where the penalty constrain is applied is artificially increased (mass scaling) by adding a quantity which is proportional to the penalty coefficient $K_p$ and to the square time step $\Delta t$: $M_{ii} = M_{ii} + 1.1 \cdot K_p \cdot \Delta t^2$. 279
Snapshot collection

The snapshots can be computed \textit{a posteriori}, after the end of the regular analysis. This method allows the definition of the reduced system for model validation purposes and the snapshot collection can be the most efficient possible, since the real solution is already known. Aiming to a predictive tool, though, the snapshots should be collected during the analysis itself, \textit{in itinere}, alternating the integration in the complete system, for the snapshots collection, with the integration in the reduced system, until the snapshots previously collected are enough representative of the response. When dealing with quasi static problems, the complete system can be integrated only for a small initial time interval $\Delta T$, to capture an adequate number of snapshots, which sufficiently describe the system behavior. Then, the corresponding reduced system can be computed from the first $k$ modes and the analysis carried out in the reduced system with a greater time step. The snapshots may need to be updated to take account of any variation of the external (for instance in case of changes in applied forces, displacements, velocities) or internal conditions (for instance changes due to the constitutive law). When, after a time interval $\Delta T_R$, the old snapshots are not representative anymore of the response, the analysis should continue using the full order system, to collect a new group of snapshots and compute a new subspace. The amplitude of $\Delta T_R$ can be fixed and different ratios of them have been related to the accuracy of results. Once the first snapshots have been collected and the corresponding reduced space defined, the integration in the reduced system can start, using as initial condition for the integration the following values: $\ddot{u} = B_k^T \dot{u}$; $\dot{u} = B_k^T \ddot{u}$, where $\ddot{u}$ and $\dot{u}$ are the values of velocity and displacement given by the last time step integration in the complete system.

POD APPLICATION TO THE NUMERICAL STUDY OF FRP-CONFINED COLUMNS

Preliminary Studies

The new algorithm based on the POD method has been preliminarily tested for 1D truss elements and 2D beam elements, finding out that the efficiency of the method, based mainly on the gain in terms of stable time step, increases with the number of degrees of freedom of the original problem.

Also, just a very limited number of modes are enough to achieve high levels of accuracy of the solution: only one in case of linear response, two in case of softening. If yielding or fracture occurs at the material level, in fact, the subspace must be redefined. The POD modes can be interpreted as shape functions with a global support, as shown in Figure 2, where the dynamic oscillations are filtered by taking into account only the main modes. The gain in terms of CPU time ($T_F$: CPU time for the full order $T_R$: CPU time for the reduced order algorithm) is increasing from $PIF = T_F/T_R \equiv 7$ for 25 elements to $PIF \equiv 110$ for 200 elements in the linear response and from $PIF = T_F/T_R \equiv 4$ for 25 elements to $PIF \equiv 60$ for 200 elements in the softening response. The same algorithm was then tested for 3D simple specimens modeled with LDPM.
FRP-confined concrete with LDPM and POD

To pursue the final aim of this research, the POD algorithm has been applied to columns subjected to compressive loadings and confined with FRP sheets (see Figure 3a, $H = 300$ mm, $D = 150$ mm). The geometry and material parameters are accurately described in Ceccato et al. 2015; in this application, the FRP jacket and the external surface of the concrete column are sharing the same nodes. Figure 3b shows the numerical results from the reduced order algorithm compared with the ones from the full algorithm and the experimental data. Similarly to the 1D and 2D tests, the linear response is easily captured by the reduced algorithm with the 1st mode only, while the post-peak response needs at least the 1st and 2nd mode. However, frequent updates (which are automatically set) are required after the elastic phase, because of the progressive and diffused fracturing process of the material, which makes the POD modes almost immediately no longer representative of the ongoing response. In this specific case, the stable time step in the reduced algorithm is 60 times greater than the full algorithm, but the index of performance is limited to $\text{PIF} = 3$. In fact, the advantage in terms of time step is partially lost because of the frequent updates. The algorithm has still room for improvement and the objective would be to achieve a global gain of 10 times so that LDPM can be used also for practical applications. Anyway, the algorithm as it is can still be considered useful in the calibration process, to check the trend of the response in a shorter time. The oscillations in the reduced order curve can be minimized with a smoothing algorithm.

CONCLUSIONS

A three-dimensional mesoscale model based on the Lattice Discrete Particle Model (LDPM) had been successfully developed for the simulation of FRP confined concrete columns subjected to compressive loading. To cope with
the high computational costs of the numerical simulations of LDPM problems, the Proper Orthogonal decomposition (POD) has been explored as a model reduction technique, in order to speed up the analysis. After some preliminary studies, the method has been applied to the case of interest: the response of FRP confined circular columns has been evaluated, comparing the numerical results with the fully explicit algorithm to the ones with the reduced algorithm. The reduced order response approximates the regular LDPM simulation, with some oscillations that can be minimized with a smoothing algorithm. Even if the gain in terms of stable time step is consistently high, POD modes need to be updated quite frequently during the inelastic phase in compression so, the global gain in terms of CPU time remains limited. The reduced solution can still be considered a good approximation and be a useful tool in the LDPM calibration process, and the authors are still working on improvements of the POD application for LDPM in compression, aiming to achieve a higher global CPU time gain.

ABSTRACT

The present paper intends to investigate the behaviour of plastic hinge of fibre reinforced polymer (FRP)-confined RC columns numerically using three-dimensional finite element method (FEM). As FEM results largely depend on the model and its parameters, the FEM model is first calibrated with test results to show that the results are reliable even different models/parameters are adopted. To gain insights into the influence of FRP confinement ratio, lengths in the plastic hinge zones involving rebar yielding zone, concrete crushing zone, and curvature localization zone are investigated in detail. The FEM results show that all three zones are significantly affected by FRP confinement. Both the lengths of the rebar yielding zone $L_{sy}$ and the curvature localization zone $L_{pc}$ increase first and then decrease as confinement ratio increases, while the length of concrete crushing zone $L_{cs}$ keeps decreasing with the increase in the confinement ratio.

Plastic hinge, FRP, RC columns, confinement, FEM.

INTRODUCTION

In recent years, fiber-reinforced polymer (FRP) jackets have become popular in providing confinement to reinforced concrete (RC) columns in construction industry (Ibell et al. 2009). A sufficient deformation for RC columns can be achieved by FRP confinement at a potential plastic hinge region (Seible et al. 1997; Saadatmanesh et al. 1997). The plastic hinge region is defined as the physical region over which the member experiences inelastic deformations and severe damage. Qualification of plastic hinge length $L_p$ for FRP-confined columns is critical not only for the design of new members but also for the rehabilitation of load structures.

Due to high nonlinearity of materials and complicate interactions between constitutive materials involved, the behavior of plastic hinge of FRP-confined RC members has been previously focused on experimental study. Priestley et al. (1996) and Elsanadedy and Haroun (2005) showed that $L_p$ of an FRP-confined RC column is smaller than that of a traditional RC column. However, some experimental results have shown that $L_p$ of FRP-confined columns is larger than that of traditional RC columns (Ozbakkaloglu and Saatcioglu 2006). Other researchers reported that the $L_p$ of FRP-confined columns is equal to that of a traditional RC column (Monti et al. 2001; Binici 2008). Jiang et al. (2014) observed that $L_p$ first increases and then decreases with FRP confinement ratio. Hence, there is no consensus among researchers on the qualification of $L_p$. The literature reveals contradictory conclusions about the plastic hinge length of FRP-confined RC columns. Based on these findings, it is clear that $L_p$ of FRP-confined RC columns needs further investigations.

Previous studies on finite element modeling of FRP-confined RC members have focused on the strength and ductility of structural members (Kachlakiev et al. 2001; Mostofinejad and Talaeitaba 2006; Ibrahim and Mahmood 2009; Abdelkarim and ElGawady 2014) and few concerned the plastic hinge modeling. This paper aims to investigate the plastic hinge problem of FRP-confined RC columns in greater detail through finite element method (FEM). The FEM model is first calibrated with test results. After that, a systematic parametric study was subsequently carried out to investigate the effect of the confinement ratios on the rebar yielding zone, concrete crushing zone and curvature localization zone of FRP confined RC columns.
FINITE ELEMENT MODELLING AND IMPLEMENTATION

In the present work, the plastic hinge regions of FRP-confined RC columns are investigated in a detailed manner by numerical simulation. General finite element software ABAQUS (2010) is used in this work. The constitutive models involve concrete, steel reinforcement, FRP and interfaces between concrete-steel reinforcement and concrete-FRP. Detailed modeling and the parameters are summarized below.

The 8-node linear brick element C3D8R in ABAQUS is employed for concrete elements. The mesh size of the concrete element for RC columns is 20 mm. Elements smaller than 20 mm make little difference to the results, according to the mesh convergence study.

Damaged plasticity model is adopted to model the material behavior of concrete. The ascending section of the tensile relationship is assumed to be linear and softening is assumed to be exponential. The fracture energy method is adopted for post-peak cracking of concrete. The strain at peak stress \( \varepsilon_{cr}^c \) is assumed to be 0.0001. The fracture energy for concrete \( G^f \) is assumed to be 170 N/m (Hillerborg 1985).

In compression, the analysis-oriented stress-strain model by Teng et al. (2007) is employed for both unconfined and confined concrete. The default values in ABAQUS are adopted for yield criterion parameters of unconfined concrete. Since the flow rule for confined concrete is significantly different from the unconfined, variations of dilation angle for the two cases are very different (Yu et al. 2010; Jiang and Wu 2012). The dilation angle of 30° is selected for unconfined concrete and the yield criterion parameters and the flow rule parameters proposed by Yu et al. (2010) is employed for confined concrete.

A 2-node truss element T3D2 in ABAQUS is employed for steel reinforcement. The bilinear model which considers strain hardening is adopted to model the stress-strain relationship of the steel reinforcement.

The Spring2 element is selected to define the nonlinear behavior between concrete and longitudinal tensile reinforcement. The concrete nodes and steel nodes with the same coordinates are connected by springs. A large linear stiffness is applied in the normal direction of the interface, while the unified bond-slip relationship proposed in (Wu and Zhao 2012) is applied in the tangential direction to consider the nonlinear slip between concrete and steel bars. The bond stress-slip relationship can be transformed into the nonlinear spring force-relative displacement relationship.

The FRP jacket is modeled by 4-node membrane elements M3D4R and is treated as linear elastic laminar with orthotropic elasticity. Elastic modulus of FRP jacket is assigned only in the fiber direction, which means that the FRP jacket has stiffness only in hoop direction and provides confinement effect to concrete. The FRP sheet fails when its rupture strain is reached. Perfect bond between FRP sheet and concrete is assumed.

MODEL VERIFICATION

![Displacement vs Moment](image1)

![Curvature vs Moment](image2)

Figure 1 Load versus deformation curves

Two FRP confined RC columns (one square and another circular), are simulated herein using the above described FEM model. Specimens RS-1 (Ozbakkaloglu and Saatcioglu 2004) and ST-4NT (Sheikh and Yau 2002) were tested under constant axial loading and cyclic lateral deformation. It can be seen from Figure 1 that the initial stiffness and load-carrying capacity from the numerical results match well with those of measured results. Reasonable agreements are observed between measured load-deformation responses and FEM results.
PLASTIC HINGE ANALYSIS OF FRP-CONFINED RC COLUMNS

The influence of FRP confinement on the development of plastic hinge region is analyzed in detail for FRP-confined RC columns in this section. Nine specimens with FRP confinement ratios ranging from 0 to 0.466 (corresponding to 0 to 2 layers of FRP jacket) are studied. The confinement ratio \( \lambda_f \) is defined as follows:

\[
\lambda_f = \frac{f_{f}}{f_{c}} = \frac{2E_f \varepsilon_{f \mu} f_{f}}{bf_{c}}
\]

where \( f_{f} = 30 \text{ MPa} \) is the compressive strength of unconfined concrete; FRP fracture strain \( \varepsilon_{f \mu} = 0.0171 \); elastic modulus \( E_f = 245 \text{ GPa} \); and thickness \( t_f = 0.167 \text{ mm} \). The lateral displacement is monotonically increased under a constant axial force. The axial force is fixed to be 0.2\(N\), where \( N = f_{s} A_{s} \) in which \( A_{s} \) is the gross cross-sectional area of the column. All specimens have the same geometric dimensions and material properties. Due to the symmetry of the column, half of the column is modeled. The specimen sizes are 200 x 200 x 800 mm connected to a 300 x 400 x 900 mm stub (Figure 2). The corner radius of the columns is 20 mm and the effective cantilever length is 730 mm from the center of the loading to column base. For all specimens, steel bars of 16 mm diameter are employed as the longitudinal bar and steel bars of 8 mm diameter and spacing of 100 mm are adopted as transverse reinforcement. The steel has a yield strength of \( f_{s} = 400 \text{ MPa} \), an ultimate strength of \( f_{u} = 579 \text{ MPa} \) and elastic modulus of \( E_s = 194 \text{ GPa} \). The reinforcement details and geometric dimensions of the columns are as shown in Figure 2.

Investigation of rebar yielding zone

The regions where the strain of tensile reinforcement has reached or exceeded its yielding value is defined as the rebar yielding zone. Figure 3(a) shows the development of rebar yielding zone of FRP-confined RC columns with different confinement ratios. It can be found that the length of rebar yielding zone increases significantly with the increase of the column deformation after it yields and keeps almost constant after the drift ratio of 8%, which means that the maximum length of rebar yielding zone \( L_{sy} \) is limited to a certain value. This observation is consistent with the test results in literature (Scott 1996).

The influence of FRP confinement ratio on \( L_{sy} \) and moment capacity at the drift ratio of 8% is shown in Figure 3(b). \( L_{sy} \) first increases and then decreases as the confinement ratio increases. However, the maximum moment value of the columns always increases with increase of the confinement ratio. The compressive strength of confined concrete increases with the confinement ratio, resulting in an increase in the lever arm of the moment and hence an increase in the cross-sectional moment capacity. In the meantime, the yield moment does not change and hence the yielding section moves up along the column with the increase in the moment capacity at the column base. As a result, the distance from the column base to the first yielding section increases, which increases \( L_{sy} \). However, the frictional bond between longitudinal tensile reinforcement and concrete increases linearly with increase in the confinement ratio, which opposes the rebar stress and has an adverse effect on the strain penetration length and hence \( L_{sy} \). In other words, both moment capacity and bond stress increase with the increase in the confinement ratio. On the other hand, \( L_{sy} \) is dominated by moment increase when the confinement ratio is lower than 0.2. After that, the growth rate of moment capacity slows down when confinement is high and then the other mechanism,
friction, dominates the variation of $L_{sy}$. As a result, $L_{sy}$ first increases and then decreases with the increase in FRP thickness. This conclusion is consistent with Gu et al. (2010) and Jiang et al. (2012).

Investigation of concrete crushing zone

To study the damage zone of FRP-confined RC column, the lengths of compression region $L_{cs}$ and $L_{cc}$, are investigated, where $L_{cs}$ is defined as the length of the region where the concrete compressive strain is larger than the strain at peak stress of unconfined concrete (0.002) and $L_{cc}$ is defined as the length of the region where the compressive strain is greater than the crushing strain of unconfined concrete (0.006). It is found from the simulation results that the stable region of $L_{cs}$ moves towards the column base as the confinement ratio increases, which means that the damage zone of concrete becomes smaller when confinement increases, and concrete strain with a lower confinement distributes more evenly than that with a higher confinement. The compressive strain contours with different confinement ratios at the drift ratio of 8% are shown in Figure 4. The regions with strain value greater than 0.002 and 0.006 are displayed in the figure. It can be found that the area and height of the display regions decrease with the increase of confinement ratio, which means that confinement reduces $L_{cs}$ and $L_{cc}$. This is consistent with the experimental observations that higher level of FRP confinement results in a smaller damaged zone (Iacobucci et al. 2003; Ozbakkaloglu and Saatcioglu 2006). It can be found from the simulation results that there are sudden increases of strain value when it exceeds 0.002, which corresponds to the inflection point of axial stress-strain curve of unconfined concrete, after which the unstable process of crushing of concrete begins. With the increase in FRP confinement, the compressive strength of concrete increases and the area of compression failure reduces, leading to a smaller $L_{cc}$. 

---

**Figure 3** Effect of FRP confinement ratio on rebar yielding zones

---

**Figure 4** Concrete compressive strain contour at drift ratio of 8%
Investigation of curvature localization zone

Figure 5 Curvature distribution of FRP-confined RC columns

Figure 5 shows the curvature distributions at different deflections beyond yielding for FRP-confined RC columns. It can be seen that the curvature varies significantly along the column length due to concrete cracking. After a column yields, most of the plastic curvature gets concentrated within a certain zone. A dividing point exists from which to the column base the curvatures increase rapidly after yielding while those outside the region remain almost constant. This numerical result is consistent with experimental observations reported in literature (Hines et al. 2004; Gu et al. 2010). The distance from the dividing point to column base is defined as the length of significant curvature localization zone \( L_{pc} \) in this work.

The influence of confinement ratio on \( L_{pc} \) can also be found in Figure 5. It is clearly seen that the dividing point mentioned above moves toward the column base when the confinement ratio increases. However, the maximum curvature value increases from \( 3.83 \times 10^{-4} \) mm\(^{-1} \) to \( 4.36 \times 10^{-4} \) mm\(^{-1} \) when FRP layers increase from 0.5 to 2. Both tensile strain and compressive strain contribute to curvature. Therefore, curvature concentration is caused not only by rebar yielding but also by concrete plastic deformation.

CONCLUSIONS

This paper investigates the plastic hinge region of FRP-confined RC columns by the finite element method. The accuracy of the FEM model was first calibrated with test results. A systematic parametric study was subsequently carried out to investigate the effect of the major parameters on the rebar yielding zone, concrete crushing zone and curvature localization zone of FRP confined RC columns. The plastic hinge length of FRP-confined RC columns is very different from that of normal RC columns. Lengths of both the rebar yielding zone \( L_{sy} \) and the curvature localization zone \( L_{pc} \) increase first and then decrease as the confinement ratio increases, while the length of concrete crushing zone \( L_{cs} \) keeps decreasing with the increase in the confinement ratio.

ABSTRACT

Recent research has shown that compressive membrane action (CMA) has a significant benefit in enhancing the load bearing capacities of FRP strengthened concrete beams. Generally two methods are used to predict the behaviour of FRP strengthened concrete beams with consideration of CMA. One method is using plasticity theory to obtain the beam’s resistance under CMA by considering strain compatibility and force equilibrium at the sectional level. Another main method accounts for the ultimate load of a laterally restrained beam by taking the sum of the bending capacity and the additional three-hinge arch load due to CMA. These two methods are compared analytically in this paper from the perspective of load bearing capacity. Results show that, when compared with the second model, the first model is more accurate to predict the load bearing capacity of a FRP strengthened concrete beam considering CMA because the first method considers CMA to be initially associated with the bending capacity.

KEYWORDS

Compressive membrane action, FRP strengthening, RC beams, model comparison.

INTRODUCTION

Since compressive membrane action (CMA) was first recognized by Turner in 1909 (Turner 1909), much work has been done on this topic particularly in the field of reinforced concrete (RC) slabs, as can be seen in the detailed overview by Taylor (2002). Research results have shown that CMA is beneficial for strength enhancement in normal concrete structures and FRP strengthened concrete structures (e.g. Taylor 2003; Taylor and Mullin 2006; Muthu et al. 2007; Zheng et al. 2007; Wang et al. 2011; Valipour et al. 2013; Zeng et al. 2015a, 2015b). With regard to the investigation of CMA (i.e. the prediction of load bearing capacity) in concrete beams, on the one hand a commonly applied method first proposed by Park (1969), is using the plastic theory to obtain the beam’s resistance. This method (Method I) considers CMA to be initially associated with the bending capacity and is good at estimating the CMA capacity of laterally restrained concrete beams. On the other hand, another method proposed by Rankin and Long (1997) is also widely adopted. This method (Method II) evaluates the load bearing capacity under CMA as the sum of the load bearing capacity due to bending capacity and the additional capacity due to the CMA effect. Both methods are proven to be effective in predicting the load bearing capacity of the laterally restrained concrete beams and a basic comparison can be found in review publications (e.g. Taylor 2002). However, the application of these two methods is not clear in the context of FRP reinforcements. This paper presents an analytical comparison between these two methods regarding the prediction of load bearing capacities of FRP strengthened concrete structures.

METHOD OF SOLUTION

General Assumptions

The following basic assumptions apply for both methods:
1) Plane sections remain plain.
2) The considered one-way concrete beam is completely symmetrical regarding geometry, reinforcement, loading and deformations.
3) The major cracks at the central and end sections after hinge formations (yielding) divide the beam into three rigid portions which keep flat until the ultimate state, as shown in Figure 1a. The length ratio of the left portion to the whole beam is assumed as $\beta$. The state of the left portion after yielding is shown in Figure 1b and 1c for the two methods to be mentioned below. 

4) Concrete stresses are characterized by an idealized equivalent rectangular block with an ultimate strain of $3.5\%$ (fib Bullein 14 2001); 

5) Steel reinforcement is believed to be perfectly elastoplastic and FRP is viewed to be linear and intact (no debonding or fracture occurs) with an ultimate strain of 1.5% if not specified.

**Method I**

In this method, plasticity theory is made use of to obtain the beam’s resistance under CMA by considering strain compatibility and force equilibrium at the sectional level (Park 1969). Recently, this method was extended to the application for FRP strengthened concrete beams (Zeng et al. 2015a). The method is briefly explained below. For detailed information, please refer to Zeng et al. (2015a). In this method, the axial force at beam end ($N_1$) is assumed to be equal to that at the mid-span ($N_0$) i.e. $N = N_0 = N_1$, and a constant elastic compression strain distribution along the span is assumed. With the assumption above, the compatibility requirement from Figure 1a can be expressed as

$$\frac{\beta l + t + 0.5\varepsilon (1 - 2\beta)l}{\cos \theta} = \frac{(1 - \varepsilon)\beta l}{2} + \left(\frac{h}{2} - x_0\right) \tan \theta + \left(\frac{h}{2} - x_1\right) \tan \theta$$

(1)

where $x_0$ and $x_1$ are the neutral-axis depths at the span and at the beam ends, respectively; $h$ is the depth and $l$ is the length of the beam; $\theta$ is the rotation angle; $t$ is the lateral displacement of the surrounding restraints and $\varepsilon$ is the uniformly distributed strain along the considered portion. By implementing $t = N/K$, $\varepsilon = N/E_cA_c$ and $\tan \theta = \delta / \beta l$, Equation (1) is simplified to:

$$h - x_0 - x_1 = \frac{\delta}{2} + \frac{N \beta l^2}{2\delta} \left(1 + \frac{2}{E_cA_c} + \frac{2}{KL}\right)$$

(2)

in which $\delta$ is the center deflection; $E_c$ is the elastic modulus; $A_c$ is the concrete area of the cross-section; and $K$ is the axial stiffness of the surrounding lateral restraints.

For a model of double-reinforcement sections, the internal axial force equilibrium can be written as

$$N = C_{c0} + C_{c1} - T_0 - F_0 = C_{s0} + C_{s1} - T_1 - F_1$$

(3)

where $C_{c0}$ and $C_{c1}$ are the concrete compressive forces, $C_{s0}$ and $C_{s1}$ the steel compressive forces, $T_0$ and $T_1$ the steel tensile forces, and $F_0$ and $F_1$ the FRP tensile forces, acting on sections at the mid-span and the beam end, respectively.
Considering that all terms in Equation (3) can be expressed by given geometric and material properties and the unknowns $x_0$ and $x_1$ based on a sectional force equilibrium analysis, $x_0$ and $x_1$ are obtained by solving the Equations (2) and (3) simultaneously for a given $\delta$. Further, the moments at the mid-span and the beam ends can be calculated as well as the load bearing capacity. When repeating such procedures for different values of $\delta$, a series of the load bearing capacities are obtained, and the maximum value can be seen as the ultimate load bearing capacity. Consequently, the load bearing capacity for a pointed load pattern is determined by

$$P_I = \frac{2(M_{u0} + M_{u1} - N\delta)}{\beta l}$$

where $M_{u0}$ and $M_{u1}$ are the ultimate moments at the span and the beam ends, respectively.

**Method II**

As mentioned above, in the second method the load bearing capacity of a lateral restrained beam is considered as the sum of a bending capacity and an additional capacity. This idea is adopted in this paper and the formulae are given separately.

**Bending capacity**

The bending moments, $M_{b0}$ and $M_{b1}$ at respectively the beam mid-span and ends, can be easily obtained by moment-curvature analysis and the corresponding bending capacity regarding a pointed load pattern can be calculated by equalling the external work of vertical load, $P_b$, and the internal work of the resistant moments at yielding

$$P_b = \frac{2(M_{b0} + M_{b1})}{\beta l}$$

**Additional capacity**

With respect to calculating the additional capacity, the main task is to obtain the level arm, $a$, as shown in Figure 1b. For the internal compressive force and the compatibility requirement, Equations (2) and (3) still apply. Considering the shape of the compressive stress of concrete after yielding, the level arm is estimated by

$$a = h - \delta - \frac{1}{2}(x_0 + x_1)$$

Then the additional capacity, $P_a$ is given as

$$P_a = \frac{2Na}{\beta l}$$

The calculation procedure is almost the same as that in Method 1: Equations (2) and (3) are solved for a give initial deflection $\delta$. The outcome values of $x_0$ and $x_1$ are used to calculate the additional capacity in Equation (7). Then the calculation procedure is repeated with a larger deflection. The iteration stops when the obtained additional capacity is smaller than that in the previous step, which is taken as the ultimate additional load bearing capacity. Finally, the load bearing capacity under CMA consideration is the sum of bending capacity and the additional capacity, i.e.

$$P_{II} = P_b + P_a$$

**COMPARISON OF RESULTS AND DISCUSSION**

**Qualitative Comparison**

These two methods are first compared qualitatively. Based on the theories above a conclusion is directly drawn: these two methods share the same kinetical mechanisms. This is straightforward as they share the same main assumption that the formed hinges due to yielding divide the considered beam into three rigid portions which keep flat until the ultimate state. This assumption leads to the analysis of geometries after deformation and further to Equation (2). Furthermore, it is logical to believe that the compressive forces at the beam mid-span and ends are equal, which gives rise to Equation (3).
The difference between these two methods is also evident. The interaction effect between the bending moment and the axial force is combined in Method I, whereas in Method II this effect is not explicitly considered.

**Quantitative Comparison**

These two methods are compared quantitatively by a case study. Considering that in FRP strengthened concrete structures the load bearing capacity is at least enhanced by the FRP strengthening and the effect of CMA, it is necessary to select a dimensionless quantity to differentiate the enhancement due to FRP strengthening and the enhancement due to the CMA effect. Therefore, a strength enhancement factor to evaluate the effect of CMA and/or the effect of FRP strengthening is adopted and defined as \( \alpha_{p,FRP} = \frac{P_{FRP}}{P_0} \) and \( \alpha_{p,CMA,FRP} = \frac{P_{CMA,FRP}}{P_0} \), where \( \alpha_{p,FRP} \) and \( \alpha_{p,CMA,FRP} \) are the enhancement factors considering the enhancement of FRP, and of FRP and CMA together, respectively; \( P_{CMA,FRP} \) is the peak resistance considering CMA calculated by methods in this paper, \( P_0 \), and \( P_{FRP} \) are the beam peak resistances calculated by *fib* bulletin 14 (2001), each time for normal concrete beams and FRP strengthened concrete beams, respectively.

A beam similar to the four-point loaded two-span beam in Vasseur *et al.* (2006) is adopted as the benchmark beam in this parametric study, as sketched in Figure 2a. This 10 m beam with a 200 \( \times \) 400 mm section and a value of 0.2 for \( \beta \) is assumed to be laterally restrained (\( K = 10^8 \) kN/m) at both ends. C30/37 concrete is used and three steel bars are initially placed along the beam length at both the beam top (2\( \phi \)12+1\( \phi \)18) and the beam bottom (2\( \phi \)12+1\( \phi \)20). The elastic modulus and the yield stress of the steel bars are 200 GPa and 500 MPa, respectively. In cases of FRP strengthening, a CFRP layer with a thickness of 1.2 mm is applied along the beam at the location of tension zones and the elastic modulus and the ultimate strain of the FRP are considered 190 GPa and 1.5%, respectively. All these values apply if no further information is indicated.

By using methods I and II, Figure 2 shows the results of the enhancement factors for varying ratios of FRP reinforcement. Figure 2a clearly indicates that the load bearing capacity increases with increasing FRP reinforcement. However, the enhancement due to the CMA effect decreases if the beam is increasingly reinforced, as shown in Figure 2b.

In regard to the difference of the prediction of load bearing capacity using these two methods, it can be concluded from Figure 2a that Method II is generally more conservative than Method I, which also applies to the case of the enhancement due to the CMA effect as shown in Figure 2b. Figure 2 further also shows that the difference is negligible if the considered beam is heavily reinforced. For example, in this specific case study, the difference between these two methods is about 1% for the overall enhancement and 5% for the enhancement due to the CMA effect, as long as the FRP reinforcement ratio is larger than 0.12%.

These findings are consistent with the conclusions in Zeng *et al.* (2015a) and Wang *et al.* (2011). On the one hand, the predictions of Method I in Zeng *et al.* (2015) show approximately 5% overestimation compared to the test results. On the other hand, the predictions in Wang *et al.* (2011) using a method similar to Method II show about 15% underestimation compared to the test results. Therefore, from the perspective of accuracy, it is believed that Method I is relatively more accurate than Method II. This could be explained by the fact that Method I considers the effects of bending and compression to be inherently related, which is corresponding to reality. However,
because Method I overestimates the load bearing capacity while Method II underestimates the load bearing capacity, an average of the results from these two methods could be considered.

CONCLUSIONS

Two methods of prediction of the load bearing capacity of laterally restrained FRP strengthened concrete beams are summarized in this paper. These two methods are compared qualitatively and quantitatively using a case study. Results show that in general Method II is more conservative than Method I. Together with the findings of previous research a combination of these two methods i.e. an average of the predictions of these two methods could be considered.

FORCE DISTRIBUTION BETWEEN INTERIOR STEEL REINFORCEMENT AND EXTERNALLY BONDED CFRP OF RC BEAMS UNDER CYCLIC LOADING

T. Leusmann \(^1\) and H. Budelmann \(^1\)

\(^1\)Institute of Building Materials, Concrete Construction and Fire Protection (iBMB), TU Braunschweig, Germany

ABSTRACT

The distribution of forces between interior steel and externally bonded reinforcement (EBR) of reinforced concrete members is normally determined assuming a plane strain distribution. But the different bond characteristics of the reinforcement types lead to a force distribution, which can be different from the determined distribution of forces. Experimental test results show that the strain in the EBR is higher than assumed particularly at low strain values, as they occur in the load cases of fatigue. In case of cyclic loading the difference between assumed and measured strain is reduced as a result of bond damage. However, an accurate prediction of the force distribution is only possible if the bond behavior of EBR and the cast-in reinforcement under cyclic loading is considered.

In this paper a model for the determination of the force distribution between internal and external reinforcement under fatigue loading is presented. For the validation of the model combined shear and pull out tests under cyclic loading were carried out. The test results can be recalculated using a formulation for the redistribution of internal forces under cyclic loads considering the bond behavior under cyclic loading for both reinforcement types.

INTRODUCTION

Many reinforced concrete bridges in Germany show damages caused by aging and overloading. Strengthening with externally bonded carbon fiber reinforced plastics (CFRP) is an effective technique to counteract both problems. Externally bonded reinforcement (EBR) leads to a higher load capacity which counteracts overloading. The second effect is that EBR causes a tension release from the interior reinforcement which can be affected by aging phenomena like fatigue or corrosion. In this case the application of EBR can extend the lifetime of a reinforced concrete bridge. For the prediction of the service life prolongation the distribution of forces between interior steel and EBR has to be exactly known. The change of the force distribution can be observed in combined double shear and pull-out tests under cyclic loading and described with a model taking the different bond stress slip behaviour of both reinforcement types into account.

EXPERIMENTAL TESTS

Test Setup

The cyclic tests are carried out in a hydraulic testing machine with pulsator for applying sinusoidal loads. The test setup is designed as a double shear test with near end support combined with a pull-out test at four steel bars under cyclic loading. The concrete test specimen have a length \(l = 1.35\) m and a square cross section with an edge length \(a_c = 25\) cm. The two externally bonded CFRP strips have a length \(l_L = 1.95\) m, a width \(b_L = 50\) mm and a thickness \(t_L = 1.4\) mm and the four steel bars have a diameter \(d_s = 16\) mm. The load is applied over a load distribution where the CFRP strips are applied over a clamping device and the steel bars are connected with a bolt nut over Belleville washers and spherical bearings. The concrete body is guided on roller bearings and compressed by a load plate connected with a threaded rod which runs bondless in a tube in the middle of the specimen. The CFRP strain is measured with a chain of strain gauges and the slip is measured with displacement transducers. The steel strains are measured with additional strain gauges on the steel bars. The strain gauges are mounted on the steel bars inside the concrete under the load plate in a bondless area. The strain gauges and the rebar are covered with a silicone layer and wrapped with a tape.
Materials

The experimental tests are carried out with CFRP strips with an average elastic modulus $E_L$ of 170,000 N/mm² and a cross section $A_L = 2 \times 1.4 \times 50$ mm². The adhesive is a two-component epoxy resin filled with rock flour. The thickness of the adhesive layer is set to 1 mm. The compressive strength of the epoxy after 7 days curing at 20 °C and 65 % humidity is 85.5 N/mm² the flexural strength is 46.1 N/mm² and the bulk density is 1.74 kg/dm³.

The specimen for the combined shear and pull-out test are made of concrete with a strength class C 20/25 according to Eurocode 2. The compressive strength $f_{cm}$ is determined in compressive tests on sample cubes with an edge length of 150 mm after 28 days to 39.0 N/mm². The tensile strength at the surface $f_{ctm, surf} = 1.4$ N/mm² is measured corresponding to EN 1542. The interior reinforcement steel is a B 500 B according to DIN 488 with a yield stress $f_{yd} = 500$ N/mm² and an elastic modulus $E_s = 210,000$ N/mm².

Test Procedure and Results

Four combined double shear pull-out tests are carried out under sinusoidal cyclic loading with a constant upper and lower load. The frequency was set to 4 Hz. The load level is adjusted to the static debonding load of the externally bonded reinforcement $F_{LRd}$, which has been determined in static double shear tests without interior reinforcement. In the first two tests of series A the lower load level of the externally bonded reinforcement is set to 15 % of the static debonding load. In Series B the lower load level is set to 34% and 33%. In the first tests of each series the upper load level is set to a value, where no damage occurs and two million load cycles were tested. In the second test the upper load was increased until decoupling occurs. Table 1 is showing the values of the lower and the upper load level $F_{UL}/F_{LRd}$ and $F_{OL}/F_{LRd}$ during the tests and the number of load cycles $N$ reached.

![Figure 1 Experimental setup for combined double shear pull-out test](image1)

![Figure 2 Strain at upper load level dependant on the number of load cycles during test A2 and B2](image2)
The redistribution of the forces during the tests A 2 and B 2 can be observed by the strain measurements, shown in Figure 2. The decoupling caused by the crack formation in the concrete substrate along the bonded length leads to a decrease of the CFRP strain $\varepsilon_L$ and an increase of the steel strain $\varepsilon_S$.

**MODEL AND CALCULATION**

The following model allows the determination of the force distribution between internal and external reinforcement under cyclic loading. With the crack propagation rate $da/dN$ the slip increase per load cycle $ds/N$ is calculated. The increasing slip of the externally bonded reinforcement leads to a redistribution of forces. The force in the EBR is decreasing while the force in the interior reinforcement is rising. The increase of the steel strain can be calculated using the formulation for the crack propagation rate according to Carloni (2015) and Leusmann (2015) together with the engineering approach for the force distribution after Zehetmaier (2006).

**Crack Propagation**

The bond behaviour of EBR under cyclic loading can be observed in cyclic shear tests. In a well-matched strengthening system, consisting of CFRP and adhesive, bond damage mostly occurs in form of cracking in the concrete substrate along the adhesive joint. In cyclic shear tests the crack formation can be observed with suitable measurement technology like optical measurement, see Carloni (2012) and Carloni (2013), or with a chain of strain gauge, see Leusmann (2015). The crack formation leads to an increase of the CFRP strain in the bonded area until a maximum value at the loaded end is reached. After that the stress transfer length remains constant and the S-formed strain distribution moves from the loaded end over the bonded length. Figure 3 shows schematically the experimental setup and the development of the CFRP strain $\varepsilon_L$.

![Figure 3 schematically experimental setup and development of CFRP strain $\varepsilon_L$.](image)

The crack propagation rate depends on the upper and lower load level and the static debonding load and can be determined with equation (1) after Carloni (2015).

$$\frac{da}{dN} = \frac{1}{N^*} \left( \frac{F_L^O - F_L^U}{\epsilon_1 \cdot (\Delta F_{L,Rd} - F_L^U)} \right)^k$$

The equation is applicable when the upper load $F_L^O$ exceeds the elastic limit $F_{L,Rd, fat_1}$, see German Committee for Structural Concrete (2012).

$$F_{L,Rd, fat_1} = 0.348 \cdot f_{ctm, surf}^{\frac{1}{4}} \cdot F_{L,Rd}$$

For smaller loads the CFRP to concrete bond responds perfectly elastic and there is no damage. Moreover, the upper load $F_L^O$ must not exceed the static debonding load $F_{L,Rd}$. In this case an immediate complete decoupling of the EBR would occur. Within these limits, the crack propagation can be calculated in mm for each load step $dN$ with equation (1).

**Force Distribution**

With the model from Zehetmaier(2006) the force distribution between steel rebar and EBR can be determined under static load. In agreement with force and moment balance and strain and slip distribution in a cracked cross...
section, the force contribution in the concrete, steel reinforcement bars and EBR are calculated with an iterative procedure. Initially a linear course of the strain distribution and the slip or the crack opening is assumed. The slip and strain states are coupled with coefficients \( k_{i} \) which are calibrated on measurement data depending on the reinforcement stiffness \( E_{lt} \), \( E_{st} \) and the concrete strength. Figure 4 shows the reinforced concrete cross section and the idealized distribution of strain, and displacement as well as the internal forces.

\[
\frac{\delta_{lk}}{\varepsilon_{s}} = \frac{d - x}{d_{L} - x} = \frac{2s_{L} - s_{L1} - \left( s_{L} - s_{L1} \right)^{2}}{s_{L0} - s_{L1}} \left( \frac{d_{L} - x}{d_{L} - x} \right) \left( \frac{\alpha_{s} + 1}{\alpha_{s} + 1} \right) \frac{s_{L}}{k_{si}} \frac{d_{L} - x}{d - x}
\]

(3)

For design applications Zehetmaier has developed a simplified model that allows the determination of the force distribution using the bond coefficient \( \delta_{lk} \) according to equation (3) which is the ratio of CFRP strain \( \varepsilon_{L} \) to steel strain \( \varepsilon_{s} \), adjusted for the distance of the reinforcement strands to the neutral axis, see Zehetmaier (2006). CFRP and steel strain \( \varepsilon_{L} \) and \( \varepsilon_{s} \) can also be determined with respect to the bond stress slip relationship of each reinforcement type using the CFRP slip \( s_{L} \) adjusted with the coupling coefficient \( k_{i} \). A method for the identification of \( s_{L} \) is shown in Zehetmaier (2006). The necessary parameters are listed in Table 2.

The bond coefficient \( \delta_{lk} \) is used for the calculation of the CFRP strain \( \varepsilon_{L} \) with equation (4) from the CFRP strain assuming a plane strain state \( \varepsilon_{L}^{II} \).

\[
\varepsilon_{L} = \left( 1 + \frac{E_{L} \cdot A_{L}}{E_{s} \cdot A_{s}} \frac{z_{L}}{z_{s}} \frac{d - x}{d_{L} - x} \right) \cdot \delta_{lk}
\]

(4)
Figure 5 shows the bond coefficient $\delta_{Lk}$ and the bond stress slip behaviour for the internal reinforcement according to Eligehausen (1983) and for the EBR corresponding to Holzenkämpfer (1994).

The development of $\delta_{Lk}$ can be described very well considering the bond stress slip relationships of steel and EB reinforcement. First the EBR to concrete bond reacts stiffer. This leads to a start value for $\delta_{Lk}$ smaller than 1. Subsequently the bond stress of EBR exceeds for a short section the bond stress of the cast-in reinforcement and $\delta_{Lk}$ reaches a value greater than 1. However, after reaching the maximum bond stress value $\tau_{L1}$ the EBR to concrete bond starts softening while the bond stress of the internal reinforcement is rising further. This is resulting in a decreasing bond coefficient $\delta_{Lk}$.

**Calculation Method**

The test results can be recalculated taking the crack propagation after equation (1) and the bond coefficient after equation (3) into account using the following procedure for every load step. In a first step the crack growth $da$ is calculated with equation (1). The resulting slip increase is determined with equation (5) and the actual slip $s_{L,i}$ with equation (6). After that the actual bond coefficient $\delta_{Lk,i}$ is calculated with equation (7) and the actual CFRP strain $\varepsilon_{L}$ can be calculated from $\varepsilon_{L,II}$ with equation (4). The results of the recalculation are shown in Figure 6.

\[
\begin{align*}
    ds_L &= da \cdot \frac{F_{L}}{E_L \cdot A_L} \\
    s_{L,i} &= s_{L,i-1} + ds_L \\
    \delta_{Lk,i} &= \frac{e_{L,i-1} \cdot d - x}{d_L - x} \\
    \sqrt{8k_s \sqrt{f_{cm}}} &\left( \frac{s_{L,i}}{E_s d_s} \right) \left( \frac{d_L - x}{k_{SL} d_L - x} \right)
\end{align*}
\]

</table>
The slip increase of the interior steel caused by fatigue damage is very low at the observed level and therefore it is neglected in the recalculation procedure. The factor for the distance of the reinforcement strands to the neutral axis \( d - x \) and the relation of the lever arms \( \frac{z_h}{z_c} \) is set to 1. The parameter \( c_1 \) for the determination of the crack propagation rate is fitted to a value of 0.35 for test A2 and to 0.38 for test B2. Other necessary parameters are listed in Table 2.

CONCLUSIONS AND PERSPECTIVE

The evolution of the force distribution between internal and external reinforcement under fatigue loading can be observed in combined shear and pull out tests under cyclic loading. The test results can be recalculated with the method presented in this paper taking into account the crack propagation and the bond behavior for both reinforcement types. Calculated and experimental results show a good correlation. The above given equations can also be used for the calculation of the force distribution at the end anchorage of CFRPs externally bonded to RC beams. The presented method above is a first step towards a model for the prediction of the service life prolongation of RC beams subjects to cyclic loading. For a precise analyse of a full strengthened rc beam a method for the consideration of debonding between cracks has to be developed. Furthermore creeping and fatigue in the concrete compression zone, bond creeping and the influence of cyclic loading on tension stiffening has to be considered.

ABSTRACT

Externally-bonded fibre-reinforced polymer (FRP) sheets and plates have grown in popularity for structural retrofitting due to their high-strength-to-weight ratio, corrosion resistance and flexibility; however, they remain an unsustainable solution. Furfuryl alcohol resins, which are fully-derived from corn cob and sugarcane, represent a potential alternative to conventional petroleum-derived epoxy resins, although insufficient research has been done to verify their long-term durability – one of the most critical aspects due to the harsh environmental conditions experienced by infrastructure. In this article, the short- and long-term performance of the carbon fibre and furfuryl alcohol resin composites were examined for externally-bonded retrofitting applications. Long-term conditioning consisted of submersion in a 3.5%-by-weight saline solution at 23°C, 40°C and 50°C for up to 240 days. Sixty-five tension FRP coupons and thirty-nine FRP-bonded notched concrete prisms and cylinders were tested. The FRP tensile strength and modulus were 860MPa and 92.8GPa, respectively. After conditioning, the lowest strength and modulus retention were 81% and 87%, respectively. The FRP-bonded notched-concrete prisms demonstrated a normalized shear stress retention ranging from 88% to 104%. Fluctuations were observed throughout the conditioning periods due to the combined effects of the FRP, concrete and bond. After conditioning, the maximum stress experienced by the externally-bonded FRP was 54% of its conditioned strength.

INTRODUCTION

Over the past decade, the application of externally-bonded fibre-reinforced polymer (FRP) sheets and plates for structural retrofitting has grown into a well-established technology due to its high-strength-to-weight ratio, corrosion resistance and flexibility; however, the main challenge in terms of widespread application is durability. Infrastructure is exposed to harsh environmental conditions, such as de-icing salts, freeze-thaw cycles and extreme heat and humidity. These conditions cause degradation of the FRP as well as the interface.

Research and field application of externally-bonded FRP to concrete beams typically involve the use of conventional FRP systems, such as those manufactured with carbon fibre and epoxy. Although the carbon fibers are inert, the resin system and the bond can be greatly affected by humidity as well as thermal and chemical conditions. These conditions have been simulated in laboratory environments (Rivera and Karbhari 2002; Cromwell et al. 2010; Robert and Fam 2012), including a proposed accelerated aging protocols for concrete-FRP bond (ACI 440.9R 2015) based on bond test recommendations and research by Gartner et al. (2011).

Although there has been significant progress in terms of durability, conventional FRP systems do not present a long-term solution. They are fundamentally unsustainable due to their reliance on petroleum. To address this challenge, several studies have assessed the use of natural thermosetting polymers, which can be derived from corn, soybean and tung oil (Lu et al., 2005; Li et al. 2003; Casado et al. 2009) as well as their use in combination with natural fibres (O’donnell et al. 2004; Mak et al. 2015); however, natural fibres systems demonstrated insufficient strength and stiffness for rehabilitation applications.
Furthermore, most commercially-available natural resins are resin blends, where the majority of the blend consists of conventional petroleum-derived resin. One promising alternative is furfuryl alcohol resin, which is fully derived from corncobs and sugarcane. Its derivative is furfural, which has one of the highest yields per ton of dry biomass at 220kg for corncob. It is also an agricultural by-product with Canada producing over 1.4 million tons of corn cob waste per year at approximately 10 cents/kg.

Structurally, furfuryl alcohol resin has been reported to have a similar response as epoxy when used in conjunction with fibreglass as a composite and for concrete cylinder confinement (Fam et al. 2013; Eldridge and Fam 2014a,b). Due to the required high stiffness of concrete retrofits, carbon fibre is favoured over fibreglass; however, limited research has been done on the application of furfuryl alcohol resin-impregnated carbon FRP.

This article presents an experimental program on the durability of furfuryl alcohol-based resin used in combination with carbon fibre with the goal of flexural concrete retrofitting. The study addresses short- and long-term performance of the novel FRP system as a pure composite and when externally-bonded to concrete. The long-term exposure was conducted in a 3.5%-by-weight saline solution at 23°C, 40°C and 50°C for up to 240 days.

MATERIAL SPECIFICATIONS AND TEST REGIME

Materials

**Furfuryl alcohol resin** \((C_5H_6O_2)\): is a low-viscosity resin, commercially available as QuaCorr1001. It is derived from renewable resources such as sugar cane and corncobs. It has a dark-reddish to brown color, and has the following physical characteristics: a specific gravity of 1.22, viscosity of 300-600 cps and a flash point of 75.6°C. p-Toluenesulfonic acid monohydrate 97.5% was used at 3%-by-weight to cure the resin.

**High viscosity epoxy resin**: is an epoxy paste specifically designed for rehabilitation, commercially available as Sikadur® 30. The reported tensile strength and elastic modulus after 7 days of curing at room temperature are 24.8 MPa and 4.5 GPa, respectively. The reported \(T_g\) after 7 days curing at 45°C is 62°C.

**Concrete**: had a 28-day design compressive strength of 35 MPa with a maximum aggregate size of 19 mm.

**Specimen Fabrication**

**FRP Tensile Coupons**

The FRP laminates were manufactured using the wet lay-up process. A single layer of carbon fibre fabric was laid out on a flat surface and covered with furfuryl alcohol resin. A flexible spreader was used to disperse the resin until the fabric was fully saturated. To ensure a consistent thickness, the saturated layer of fabric was sandwiched between two high density polyethylene plates and weights were placed on top of the plates. After two weeks of room temperature curing, the sheets were cut to nominal dimensions of 254x25 mm using a wet tile saw. They were then post-cured at 200°C for three hours, as recommended by Ma et al. (1995).

Carbon-epoxy tabs, manufactured similar to the above-described FRP laminates, were adhered to the gripping region using high viscosity epoxy resin to reduce the potential of grip failure, as suggested by ASTM D3039 (2007). For conditioned specimens, tab adhesion was done at least seven days post-removal from the tank.

**Notched-concrete Prism FRP-Bond**

Concrete prisms of 102x102x356 mm\(^3\) dimension were cast. After 28 days, the prisms were cut at mid-span to mid-depth using a sliding stone saw of 3 mm width. The notched half of the prism represents the tension side of the block, which was sandblasted prior to adhering the FRP sheet.

FRP sheets were fabricated in the same manner as the FRP tension coupons; however, the FRP sheets were cut to a nominal dimension of 25x204 mm\(^2\) after two days. Upon full cure, high viscosity epoxy resin was applied to the concrete surface and the FRP sheet. An aluminum roller was used to apply the sheet onto the concrete. All prisms were cured at room temperature for 14 days prior to testing or conditioning.

**Conditioning**

The conditioning procedure consisted three salt water tanks with an initial salt concentration of 3.5%-by-weight at 23°C, 40°C and 50°C as per Bank et al. (2003). Screw-plug heaters were used in conjunction with an electric
temperature controller to maintain the temperature at 40°C and 50°C to a 1°C variation, whereas the 23°C tank was maintained at room temperature. Pumps with a 0.12 L/s flow rate were installed in the tanks to eliminate temperature differentials. A handheld thermistor was used to verify the temperature. An insulated sheet sealed the top of the tank to reduce evaporation and heat loss. Additional insulation surrounded the walls of the heated tanks.

After five months of conditioning, the 40°C tank heating element failed. Specimens in the tank were removed and stored temporarily in standard lab conditions. Due to the backorder of the failed mechanism, the specimens were placed back in the conditioning tank after 32 days and the remaining period of conditioning was completed.

**Test Setup**

**FRP Tensile Coupons**

FRP specimens were tested in tension according to ASTM D3039 (2007). An extensometer with a 25 mm gage length was used to measure the FRP strain. It was removed prior to specimen failure to ensure that it would not be damaged. The stress-strain response was extrapolated until failure. The linear stress-strain trend was verified with a strain gauge. Load was measured directly from the testing frame.

**Notched-concrete Prism FRP-Bond**

Prisms were tested in three-point bending with a span of 305 mm (Gartner et al. 2011; ACI 440.9R (2015)) at a loading rate of 0.25 mm/min (Figure 1(a),(b)). The load was applied using a 25 mm diameter steel cylinder. Load was measured from the testing frame, and the mid-span deflection was measured using a linear potentiometer.

The measured maximum load at failure was used to calculate the average interfacial shear strength (Gartner et al. 2011). For this calculation, the concrete compressive stress level at bond failure is assumed to be small and as such, stress is linear and the neutral axis is stable at mid-depth (Figure 1(c)). Based on the simple geometry, interfacial shear strength (τ) at bond failure, is calculated as a function of the measured ultimate load (P), where \( L \) is the span, \( h \) is the prism height, \( w \) is the CFRP laminate width and \( S \) is the CFRP laminate length as follows:

\[
\tau = \frac{3PL}{5hwS}
\]

ASTM C39 (2015) was used to determine the concrete compressive strength at each conditioning stage.

![Figure 1 Notched-concrete prism: (a) test set-up, where AE is aluminium extender and LP is linear potentiometer, (b) schematic of specimen and (c) idealized internal forces and shear](image)

**EXPERIMENTAL RESULTS AND DISCUSSION**

**Failure Behaviour**

**FRP Tensile Coupons**

A summary of the tensile test results is shown in Table 1. To determine the tensile properties, the average thickness of 1.78±0.13 mm and average width of 25.34±0.12 mm were used. All failure modes were acceptable, either as explosive or delamination within the middle of the gauge length. No trends were observed between failure mode, conditioning temperature and conditioning period. All coupons showed a linear stress-strain response until failure.

**Notched-concrete Prism FRP-Bond**

A summary of the notched-concrete prism test results is shown in Table 2. The interfacial shear strength was calculated based on the ultimate load using Eq. (1). The normalized shear strength was done so by dividing by their respective square roots of \( f' \). Concrete cylinders were conditioning to determine the compressive strength.

Two failure modes are acceptable: adhesive and cohesive bond failure. Adhesive failure is defined by traces of cement paste and fine aggregates on the laminate, whereas cohesive failure is defined by a thick layer of concrete and coarse aggregates on the laminate. Concrete shear failure is not acceptable, as it does not provide a gauge of bond performance of the system. Cohesive bond failure was the primary failure mode specimens and was consistent regardless of the conditioning regime. Due to the constancy of cohesive failure, the bond between the furfuryl alcohol resin and the high viscosity epoxy resin was excellent as interface never governed failure.

**Effect of Conditioning**

**FRP Tensile Coupons**

The average tensile strength and modulus of unconditioned specimens were 860±110 MPa and 93±6 GPa, respectively. After 240 days, the strength retention at 23°C, 40°C and 50°C was 83%, 81% and 82%, respectively,
whereas the tensile modulus retention at 23°C, 40°C and 50°C was 92%, 94% and 87%, respectively. The variations in strength over time can be observed in Figure 2(a).

![Figure 2](image_url)

**Concrete**

The unconditioned concrete compressive strength was 33MPa. Throughout the conditioning phases, the concrete strength varied from -3% to +34%. This can be attributed to two opposite effects: moisture allowed for further curing and the continuation of the hydration process, which results in strength gain; conversely, calcium leaching resulted in an pH imbalance between the cylinders and the water, which resulted in the disintegration of Calcium-Silicate-Hydrate (CSH) and a subsequent strength loss. The combined opposing effects can be seen in Figure 2(b).

**Notched-concrete Prism FRP-Bond**

The unconditioned notched-concrete prisms showed a normalized shear stress of 0.97 MPa. After 240 days, the normalized shear stress retention at 23°C, 40°C and 50°C was 100%, 104% and 103%, respectively. However, this does not always represent the highest strength loss. For example, the lowest strength retention at 23°C and 40°C were 88% and 97%, respectively, at 60 days of conditioning, whereas the lowest strength retention at 50°C was 93% at 30 days of conditioning. The fluctuations observed in strength are due to the combined effects of the changing FRP, concrete and bond strength. Further research is necessary to determine the exact implications. The variation in normalized shear stress is presented in Figure 2(c).

To determine the efficiency of the FRP system, the stress in the FRP at bond failure for the notched-concrete prisms was compared to the strength of the tensile FRP coupons with the same conditioning regime. In an unconditioned state, bond failure occurred when the FRP reached 36% of its strength. After 240 days, the percentage of stress in the FRP compared to the strength at 23°C, 40°C and 50°C was 44%, 54% and 47%, respectively. Fluctuations similar to that of the normalized shear stress were observed throughout the conditioning period; however, the maximum observed value was 54% of the strength after 240 days of conditioning at 40°C. The variation in percentage strength is presented in Figure 2(d).

**CONCLUSION**

This study examined the short- and long-term performance of carbon fibre and furfuryl alcohol resin composites aimed at concrete retrofitting. Long-term conditioning occurred throughout 240 days at 23°C, 40°C and 50°C in a 3.5%-by-weight saline solution. The following conclusions were drawn:
1. The FRP tensile strength and modulus are 860 MPa and 92.8 GPa, respectively. After 240 days at 23°C, 40°C, and 50°C, strength retention was 83%, 81% and 82%, respectively, and modulus retention was 92%, 94% and 87%, respectively.

2. Throughout the conditioning period, concrete strength fluctuated by -3% to +34% due to moisture, which allowed for additional curing, and calcium leaching, which caused disintegration of the cement paste.

3. Throughout the conditioning period, the normalized shear/bond stress at failure ranged from 88% to 104%. This value fluctuated due to the combined effects of the FRP, concrete and bond.

4. Taking FRP deterioration into account, the maximum stress experienced by the externally-bonded FRP was 54% of its strength when bond failure occurred after 240 days of conditioning at 40°C. This increased from 35% when tested in an unconditioned state.

ABSTRACT

Increase in traffic volume and load on highway bridges requires replacement of the bridge superstructure or adoption of a structural strengthening system. Strengthening of existing prestressed concrete bridges with conventional construction materials results in an increase in dead load. In addition, it may also result in decrease in bridge clearance. The use of Carbon fiber reinforced polymer (CFRP) composites is considered a practical alternative for flexural strengthening of prestressed concrete bridge girders. However, the effectiveness of the CFRP depends on several factors, which have not been quantified well. AASHTO type II prestressed girder is one of the most popular girders carrying highway bridge decks, in the U.S.A. This paper presents a finite element analysis of CFRP strengthened AASHTO type II prestressed girder. Several variables were investigated: concrete strength, ratio of prestressing strands, and ratio of CFRP composites. For CFRP strengthened PC girders, the results of this investigation suggest that for the same amount of CFRP, the lower the ratio of prestressing strands, the higher the percentage increase in flexural strength. In addition, strengthened girders exhibit comparable ductility as un-strengthened PC girders.

INTRODUCTION

According to the Transportation Research Board (TRB) reports in United States, over 40% of the nation’s bridge are structurally deficient and functionally obsolete which are in need of repair, strengthening or replacement. Compared with replacement of the outdated and deficient bridge components which could be economically unfeasible, using FRP systems in the form of “external” reinforcement to strengthen the deficient prestressed structures may lower the costs and be more efficient for prestressed concrete bridges (Mayo et al. 1999).

During the past two decades, several experimental researches have been conducted to investigate the compact of CFRP on the behaviour of concrete members. Aboutaha (1999) did an experimental investigation on the application of CFRP for strengthening a damaged AASHTO type II prestressed concrete girder. The experimental results showed that CFRP could restore the stiffness and increase the strength of the damaged prestressed concrete girders. Mayo et al. (1999) performed several in-situ field tests using CFRP to strengthen a simple span reinforced concrete beam. Based on the test results, they concluded that the CFRP could increase the flexural strength of reinforced concrete beam. Ross et al. (1999) investigated the effect of the reinforcement ratio on the impact of the externally strengthened beams with CFRP. They found that for the light reinforcement ratio, the tensile strength was controlled by the concrete in the tension zone and the failure of the tested beam was the debonding of the CFRP. The CFRP could increase the load capacity of the beam effectively. For the heavy reinforcement ratio, the failure mode was the crushing of the concrete on the compression zone. CFRP had less impact on the load capacity of the beam.

Moreover, finite element models have been increasingly used as a numerical tool to study the behavior of concrete structures with CFRP in the past decade. Hu et al. (2004) did a nonlinear finite element analysis of reinforcement concrete beam strengthened with FRP. Nonlinear constitutive equations for the FRP are coded in FORTRAN language as a subroutine and linked to the ABAQUS program. Perfect bond was assumed during the modeling, 4-node shell element was used to model the FRP strips (Hu et al. 2004). Jose (2005) modeled a FRP strengthening
system on the bridge with ABAQUS. The FRP material was assumed to be homogeneous, linearly elastic and orthotropic. The 2-D analysis was considered because the FRP strips have two dimensions much larger than the third one. The bending stiffness and the stresses in the out of plane direction were neglected. The ABAQUS tool called “Skin Reinforcement” was used to model the FRP strips. For “Skin Reinforcement”, only one skin can be placed on a surface of an element, which means that the skins cannot overlap. To model the cases for 2 layers of strips, the same section used for 1 layer cases was applied, but doubling the value for the thickness of the section. Perfectly bond between the concrete surface and FRP was assumed. Membrane elements were used to model the FRP (Jose, 2005). Charalambidi et al. (2012) modeled a RC column with FRP jacket with ABAQUS. The material properties of FRP was assumed to be homogeneous, linearly elastic and orthotropic. Also, perfectly bond between the concrete surface and FRP was assumed and membrane elements were used to model the FRP jacket (Charalambidi et al., 2012).

The aim of this study is to pursue a finite element analysis of CFRP strengthened AASHTO type II prestressed girder using ABAQUS/CAE. The verification of the FEA model was a prestressed AASHTO Type II girder tested by Aboutaha (1999). In the finite element analysis, several variables were investigated: concrete strength, ratio of prestressing strands, and ratio of CFRP composites.

FINITE ELEMENT MODEL

Element Types

In order to model the behavior of concrete, an 8-node linear brick, reduced integration with hourglass control element (C3D8R) was used. The brick elements in ABAQUS are used for linear analysis and nonlinear analysis involving contact and plasticity, and they are available for stress analyses. C3D8R element has 8 nodes and each node has 6 degrees of freedom (displacement and rotation in x, y, z-directions). The C3D8R elements are first-order elements, so the strain operators provides constant volumetric strain throughout the element. The reduced integration for this element uses a lower-order integration to form the element stiffness, which reduce running time in 3-D modeling. The hourglass control prevent the uncontrolled distortion of the mesh. Prestressing strands were modeled using a 6-node linear triangular prism (C3D6) element with an equivalent round section. The C3D6 element has 6 nodes and each node has 6 degrees of freedom (displacement and rotation in x, y, z-directions). The stirrups in the prestressed girder were modeled with 2-node truss elements (T3D2). The truss elements support loading along the axis of the element without moments or forces perpendicular to the centerline. The CFRP strips are modeled with shell elements (S4R). Shell elements are usually used to model structures which can be analyzed with plane stress theory. S4R is a 4-node with reduced integration, general purpose, and finite-membrane-strain shell element. The uniformly reduced integration avoid shear and membrane locking.

Material Model

The accuracy of the FEA results depend heavily on the material properties used in the model. The constitutive relations of the concrete, strand, CFRP are discussed in this section.

Concrete material properties

The concrete material model used in this FEA analysis was the “Concrete Damaged Plasticity (CDP)” model in ABAQUS/CAE. The constitutive relation of the concrete was based on AASHTO LRFD Bridge Design
Specifications and previous research studies as shown in Figure 1. The elastic modulus is assumed to be the same for both compression and tension behaviour (Figures 1 and 2) which was calculated based on the AASHTO LRFD Bridge Design Specifications. The elastic range for the compressive behaviour was assumed to be 0.3fc’. The Thorenfeldt et al. (1987) constitutive model for concrete in compression was used which was applicable for concrete strength from 2000 psi to 18000psi. The parameters used in the CDP model are summarized in Table 1. The concrete tension stiffening was considered and a simplified curve was used in this model as Figure 3.

Strand material properties

The prestressing strand are 270ksi, low-relaxation strand. The material properties of the strand are based on the model provided by PCI manual (6th Edition) as Figure 4.

![Figure 4 PCI Standard 270 ksi. Low-relaxation strand constitutive model (PCI Manual)](image)

CFRP material properties

The prestressed concrete girder was strengthened using Mitsubishi’ Replark system (Replark™ Type 30 (MRK-M2-30)). The material properties provided by the manufactures are as following:

<table>
<thead>
<tr>
<th>Properties</th>
<th>Width (in)</th>
<th>Thickness (in)</th>
<th>Tensile Modulus (ksi)</th>
<th>Ultimate Strain</th>

</tr>
</tbody>
</table>

FRP material has been assumed to behave as a linearly elastic and orthotropic material. The “lamina” option for the elastic material behavior was chosen, which describe the orthotropic elasticity in plane stress. For this type of material, ABAQUS requires the longitudinal, transverse and shear modulus of elasticity. The manufactory of Replark™ Type 30 (MRK-M2-30) only provided the longitudinal modulus of elasticity, the transverse and shear modulus were assumed based on the average properties of carbon fibers (Jose, 2005).

Contact Model

For the contact behavior between prestressing strand and concrete, several methods are available. The most common ways are perfect bond which can be achieved by using embedded or tied constraints, non-linear spring elements, and surface friction interaction model. The embedded or tied constraints are easy to model, however, they cannot model the bond-slip phenomena at the strand end region which exists in the prestressing girder after the strand release. The non-linear spring element can model the bond-slip behavior, however, this method is time consuming for 3-D modeling. So, the bond between prestressing strand and concrete was modeled with a surface-to-surface contact element with tangential and normal behavior. The tangential behavior was modeled with penalty friction formulation with. The friction coefficient was assumed to be 1.4 after calibration. The default value of the maximum elastic slip in ABAQUS/CAE was used, which was 0.005. The normal behavior was modeled with “Hard” Contact which minimize the penetration of the slave nodes into the master surface at the onset of the contact and prevent the transfer of tensile stresses with the contact surface. The contact between CFRP strips and concrete surface are assumed fully-bonded without bond failure. The different layers of CFRP were modeled with different thickness of the CFRP, such as two layers of CFRP were modeled with a CFRP strip with a thickness of 0.0132 in.
Boundary Conditions and Loading

Due to symmetry in both x-direction and z-direction, only quarter of each girder was modeled. To model the x-direction symmetry, the girder was cut with a vertical plane in y-z plane. The displacement in x-direction and rotation around y, z-direction were constrained with a roller supports (U1=UR2=UR3=0). To model the z-direction symmetry, the girder was cut with a vertical plane in x-y plane. The displacement in z-direction and rotation around x, y-direction were constrained with a roller supports (U3=UR1=UR2=0). The girder was supported with roller supports. The displacement in y-direction at the support plate was restricted (U2=0). To avoid the load concentration, the external load was applied in y-direction as a pressure on a rigid load plate which was fully bonded with the concrete surface. The prestressing force was applied in the initial step as an initial condition using the PREDEFINED FIELD of ABAQUS/CAE.

VERIFICATION OF THE FE MODEL

The FEA model was verified against 2 different experimental results from Aboutaha (1999). Aboutaha tested one prestressed AASHTO Type II girder under two different tests as Figure 5. A comparison between the load-deflection curves obtained by Aboutaha (1999) and the load-deflection curves obtained by the FEA model with ABAQUS/CAE are shown in Figure 6 and Figure 7. It can be seen that the FEA model can reasonably estimate the ultimate capacity of the prestressed concrete girder.

RESULTS AND DISCUSSIONS

In this section, the effects of reinforcement ratio (strand ratio, SR), concrete compressive strength, and layers of CFRP strips on the ultimate flexural strength of AASHTO Type II prestressed concrete girders are investigated. The load-deflection results for different layers of CFRP (0, 1, 2, and 3) with different concrete compressive strength and reinforcement ratio are shown in Figure 8.
From the load-deflection and ultimate capacity enhancement ratio above, we can find that, CFRP has almost no impact on the initial flexural stiffness of the prestressed concrete beam. As the strand ratio equals to 0.3%, the ultimate flexural capacity of the prestressed girders increased with the increase of the amount of CFRP. As the strand ratio equals to 0.6% and 0.9%, the amount of CFRP has little impact on the ultimate flexural capacity of the prestressed girders. This might be caused by the following two reasons:

1. As the amount of CFRP increases, the depth of the neutral axis increases, which leads to a smaller moment arm between tension and compression force. Consequently, the flexural capacity will not increase much.
2. Compared to the force in the prestressing strand, the internal forces in the CFRP are relatively small, therefore, the impact of the CFRP on the flexural strength is very limited.

Based on these two reasons, the neutral axis and the tensile force provided by the CFRP compared with the total tensile force at ultimate state for each girder was tested. It was observed that the neutral axis decrease largely for several girders strengthened with CFRP (Girder case: fc'=5ksi, SR=0.3%, CFRP=0,1,2,3 layers). However, for most girders, the neutral axis didn’t change too much. The tensile force provided by different layers of CFRP for the girders (fc'=5ksi, SR=0.3%) are 5.671%, 9.14%, and 11.181%, respectively. The tensile force provided by different layers CFRP for the girders (fc'=10ksi, SR=0.3%) are 9.544%, 15.583%, and 19.746%, respectively. The tensile force provided by the CFRP for the girders (fc'=5ksi, SR=0.6% and 0.9%) are from 0.626% to 3.027%.

Figure 8 FEA load-deflection results for different layers of CFRP (0, 1, 2, and 3) with different concrete compressive strength and reinforcement ratios.
The tensile force provided by the CFRP for the girders (fc' = 10 ksi, SR = 0.6% and 0.9%) are from 0.988 % to 5.374%. Based on these FEA results, we can find that the force provided by the CFRP are too small compared with the force provided by the prestressing strand. So, the impact of the CFRP on the ultimate flexural capacity of the prestressed concrete girder are small. In addition, for the same amount of CFRP, the higher the amount of prestressing strands, the lower the increase in the flexural strength.

**CONCLUSIONS**

- For the AASHTO Type II girders, the CFRP has very limited impact on the initial flexural stiffness of the girders.
- For the same amount of CFRP, the higher the amount of prestressing strands, the lower the percentage increase in the flexural strength.
- The higher the ratio of CFRP to steel strand ratio the higher the increase in the flexural strength.
- The CFRP strengthened prestressed concrete girders exhibited good ductility, which were comparable to those of ordinary prestressed concrete girders designed according to the current AASHTO specifications.

ABSTRACT

In this study a type of FRP with large rupture strain known as PET (Polyethylene Terephthalate) FRP was employed to strengthen unconfined and confined masonry walls. Four full-scale masonry walls were designed and prepared, one was unconfined control specimen, one was confined control specimen, one was unconfined masonry wall strengthened with PET placed along two diagonals and vertical edges, and one was confined masonry wall strengthened with PET only placed along two diagonals with end anchorage. The PET was applied symmetrically on both sides of masonry walls. The failure of all specimens was triggered by the opening of diagonal cracks. The test results showed that the peak strength, the displacement at failure, the energy dissipation capacity and the ductility factor of strengthened unconfined masonry wall had 90%, 87%, 406% and 74% increase respectively compared with that of the unconfined control specimen, while for the strengthened confined masonry wall, the peak strength, the displacement at failure, the energy dissipation capacity and the ductility factor were 52%, 40%, 145% and 23% higher than that of the confined control specimen, respectively.

KEYWORDS

Masonry wall, large rupture strain (LRS) FRP, polyethylene terephthalate (PET), strengthen, cyclic loading.

INTRODUCTION

In the past two decades, a number of experimental research works have been carried out to investigate the in-plane behaviour of masonry walls strengthened with typical FRP materials. Different layouts of FRPs were applied either on double sides or single side of precracked or uncracked specimens. Results showed that the shear capacity and deformation capacity of uncracked walls were significantly increased (Schwegler 1994; Valluzzi et al. 2002; Holberg and Hamilton 2002; Chuang et al. 2003; Stratford et al. 2004; Santa-Maria et al. 2006; Alcaino and Santa-Maria 2008; Rahman and Ueda 2015, 2016; Lei et al. 2016), and the bearing capacity and ductility of damaged walls were restored or even exceeded the original capacity (Vandergrift et al. 2002; ElGawady et al. 2007; Santa-Maria and Alcaino 2011; Jing and Raongjant 2015). A little or none uneven response due to strengthening on single side was observed (Valluzzi et al. 2002; Holberg and Hamilton 2002; Chuang et al. 2003; Stratford et al. 2004; ElGawady et al. 2007; Jing and Raongjant 2015).

One of the important factors that influence the behaviour of strengthened walls is the reinforcement layout. It was found that the full surface coverage resulted in the highest bearing capacity but the least amount of deformability. The diagonal configuration was found more efficient in terms of shear capacity than the grid layout, but the latter offered a better stress redistribution and caused a less brittle failure (Schwegler 1994; Valluzzi et al. 2002; Santa-Maria et al. 2006; Alcaino and Santa-Maria 2008; Rahman and Ueda 2015, 2016; Jing and Raongjant 2015).

Since typical FRP materials such as CFRP, BFRP, and GFRP are stiff materials and vulnerable to debonding, failure of most test specimens were characterized by brittle failure across the masonry-FRP interface(Vandergrift et al. 2002; Stratford et al. 2004; Santa-Maria et al. 2006; ElGawady et al. 2007; Alcaino and Santa-Maria 2008; Santa-Maria and Alcaino 2011; Lei et al. 2016), unless the debonded length of FRP were controlled using intermediate anchorages (Holberg and Hamilton 2002; Chuang et al. 2003; Stratford et al. 2004; Lei et al. 2016).

Polyethylene Terephthalate(PET) fiber is one of the retrofitting material that has drawn a significant attention as an unique alternative to typical FRP due to its ductile behaviour, but not compromising the other advantages of FRP. Rahman and Ueda (Rahman and Ueda 2015, 2016) investigated in-plane shear performance of masonry walls...
strengthened with PET-FRP and CFRP sheets under monotonic lateral loading. The in-plane shear strength of the strengthened wall was considerably improved by using either of the FRPs, but PET-FRP had a better seismic performance than CFRP as it showed a better ductile behaviour especially in postpeak region.

In this study, PET FRP was used to strengthen unconfined and confined masonry walls which were tested under cyclic lateral loading. The purpose is to learn more about the seismic performance of masonry walls strengthened with PET FRP. Ultimate load bearing capacity, deformability and energy dissipation capacity were observed during the experiment.

**EXPERIMENTAL PROGRAM**

**Test specimens**

In this experimental study, a total of 4 clay brick masonry walls with nominal dimensions of 2115mm×1750mm×240mm were constructed. All of the walls were fabricated with bricks having a dimension of 240mm×115mm×48mm, and 10mm thick mortar. Details of the walls are shown in Figure 1 and measured material properties are listed in Table 1.

Two walls (W-1 and LW-1) were unconfined walls and the other two (W-2 and LW-2) were confined with reinforced concrete constructional columns at two ends. The constructional columns of W-2 and LW-2 were cast after the masonry wall and toothed edges were left on each side of the wall panel at the interface. The height of toothed edges was provided equal to the thickness of five brick course (290mm), and the toothing length was taken as 60mm. Columns were of rectangular cross-section with dimension of 240×125mm (the short side parallel to the plane of the wall) with the longitudinal reinforcement consisted of four 8mm diameter steel bars and 6mm diameter stirrups spaced at 150mm.

Two specimens (W-1 and W-2) were reference walls, and the other two (LW-1 and LW-2) were strengthened with 0.841mm thick, 300mm wide PET FRP sheet with unidirectional fiber. The PET FRP sheet was applied on both sides of the specimens in two different layouts as shown in Figure 1 (c) and (d). LW-1 was strengthened with PET FRP placed along two diagonals and vertical edges, and vertical strips were laid over the ends of diagonal strips to keep them in place. LW-2 was strengthened with PET FRP only placed along two diagonals with end anchorage system consisting of a 350mm×30mm×10mm steel plate and two expansion bolts placed at two ends of the steel plate.

---

![Figure 1 Specimens and test setup](image-url)
Test setup

A combination of vertical compression and in-plane shear load was applied to each specimen as shown in Figure 1(e). A pre-compression of 304.6kN which was equivalent to a uniform pressure of 0.6MPa was applied on the top of the wall through two hydraulic jacks to simulate the load of structural component coming on the wall from the above in the real structure. The cyclic lateral load was then applied following a specified load-control regime. Before yielding, the applied load was increased gradually with increments of 30kN. Once yielding can be observed from hysteretic response, the displacement-control regime was adopted. At each load level, one cycle was used for each level of load controlled loading, and three full cycles were used for each displacement controlled loading. When the lateral load dropped to less than 85% of the peak load, the specimen would be considered as failed.

TEST RESULTS AND DISCUSSION

Observation of failure

W-1: At the second load-control stage (±60kN), flexural cracks appeared at the foot of the wall. After the third load-control stage (±90kN), the lateral load was applied under displacement control, and the displacement increment was 2mm starting from ±2mm. During the first ±10mm cycle, the lateral load in both directions reached the peak value, and one major diagonal crack appeared along each diagonal direction. During the second and the third ±10mm cycles, the crack width increased and the lateral load decreased. During the first ±12mm cycle, failure occurred. The cracking pattern was presented in Figure 2(a) and (b).

W-2: After the cycle of ±150kN, the displacement reached ±3.5mm and flexural cracks had already appeared at the wall toe and then the displacement controlled loading was adopted. During the second displacement control stage (±6mm), several horizontal cracks appeared on confining concrete columns. After 3 cycles of ±6mm, the displacement increment was taken as 3mm. During the first cycle of ±9mm, diagonal cracks appeared at the central area and the foot of the wall. During the first cycle of ±12mm, the lateral load in both directions reached the peak amount, and major diagonal cracks appeared along each diagonal direction. During the first ±18mm cycle, failure occurred. As shown in Figure 2(d), the cracking pattern of W-2 changed from large diagonal cracks of W-1 (as shown in Figure 2(b)) to a network of several diagonal cracks of smaller width, and dozens of flexural cracks were distributed along constructional columns.

LW-1: After the cycle of ±120kN, the lateral load was applied under displacement control, and the displacement increment was taken as 2mm starting from ±2mm. During the cycles of ±4mm, flexural cracks had already appeared at the wall toe. During the cycles of ±10mm, several diagonal cracks appeared along each diagonal
Lateral load in both directions reached the peak value. During the cycles of ±16mm ~ ±20mm, debonding of PET FRP was observed accompanied by crushed bricks falling off, and vertical cracks appeared at two ends of the wall. When the displacement reached 22mm, failure occurred and crushed bricks at two ends of the wall started to fall off. As shown in Figure 3, diagonal cracks were distributed along edges of PET FRP strips, and rupture of PET FRP strips did not happen.

LW-2: During the cycle of ±90kN, the pull displacement was much larger than the push displacement, and yielding had already occurred in the pull direction. Construction flaws in the foundation anchorage of longitudinal reinforcement in confining columns were suspected to exist, which may cause this kind of asymmetry. After the cycle of ±90kN, the displacement controlled loading was adopted. The first loading stage is 1.5mm in pushing and 3mm in pulling, and the second stage is 3mm in pushing and 4.5mm in pulling. Starting with the third stage, which is 6mm in both pushing and pulling, the increment was fixed to 3mm. During the early stages of displacement controlled loading, flexural cracks had already appeared at the wall toe. Through the cycles of ±9mm, diagonal cracks appeared along each diagonal direction. During the first cycle of ±12mm, the lateral load in pushing direction reached the peak value. During the first cycle of ±18mm, the lateral load in pulling direction reached the peak amount. During the first ±21mm cycle, failure occurred. The cracking pattern of LW-2 shown in Figure 4 was quite similar to LW-1, debonding of PET FRP was observed in some areas accompanied by crushed bricks falling off. Furthermore, a few flexural cracks were distributed along constructional columns.

Hysteretic behaviour

Figure 5 shows the hysteretic behaviour of the specimens. Before diagonal cracks appeared, all specimens displayed narrow hysteretic loops. After diagonal cracks appeared, relatively larger loops were observed. Pinching phenomenon was more obvious in hysteretic loops of LW-2 than LW-1, which may be caused by suspected construction flaws in LW-2, indicating that sliding was more serious in LW-2. Therefore, applying PET FRP along two vertical edges can be considered as an alternative to constructional columns.
Load-displacement response and stiffness

In Figure 6(a), the specimens’ envelope curves for the first cycle at each level were presented. For each specimen, the experimental value for the “yield displacement” can be obtained from intersection point of the horizontal line at the peak load and the straight line from the origin passing through the point at 75% of the peak load as shown in Figure 6(b) (Park et al. 1982), in which V is lateral load, δ is lateral displacement, V_{max} is peak load, V_{yielding} and δ_{yielding} are load and displacement at yielding respectively, and test results were summarized in Table 2.

Note: + represents the pushing direction, - represents the pulling direction. Failure occurred when the lateral load dropped to 85% of the peak load. Ductility factor is the ratio between the displacement at failure and the displacement at yielding.

Two control walls had similar load-displacement response as shown in Figure 6(a) and Table 2, but the peak strength, deformability and ductility factor of W-2 had a 16%, 29% and 25% increase respectively compared with W-1. Comparison between control walls and strengthened walls shows that the technique of strengthening with PET FRP sheets appeared to be significantly effective. The peak strength, displacement at failure and ductility factor of LW-1 were 90%, 87% and 74% higher than that W-1 respectively. The peak strength, displacement at failure and ductility factor of LW-2 were 52%, 40% and 24% higher than that of W-2 respectively.

The stiffness of each specimen is displayed in Figure 6(c). The stiffness of both control walls were almost the same at early loading stage, and it decreased rapidly before the lateral displacement reached 3mm. However, a sudden decrease of stiffness after the lateral displacement reached 10mm was observed in W-1. The stiffness of the strengthened unconfined wall LW-1 was always higher than the unconfined control wall W-1, and the decreasing of stiffness clearly slowed down after the lateral displacement reached 2mm. The stiffness of the strengthened confined wall LW-2 in two directions decreased asymmetrically. In the pushing direction, the stiffness of LW-2 was almost the same as the stiffness of LW-1 and higher than the stiffness of the control specimen W-2. In the pulling direction, the stiffness of LW-2 was lower than the stiffness of W-2 initially, but gradually became higher. It can be concluded that PET FRP sheets were effective in enhancing the stiffness of masonry wall, especially after yielding.
Energy dissipation

High-energy dissipation is a desirable property. The cumulated energy dissipation of the specimens was calculated (Figure 7(a)). As shown in Figure 7(a), the strengthened specimens dissipated higher energy compared to the control walls, as LW-1 dissipated 406% higher energy than W-1, and LW-2 dissipated 145% higher energy than W-2.

The equivalent damping coefficient ($\zeta$) was calculated as $\zeta = \frac{A_{ABC+CDA}}{2\pi A_{OBE+ODF}}$, where $A_{ABC+CDA}$ is the energy dissipated in a hysteretic loop and $A_{OBE+ODF}$ is the strain energy measured at the peak force of the same cycle, i.e., the sum of the areas under the triangles in Figure 7(b). Figure 7(c) showed the calculated equivalent damping coefficient as a function of lateral displacement for all the test specimens. Before diagonal cracks appeared, the equivalent damping coefficient of all specimens was slightly decreasing as the lateral displacement increased. After diagonal cracks appeared, the coefficient of W-1 and W-2 increased drastically while the coefficient of the strengthened walls increased much more slowly.

![Figure 7 energy dissipation analysis: (a) cumulated energy; (b) definition of damping; (c) damping coefficient](image)

**DESIGN EQUATION**

The total shear load carried by the strengthened specimen was conventionally split into two components: the shear load carried by an equivalent unreinforced masonry specimen and the increase in shear capacity due to strengthening (Stratford et al. 2004). Based on truss mechanism (ElGawady et al. 2007), a simple design equation for diagonally strengthened walls was proposed as the following form:

$$V_{\text{max}} = V_{\text{m}} + \alpha \rho h f_{\text{PET}} t L$$  \hspace{1cm} (9)

Where $V_{\text{m}}=$shear strength of unreinforced wall according to the reference walls; $\alpha=$coefficient of efficiency (based on numerical fitting according to experimental results, which is suggested to be taken as 0.38); $\rho=$reinforcement ratio of FRP in the horizontal direction; $f_{\text{PET}}=$tensile strength of the PET sheet; $t=$thickness of wall; $L=$length of wall.

**CONCLUSION**

The contribution of two different configurations of PET FRP reinforcement to the in-plane shear response of unconfined and confined clay brick walls was experimentally investigated. The test results showed that the peak strength, deformability, energy dissipation capacity and ductility factor of the strengthened specimens were significantly improved, the stiffness was enhanced and the equivalent damping coefficient was stabilized attributed to the strengthening. A simple design equation for diagonally strengthened walls was proposed for future application.

Considering the cases in this paper, the strengthened unconfined masonry wall performed better than the strengthened confined wall, since LW-1 demonstrated higher shear capacity, higher deformation capacity, higher energy dissipation capacity and larger ductility. PET FRP strengthening method was more suitable for unconfined wall. Therefore, applying PET FRP along two vertical edges over the ends of PET sheets placed along two
diagonals was recommended, not only because it was proved to be effective, but also because it was easy to apply and the application can avoid construction flaws like those suspected in the confining columns of LW-2.

Further work still needs to be planned. For example, failure mechanism requires deeper understanding, design equation needs more calibration, and single-side strengthening needs to be investigated as it is often not practicable to apply the reinforcement to both sides.

ABSTRACT

The paper presents the results of numerical analysis of reinforced concrete beams strengthened with pre-tensioned CFRP laminates verified by the experimental results. The aim of the tests was to analyse the effectiveness of the active strengthening in relation to the general passive methods of strengthening RC members in flexure and to show the influence of the loading history before strengthening on the strengthening efficiency. A two-dimensional model based on the nonlinear characteristics of component materials (cracking of concrete, elastic-plastic model of steel reinforcement, bond-slip CFRP-to-concrete model) was proposed in the paper. Numerical simulations performed for the calibrated mechanical model showed a very good agreement with experimental results. Numerical analysis was broadened to include elements of non-strengthened RC members and the strengthened ones with non-pretensioned CFRP laminates as well. The analysis confirmed a suitability of the model to predict a behaviour of RC members strengthened in flexure with the CFRP materials in the whole range of loading.

INTRODUCTION

Flexural strengthening of RC structures with externally bonded (EB) carbon fiber reinforced polymer (CFRP) laminates has been already widely used in engineering practice. However, this technique is effective in the case of slightly preloaded RC members before strengthening. If the structure has been cracked and highly deformed under initial extensive preloading, strengthening with non-pretensioned (passive) composites is not significantly effective. To fulfil this efficiency and to improve the serviceability state (by crack and deflection reduction) application of pretensioned CFRP laminates is recommended. Although preloading is one of the most important parameters to be accounted in the design of strengthening existing RC structures, this problem has been investigated very rarely (Wen-Wei Wang and Guo Li, 2004).

An experimental program consisting of three series of RC beams with variations in the longitudinal steel reinforcement ratio, concrete strength, preloading level before strengthening, and adhesion between the CFRP laminates was performed in Lodz University of Technology. A practical and unique aspect of this program focused on an analysis of the influence of preloading on the strengthening efficiency with pretensioned CFRP laminates. Results of the tests were used for verification of the proposed numerical model. The main aim of this paper is to develop a computational model based on displacement control finite element method using TNO DIANA software and to verify numerical simulations with the experimental results in the whole range of loading.

EXPERIMENTAL TESTS

The experimental program consisted of three series beams (A, B, and C), which contained six 500x220mm RC beams in total. The beams were strengthened under two preloading levels. The lower preloading level was equal the self-weight of the beams only (corresponding to 25% and 14% of the yield strength of non-strengthened beam) in series A and C, respectively (the difference was caused by each series having a different steel reinforcement ratio). The higher preloading level, 76% of the yield strength of the non-strengthened member, was selected to approach the elastic limit of the unstrengthened beam behaviour. To reflect the variability seen in existing structures, the longitudinal reinforcement ratio of the test beams was varied by using two different bar diameters: 12 and 16 mm. Series A and B together included 4 beams reinforced with four 12-mm-diameter bars in tension. Series C contained 2 beams reinforced with four 16-mm-diameter bars. The shear reinforcement consisted of 8-
mm-diameter steel stirrups with a 150-mm spacing. The beams were cast on three different dates with commercially-supplied Class C30/37 concrete. The members were tested in 6-point loading over a 6000 mm simple span (Figure 1). Most of the beams were strengthened with prestressed CFRP laminates of 100 x 1.2 mm ($E_f = 173$ GPa) bonded to the concrete with epoxy adhesive. Two of them were strengthened without any adhesive between the laminates and the concrete; the laminates behaved like an external bowstring attached to the beam only at the anchorage plates. An “a” index in the beam identification indicates the presence of adhesive, while an “e” index indicates the initial external preloading. A summary of all the investigated parameters and main test results are shown in Table 1. More details of the experimental tests were published in Kotynia et al. (2013). The most common failure mode, RC beams strengthened with the CFRP laminates bonded along their entire length (B12-asp, B12-asp-e, B16-asp, B16-asp-e, and B12-a), was an intermediate crack-induced (IC) debonding of the CFRP laminate initiating at one of the middle loading points and extending toward the near support. A secondary failure, occurring after IC debonding, was the CFRP sliding from under the anchorage plate.

**NUMERICAL ANALYSIS**

Finite element model for beams

Numerical analysis of strengthened beams with prestressed CFRP laminates was performed using DIANA finite element code. The specimens were modelled in 2D (plane stress) and the topology of the finite element mesh adopted for calculation is presented in Figure [Error! Reference source not found.]. The finite element mesh of concrete matrix consists of quadrilateral eight-node isoparametric plane stress elements with shape functions described by second order polynomials.

![Figure 2 Finite element model for RC beams; a) mesh topology, b) configuration of steel reinforcement](image)
Maximum dimension of each finite element does not exceed 15 mm. The bottom steel reinforcement was modelled using three-node truss elements connected to the concrete matrix by special interface elements. This type of connection is able to model the relative displacements between the concrete matrix and reinforcing bars in the direction tangential to the reinforcement. In order to model the bond-slip behaviour between the composite laminate and concrete surface six-node interface elements with zero thickness was used.

**Numerical model of loadings and constitutive relationships for materials**

Four loading schemes were considered in numerical calculations. These loading schemes include: the dead weight, shrinkage of concrete, prestressing applied to laminates, external preloading and additional loading in the form of concentrated forces. The loading conditions were applied in sequences that follow the experimental loading program described in the previous section.

The dead weight was modelled as the mass forces applied to each node of finite element mesh. The concentrated load \( F \) was replaced by the local, uniformly distributed load over the width of 0.1 m. The evolution of shrinkage strain \( \varepsilon_{sh}(t) \) was modelled according to Eurocode 2 (2004). The shrinkage strain was added to mechanical strains of concrete in ten calculation steps to reflect the development of this strain in the time period from removing the formworks to performing the experiment. The prestress was modelled as the uniformly distributed load \( \sigma_p \) applied to the ends of CFRP laminate. The value of \( \sigma_p \) was calibrated in such a way that after immediate losses due to slip in the anchors and deformations of the specimen the value of initial strain in laminate \( \varepsilon_{p} \) obtained in calculations was equal to the strain measured in the tests (see Table 1).

The constitutive model for concrete adopted in the current analysis are based on the concept of smeared crack and is formulated in the total strains following the concept proposed in (Vecchio (1989), Vecchio (1990), Maine edit. (2014)). The fixed crack approach was used in this study. Before cracking the stress-strain relationships are evaluated in the directions of principal strains. After cracking the local directions are fixed and the stress-strain relationships are evaluated in the coordinate system determined by the first crack. Additionally, in the direction tangential to the crack the shear stiffness is reduced (Kirchhoff modulus is multiplied by shear retention factor \( \beta \times 1.0 \)). Uniaxial stress-strain relationships for concrete in compression and tension were taken after Feenstra (1993) and Cornelissen et al. (1986), respectively and they are presented in Figure 3a.

The mesh objectivity of the numerical solution was obtained by maintaining the constant fracture energy in tension \( G_f \) and compression \( G_c \) during cracking and crushing process – see Figure 3a. The crack bandwidth \( h \) was taken equal to square root of a finite element area. The main adopted material parameters for concrete are following: \( E_c = 23.7-26.7 \text{ GPa; } \nu_c = 0.2; f_c = 28.7-51.0 \text{ MPa; } f_t = 1.9-4.1 \text{ MPa; } G_f = 90 \text{ N/m; } G_c = 10^8 \text{ N/m;} \) The elastic-plastic with kinematic hardening model was used for the steel reinforcement. The material parameters that describe uniaxial behaviour of steel reinforcement (i.e. elastic modulus, yield stress, tensile strength) are determined from experimental tests by Kotyna et al. (2013).

**a)**

![Figure 3 a) uniaxial constitutive model for concrete](image)

**b)**

![Figure 3 b) traction-slip law between concrete and laminate](image)

In the case of beams strengthened in flexure with CFRP laminates the normal forces between a laminate and concrete are usually small. Due to this fact the physical relationships between tractions and relative displacements in the concrete-laminate interface are uncoupled, i.e. traction \( t_n \) in the normal direction is a function of the relative normal displacement \( \vec{u}_n \) and shear traction \( t_s \) depends only on shear relative displacement \( \vec{u}_s \). In the present analysis the normal traction is the linear function of the relative normal displacement: \( t_n = K_n \vec{u}_n \), where \( K_n \) is the normal stiffness. In the shear direction the bond-slip behaviour is described by the formula \( t_s = g_s(\vec{u}_s) \) according to Lu et al. (2005). For beams strengthened without the adhesion between concrete surface and laminate (specimens B12, B12-e) the nonlinear elastic friction model (Maine edit. (2014)) was used. The relationships...
between the tractions and the relative displacements are described by Coulomb law with two materials parameters – friction coefficient $\mu$ and cohesion $c$. For this simplified model the loading and unloading process follows the same curve. In the current study the following material properties were adopted: $K_e = 0.07\text{GPa/m}$, $\mu = 0.2$, $c = 0.15\text{MPa}$ in the case of beam B12 and $K_e = 0.05\text{GPa/m}$, $\mu = 0.2$, $c = 0.12\text{MPa}$ for element B12-e. The small value of cohesion was assumed in order to stabilize calculations.

An incremental iterative procedure was employed in order to obtain the solution for analysed structures and loading programs. The computational process was controlled by increments of external loads and prestress. For load levels close to the failure load the force controlled procedure was changed to the arc-length method. For each load increment the equilibrium between internal and external forces was calculated using Newton-Raphson procedure. The force and displacement norms were used as convergence criteria.

Test procedure contained several stages, which were precisely reflected in the numerical simulations using a phased analysis. The following phases were taken into consideration: phase I – application of the shrinkage strain to the concrete matrix; activation of concrete and steel elements; phase II – preloading of the active elements with a dead load and external load; phase III – activation of CFRP elements; CFRP pretensioning; phase IV – activation of the first new interface elements; application of the prestressing load at the CFRP ends with gradual force decreasing and transferring of prestressing by the anchors to the beam; phase IVa – deactivation of temporary supports (in the beams with external preloading only); phase V – further loading of the beam until failure.

**Comparison of experiments and numerical results**

The main goal of comparative analysis is a verification of the adopted numerical model. In the analysis all quantities measured during experiments are taken into account, i.e. vertical displacements, mean compressive and tensile strains in concrete averaged at the zone of constant curvature and mean strains of composite averaged at the same zone. Moreover, the analysis includes a comparison with calculated reference beams, i.e. non-strengthened beams and beams strengthened with passive laminates. Comparison of calculated and test load-displacement curves is shown in Figure 4. Proposed model provides the opportunity to analyze the influence of prestressing and preloading levels on the strengthening effectiveness in ULS and SLS.
The experimental and numerical results are in a very good agreement for the whole loading range and all experimental stages. It should be emphasized that numerical model is able to reproduce a reduction of stiffness due to cracking at the first stage of experiment (preloading stage), then reflects the stiffness recovery due to prestressing and finally again decreasing of stiffness as a result of crack development and slips between laminate and concrete. A good accuracy in simulations of the beams behaviour was achieved both for specimens strengthened under dead load and for the beams preloaded up to 76% of the yield strength of the nonstrengthened beam. Figures 5 and 6 present comparison of the test and predicted mean strains in the CFRP laminates and concrete (measured at the distance of 35 mm from the top and bottom surface of the specimens). The predicted CFRP strain is satisfying both for beams with and without adhesive layer between the anchor plates. The model correctly reproduces changes of the CFRP stain gradients due to crack development and the steel yielding. The comparison of numerical and experimental concrete strains (mean at the constant curvature distance, Figure 6) confirms that model is correctly calibrated and it is capable to predict the concrete compressive and tensile strain.

Numerical results verified by experimental ones (Figures 4-6) indicate that the numerical model is valuable for further parametric studies of the RC members strengthened in flexure with pretensioned FRP reinforcement. The

Figure 5 Calculated and test charts of load – CFRP strain

Figure 6 Calculated and test charts of load – concrete strain
prestress losses determined in the test with decrease in the CFRP strain based on the strain gauges, confirmed the predicted ones.

Figure 7 describes the numerical failure mechanism in the laminate-concrete interface. It shows developed debonding process between laminate and concrete surface that initiates from the middle loading point and propagates towards the support. The same failure mode was obtained on the tested beams strengthened with externally bonded CFRP laminates. Thus it can be concluded that failure mechanism observed in experiments is correctly reproduced by numerical simulation.

![Figure 7 Slip between concrete and CFRP laminate: a) specimen B12-a, b) specimen B16-a-e, x parameter is a distance from the support](image)

**SUMMARY AND CONCLUSIONS**

On the basis of a comparative analysis of the test and numerical results the following conclusions can be drawn:

- Flexural strengthening with prestressed CFRP is an efficient technique of strengthening RC members.
- Despite the preload levels in some cases exceeding the serviceability limit states prior to strengthening, the application of prestressed CFRP laminates resulted in a significant reduction of deflections and strains due to subsequently applied loads and led to a recovery of beam stiffness to a non-preloaded value.
- The developed model was used to simulate the experimental RC beams strengthened with pretensioned CFRP laminates. The model is capable to simulate the nonlinear behavior of the constituent materials.
- Comparison of experimental and computational results confirms a good predictive performance of the MES model in terms of the flexural response of RC beams strengthened with pretensioned CFRP laminates over the range covering pre-loading state, strengthening process, up to failure. It is useful for analysis of the crack propagation.
- The proposed FE model successfully predicts enhancing effects in the SLS and ULS and it can be used for parametric studies considering variable investigated parameters: elasticity modulus and cross section of FRP laminates, steel and FRP reinforcement ration, concrete strength, FRP pretensioning levels and preloading levels.

ABSTRACT
The intermediate crack (IC) induced debonding failure in externally bonded FRP-strengthened concrete beams is a main premature failure type. This failure is due to the high interfacial stresses at the locations of shear/flexural cracks. This study presents an experimental program to investigate the behavior of IC debonding failure and bond-slip relation between the FRP plates and concrete in FRP-strengthened beams. A notch was made by saw cut in concrete beam to represent a major flexural/shear crack that triggers IC debonding. To study the sensitivity of the bond-slip behavior to the location of the major flexural/shear crack through the beam span, the notch located at different locations with the beam span in different specimens. In all experimental cases, it was observed that the IC debonding initiated at the mouth of a diagonal crack close to the notch or the flexural/shear crack. The experimental results and the related numerical analysis indicate that the bond behavior of the interface is not sensitive to the location of the major flexural/shear crack.

INTRODUCTION
Intermediate crack (IC) induced debonding failure in reinforced concrete beams strengthened with Fiber Reinforced Polymer (FRP) composite materials starts at the mouth of flexural/shear cracks within the shear span and propagates towards the FRP plate termination. One of the common methods to determine the FRP/concrete bond behavior is the single shear pullout test (e.g., Chajes et al. 1996, Taljsten 1997, Leung and Tung 2006, Mazzotti et al. 2008, Mohammadi and Wan 2015). In this method, the in-plane shear stress is applied to the FRP/concrete interface by applying a uniaxial tension load in the plane of the FRP, typically in the strong or longitudinal direction of the FRP fiber orientation. The tensile strain gradient in the FRP (representing the shear strain along the interface) is recorded and is used to determine the bond-slip relation. The obtained bond-slip relation is often used for nonlinear fracture mechanics or cohesive crack models in numerical analyses to predict FRP debonding from the concrete substrate.

IC debonding failure in FRP-strengthened RC beams is due to the development of high interfacial stresses at locations of flexure/shear cracks in concrete. Since the FRP/concrete interface in strengthened beams is subjected to both flexural and shear loadings, the use of pull-out test results, in which the interface is subjected to pure shear stress, to predict the behavior of FRP-strengthened concrete beams may not represent the in situ phenomenon. Therefore, some studies have used beam tests to study the debonding behavior in FRP-strengthened RC beams (e.g., Fukuzawa et al. 1997, Benjeddou et al. 2007, Gartner et al. 2011). In this study, the beam test was used to investigate the IC debonding failure mechanisms using notched FRP-strengthened concrete beams. In order to simulate the major flexural/shear crack that triggers IC debonding failure, a half-depth notch was cut in the beam specimen. To investigate the sensitivity of the bond-slip behavior to the location of the major flexural/shear crack, the notch position in specimens varied from the midspan to the FRP plate end.
EXPERIMENTAL PROGRAM

The 28-day compressive strength of the concrete in the beam specimens was 30.4 MPa. The tensile strength of the beam specimens was determined from split cylinder tests to be 3.2 MPa. The preformed CFRP laminate strip used for strengthening was 51 mm wide and 1.5 mm thick. The manufacturer reported tensile modulus, ultimate tensile strength, and Poisson’s ratio were 155 GPa, 2800 MPa, and 0.25, respectively. The epoxy adhesive for bonding CFRP plate to concrete was approximately 1 mm thick. Its manufacturer reported tensile modulus, ultimate tensile strength, and Poisson’s ratio were 4.48 GPa, 24.8 MPa, 0.3, respectively.

Three CFRP-strengthened beams without notch were used as control specimens to investigate the behavior of the strengthened beams without cracks. Six FRP-strengthened beam specimens with a half-height notch at mid-span, as shown in Figure 1a, were tested to observe the IC debonding failure when the major flexural crack is at the mid-span of the beam. In order to investigate the sensitivity of the bond-slip behavior to the location of the major flexural/shear crack, the notch position in specimens was moved forward to the FRP plate end every 51 mm from the mid-span to the support (Figure 1b). Three specimens were tested for each position of the notch. The width of the notch was 5 mm and its height was half of the beam height (76 mm).

The test was conducted under displacement control. During the test, the applied load, the axial strains in FRP plate at different locations along the FRP plate, and the vertical deflection at the top of the notch were recorded. In the following, the experimental observations for each group of specimens are described in detail.

RESULTS AND DISCUSSIONS

Control Specimens CC-1, CC-2, and CC-3

The specimens CC-1, CC-2, and CC-3 were CFRP-strengthened beams without notch. Failure types of all three specimens were IC debonding failure and the failure processes included:

- A major vertical flexural crack initiated very close to the mid-span of the concrete beam (Figure 2a);
- A diagonal flexural/shear crack started close to the first flexural crack, about 25 to 40 mm from the first one (Figure 2b);
- FRP debonding along the FRP/concrete interface initiated at the mouth of the diagonal crack and propagated toward the support (Figure 2c);
- Sudden and essentially instantaneous failure steps included: the diagonal crack merging with the major flexural crack, the merged crack propagating to the loading point, and FRP debonding continuing to the end of the FRP plate (Figure 2d).
Specimens CMC0-1 to CMC0-6 were the strengthened beams with notch at the mid-span. The IC debonding failure processes in this group of specimens include:

- Flexural cracking initiated at the top of the notch (Figure 3a);
- A diagonal flexural/shear crack started close to the notch, about 25 mm from the notch (Figure 3b) at one or other side of the notch, or occasionally both sides;
- FRP debonding along the FRP/concrete interface initiated at the mouth of the diagonal crack and propagated toward the support (Figure 3c);
- Sudden and essentially instantaneous failure steps included: the diagonal crack merging with the notch, the crack at the top of the notch propagating to the loading point, and FRP debonding continuing to the end of the FRP plate (Figure 3d).

In all specimens, there was a wedge of concrete attached to the FRP plate (Figure 3d) that shows diagonal cracking inside the concrete. In all cases, the debonding cracking started at the mouth of the diagonal crack to either side of the notch.

By comparing Figures 2 and 3, it can be seen that the failure processes are compatible. The strengthened beams with notch at midspan followed the debonding behavior of the un-notched beams. Figure 4 compares the load vs. mid-span displacement curves for the control specimens (CC series) and those with notch at midspan (CMC0 series). Specimens CMC0 are shown by dashed lines and specimens CC are shown by solid lines. As it can be seen, specimens CC behaved stiffer before the mid-span cracking and then behaved like the specimens CMC0. It is reasonable because specimens CC did not have a notch. Once the mid-span crack initiated in the specimens CC, their behavior became very close to those of specimens CMC0, where a notch was cut at the mid-span. Therefore, specimens CMC0 could simulate the real behavior of the FRP-strengthened concrete beams (specimens CC) in their ultimate stage. This verifies the original idea to evaluate the FRP/concrete bond in real beams when this type of specimen was designed by Harries et al. (2012).
(a) Vertical flexural crack  
(b) Diagonal crack 

(c) FRP bonding initiation  
(d) Final failure 
Figure 3 IC debonding failure processes of beam CMC0-5

In order to study the sensitivity of IC debonding failure to the location of the major flexural/shear crack, the notch location was moved away from the mid-span in intervals of 51 mm. In the specimens CMC2 and CMC4 series (notches at 51 and 102 mm away from the mid-span, respectively), a vertical flexural crack formed at the location close to the mid-span at first and then the failure processes were the same as the mid-span notched beams (Figures 5a and 5b). It means that the notch triggered the IC debonding. However, in specimens CMC6 (notch at 153 mm away from the mid-span), the debonding started close to the flexural crack at the mid-span and propagated in the side without the notch (Figure 5c).

It is worth to mention that the concrete wedge attached to the FRP plate was seen in all specimens due to the diagonal crack that formed close to the major flexural/shear crack or the notch. The comparison of debonding processes of specimens CMC6 and CMC0 shows that the FRP debonding in both groups of specimens followed the same behavior. Therefore, the specimens with the notch 153 mm away from the mid-span essentially behaved exactly as the specimens without any notch.

The average and the coefficient of variation (COV) of the maximum applied loads of each group of the specimens are presented in Table 1. The maximum loads of CC, CMC0 and CMC6 are almost the same. Also the failure processes of these specimens (CC, CMC0, and CMC6) followed the same behavior as described before. The FRP debonding failure of CMC6 initiated at the mouth of the diagonal crack close to the mid-span flexural crack as the specimens CC and CMC0.

The maximum loads of CMC2 and CMC4 are slightly higher (about 1.7 and 5.4% higher than that of CMC0, respectively) and CMC4 has a maximum load 3.6% larger than that of CMC2. It seems that as the major flexural/shear crack was moved away from the mid-span, but not too far (less than 153 mm in this test), the maximum flexural loading capacity increased slightly. Of course, the numbers of specimens in each group are too small to make an accurate conclusion.

**FINITE ELEMENT ANALYSIS**

The commercial software ABAQUS/standard 6.13 was used for the finite element (FE) analysis. The plane stress 4-node bilinear 2D elements (CPS4R) were used to model all materials. The behavior of the FRP and the epoxy
were simulated using a brittle cracking model. The concrete was modeled using cohesive method in extended finite element method (XFEM). The XFEM-based cohesive method uses the traction-separation law to model crack initiation and propagation along an arbitrary, solution-dependent, path since crack propagation is not tied to the element boundaries in a mesh. In the FE analysis in this study, the crack initiation criterion was the maximum principal stress criterion, in which a crack was initiated if the maximum principal tensile stress reached the tensile strength of the concrete, \( f_t \). The crack propagated perpendicular to the direction of the maximum principal tensile stress. The evolution of the crack was governed by the mode I fracture energy of concrete, \( G_F \), which represents the assumed linear tension-softening behavior of the concrete during cracking. The detail of the FE analysis can be found in Mohammadi (2014).

The numerical analysis shows that the element at the mouth of the notch is not under pure shear stress and this is the reason for the formation of the diagonal crack (Mohammadi 2014). However, the FRP/concrete interface at the mouth of the diagonal crack is subjected to pure shear stress after the initiation of the diagonal crack regardless of the location of the major flexural/shear crack. Therefore, the bond-slip behavior of the FRP/concrete interface is not sensitive to the location of the major crack.

CONCLUSIONS

Through the experimental program, it was found that the FRP debonding in IC debonding failure in FRP-strengthened beam initiates at the mouth of a diagonal crack close (about 25mm in this study) to the major flexural/shear crack. The IC debonding failure is triggered by the major flexural/shear crack in the zone with large moment/shear ratio in a FRP-strengthened concrete beam. The load capacity of the beam increased slightly when the major flexural/shear crack was moved 51 and 102 mm away from the mid-span. However, the beam with notch 153 mm away from the midspan had similar load capacity as those without notch or with notch at the midspan. The finite element analysis shows that the bond-slip behavior of the FRP/concrete interface is not sensitive to the location of the major crack.

ABSTRACT

Use of carbon fiber reinforced polymer (CFRP) systems for strengthening concrete structures has grown considerably in recent years in Russia. The effect of preload and crack repairing factors on the debonding behavior of CFRP-strengthened reinforced concrete (CR) beams was studied in the Laboratory at Perm National Research Polytechnic University. A number of bending tests were performed to study the behavior of 22 medium-scale beams 1.27 m long having a cross section of 12 x 22 cm. Infrared thermography (IRT) was used to detect early signs of debonding. The following interesting results were obtained. Strengthening of RC beams with CFRP carried out both before and under loading provides a substantial increase in their bearing capacity. The process of CFRP debonding in the beams reinforced under loading after the appearance of first cracks and their grouting begins at strain by 4-65% lower than that of the beams reinforced before loading, and the relative area of debonding increases by 2.1-2.3 times. Grouting of cracks in beams under loading allows one to increase the limiting value of a bending moment by 45-71% compared to unreinforced beams. The CFRP debonding strain is weakly dependent on the strength of the concrete substrate. For the beams strengthened with CFRP with transverse wrapping anchorage in support sections, the FRP debonding is not in itself a failure mode.

INTRODUCTION

Various types of fibrous, woven-fabric, composite materials are widely used for structural repair and strengthening of concrete structures (Teng 2001, Teng and Chen et al. 2003). One of the common strengthening techniques is based on gluing the composite material to the concrete surface in the area on which tensile strains act. The efficiency of repair and reinforcement methods is associated with the interaction of strengthening elements with concrete surface. Some works (e.g. Zhang et al. 2006; Parikh et al. 2012; Al-Salloum) present the results of studies investigating the influence of the degree of preloading on the strength and stiffness of reinforced beams. In the present work, using the experimental data, we examine how much the interaction of composite material with concrete surface would depend on the instant of strengthening – before loading or during loading after first cracks start. We find that debonding between two materials is an important stage in the load-deformation behavior of the system “composite material-concrete”. Application of a new method that is based on infrared thermography technique allows us to successfully register debonding.

TEST PROGRAM AND PROCEDURE

Our experiments were carried out with two groups of reinforced concrete beams (B20 and B40). The scheme of a sample strengthened with steel reinforcement rods and CFRP layer is shown in Figure 1. Each of the groups was divided into 3 series with 3-5 samples: series A – control samples without CFRP layer; series B – beams reinforced prior to loading with CFRP sheet SikaWrap-230 (6 cm wide) attached to the beam with transverse wrapping anchorage by CFRP straps 20 cm wide in two support sections of the beam; series C - beams reinforced (during loading) with CFRP sheet after the appearance of first cracks and their epoxy injection repair. The basic test setup
for the four-point bending test is shown in Fig. 2a. Strain gauges were installed on steel reinforcement rods, the carbon-fiber sheet and the surface of all beams to control deformations along the beam axes.

The beams were loaded in a stepwise fashion; every loading step of 2 kN accounts for 4-6% of the fracture load. During each loading step the samples were “aged” for 5-10 minutes, which made it possible to register the crack pattern and the crack opening width. Simultaneously, they were heated and thermal pictures of the beam surface covered with a carbon fiber sheet were taken with a FLIR T620 infrared camera (e.g. Valluzzi et al. 2009; Shirazi and Karbhar 2007; Taillade et al.). Shooting parameters (power and time of heating, time of observation) were determined in advance by analyzing the numerical solution of the nonstationary heat conduction problem for the system “carbon fiber sheet – epoxy resin – concrete – debonding – concrete” (Bykov et al. 2016). The analysis shows that the best conditions for registration of debondings are achieved at the stage of beam cooling at 19th second after the start of observations (heating time 10 sec, cooling time 9 sec, heating power 932 Bt/m²). Shots were taken “through the mirror”, which ensured the safety of people and equipment at loads close to the destruction of the beam (Figure 2b).

Thermography images of the surface of the beam reinforced with the carbon fiber sheet were obtained at each loading step. The initial thermogram for each j-th step (Fig. 3a) is a two-dimensional array of differential temperature values $T_j(x, y)$ determined during the 19th and 0th seconds at points with coordinates $(x, y)$. The index $j \in [0, N]$ specifies the number of loading step; loading is absent at $j = 0$. The obtained initial thermograms were processed using an algorithm specifically designed using Matlab programs.
In the first step of the algorithm, we calculate the normalized thermograms $TN_j(x, y)$:

$$TN_j(x, y) = T_j(x, y) \frac{T_0(x', y')}{T_j(x', y')}$$

(1)

where $T_j(x, y)$ is the initial temperature difference at the $j$-th loading step at the point $(x, y)$, $T_0(x', y')$ and $T_j(x', y')$ are the initial temperature differences at the 0-th and $j$-th loading steps at the point $x', y'$ where no debonding is known to be present. Normalized thermograms for successive loading steps are given in Fig. 3b.

Next the temperature contrast $C_j(x, y)$ (Figure 3c) is determined:

$$C_j(x, y) = \frac{TN_j(x, y) - T_0(x, y)}{T_0(x, y)} \times 100\%$$

(2)

In order to make a decision on the existence of debonding at the point with the coordinates $(x, y)$, we calculate a threshold value for the temperature contrast $C^*$. For making it estimate, we determine, at each loading step, the average value $\overline{C_j}$ and the standard deviation $\sigma_j$ in those areas of the thermograms, where debonding is known to be absent. The threshold value is calculated by the formula $C^* = \overline{C_j} + 3\sigma_j$. The areas of the CRFP layer surface, where the temperature contrast value exceeds the threshold value are identified as the areas with debonding and the remaining ones as the areas free of defect. In the binary defect map shown in Fig. 3d, the defect-free areas are shown in white color and the areas of debonding in black color.

**RESULTS AND DISCUSSIONS**

The averaged data of the static test results for the beams of series A and B are summarized in Table 1, where $M_{crc}$ is the bending moment corresponding to the onset of cracking, $a_{crc}$ is the maximum crack opening width, $f_{el}$ is the elastic deflection, $M_{ult}$ is the maximum bending moment, $f_{ult}$ is the maximum deflection, $\varepsilon_{f,ult}$ is the strain of the carbon-fiber sheet at rupture. The beams of series C were tested by loading in two stages: 1) loading of unstrengthened beams until the occurrence of first visible cracks, 2) further loading of beams after the repair actions on the loaded beam. During the restoration procedure, the low-viscous epoxy material was injected into the cracks formed on the stretched surface of the beam. Then the beam was strengthened with a CFRP layer stuck to its surface with epoxy adhesive. Our experiments indicate that the debonding develops according to the cohesive scenario, i.e. the carbon fiber sheet separates together with concrete fragments. Adhesive debonding was observed in the samples, whose surface was not prepared properly before the strengthening strip was stuck.

The average bending moment – deflection curves for each of the three series of tests are shown in Figure 4. A comparison of these results shows that the reinforcement of beams with carbon fiber layer significantly improves the bearing capacity of beams. For the beams of series B and C, the maximum bending moment (a cross mark in the figure) turned out to be higher by 37-39% ($\delta M_{ult}$) and 38-49% ($\delta M_{ult}$), respectively, than that of the non-reinforced reference beams of series A. Inspection of the graphs for beams without preliminary reinforcement (series A and C) shows that the stiffness of beams at loading steps followed by the occurrence of first cracks in concrete (the areas enclosed in a circle) reduces sharply. In the beams preliminary strengthened with a carbon fiber sheet (series B), this process is partially compensated by the strengthening layer. Curve 3 clearly demonstrates the efficiency of the repair actions carried out on the loaded beam. Injection of the cracks appeared at the first loading step allows one to restore the stiffness of beams to nearly the initial state (the area enclosed by a dashed circle). Under further loading, the deformation behavior remains the same as that for the preliminary reinforced beam (curve 2). Failure in reinforced beams (series B and C) is associated with rupture of the carbon fiber layer. Our investigations indicate that the restoring procedure for loaded beams enables one to increase the value of the bending moment corresponding to the onset of secondary crack generation by 45-71% in comparison with the unreinforced beams.

![Figure 4 Bending moment-Deflection relationships: 1 –series A, 2 –series B, 3 – series C](image)

A point corresponding to the onset of cohesive debonding of carbon fiber is marked on curves 2 and 3 by a triangle. On average, the beginning of debonding corresponds to the bending moment equal to 75% of the limit value. On debonding, the beam continues to perceive the load, yet no reduction in the beam stiffness takes place. From the onset of carbon fiber layer debonding and up to the total loss of the bearing capacity, the beam has significant strength reserve ($\delta M_{ult}$, $\delta M_{ult}$). Therefore, the debonding of the CFRP layer cannot be considered to be the limit state of a beam. In the beams reinforced during loading after the appearance of first cracks and their injection, the debonding of the carbon fiber layer took place at its deformation less on average by about 25% than that of the beams reinforced in the absence of load (Table 3).

The thermogram transformation algorithm proposed in this study can be used to compute the percentage of debonding areas in different samples (Table 4). The relative area of debonding in the beams reinforced under loading (after initiation of first cracks and their injection) is on average 2.1-2.3 times greater than in the beams reinforced in the absence of loading.

A comparison of the experimental strain values associated with the onset of cohesive debonding of CFRP with the theoretical results obtained by 5 commonly used methods demonstrates their low reliability (Figure 5). For instance, the values computed in compliance with Russia standards for designing reinforced concrete structure [2] exceed the experimentally registered values by 15-75% for different classes of concrete. As for the tendency for an increase in relative debonding strain with concrete strength specified in these methods, no evidence supporting it has been found in our experimental studies.

![Figure 5 Comparison of experimental and theoretical values of cohesive debonding strain: 1 – CNR-DT 200/2004; 2 – ACI 400.2R-08; 3 – Lu et al. 2007, 4 – SP 164.1325800.2014; 5 – Teng and Smith et al. 2003](image)

Our experimental studies have revealed the inconsistency between the results obtained for different series: in series B (Fig.5, circle markers), debonding in the samples of concrete class 25 is realized at CFRP strain higher by 16-19% than that of the samples of concrete class 40; in series C (Fig.5, square markers) debonding in the samples of concrete class 25 is realized at a CFRP strain lower by 10-34% than that of the samples of concrete class 40.

**CONCLUSIONS**

1. Our experimental studies have revealed the inconsistency between the results obtained for different series: in series B (Fig.5, circle markers), debonding in the samples of concrete class 25 is realized at CFRP strain
higher by 16-19% than that of the samples of concrete class 40; in series C (Fig.5, square markers) debonding in the samples of concrete class 25 is realized at a CFRP strain lower by 10-34% than that of the samples of concrete class 40.

2. It has been established that the process of CFRP debonding in the beams reinforced under loading after the appearance of first cracks and their grouting begins at strain by 4-65% lower than that of the beams reinforced before loading, and the relative area of debonding increases by 2.1-2.3 times.

3. It has been found that the onset of debonding of the CFRP corresponds to the bending moment, which is 75% of the limit value. Therefore, the debonding does not imply the onset of failure (a limit state of) CFRP beams with transverse wrapping anchorage in support sections. This makes it possible to use the composite breaking strain as a limit state of such a beam (according to the first basic group of limit states).

ABSTRACT

Premature debonding is often observed when strengthening the existing RC structures using externally bonded fibre-reinforced polymer (FRP) sheet. Anchorage system has been proved to efficiently prevent or postpone the debonding from occurring. Although extensive research on the effect of anchorage system on intermediate crack (IC) debonding and end debonding has been carried out, the relevant research on its effect on commonly faced concrete cover separation is still in its initial stage. This paper designed seven beam-type cantilever specimens with different width and height of U-shape end anchorage to investigate its effect on concrete cover (cantilever) separation. The fully separation of cantilever was identified through the knee point of load-strain curves of CFRP laminate at the cracked section. The height of U-anchorage was proved to be more efficient than its width to improve the strength of cantilever separation, while greater width of U-anchorage more efficiently prevented the initiation of intermediate crack induced (IC) debonding of CFRP laminate.

INTRODUCTION

Strengthening by fibre-reinforced polymer (FRP) composites is an effective and convenient method to improve the static and fatigue performance of reinforced concrete (RC) structures. Previous studies (Buyukozturk et al. 2004) have shown that the application of FRP composites to strengthen RC structures can lead to premature debonding failures before the design load is reached. Among the premature debonding failure modes (Smith and Teng 2002), concrete cover separation is often observed. Current models to explain the concrete cover separation of a strengthened beam fall into three broad basis (Zhang et al. 2011, 2012 a, b): (1) the derivation of elastic stress concentrations at the FRP end (2) the shear capacity of strengthened beams and (3) the concrete tooth model.

Existing studies on steel plate or FRP laminate strengthening have proved that the application of anchorage systems is effective to resist the onset and propagation of failure in the external reinforcement-concrete interface or concrete cover to the internal rebar. The most commonly used anchorage types are (Kalfat et al. 2011): 1. Mechanically fastened metallic anchors, 2. U anchors and 3. FRP anchors. Nowadays there have been many studies on the FRP U-anchorage (Khan and Ayub 2011; Jumaat and Alam 2010; Li et al. 2013). Previous research (Smith and Teng 2003) showed that the critical debonding failure mode could be shifted from concrete cover separation to IC debonding with the addition of plate-end U anchorage, further research (Sawada et al. 2003) explained that CFRP U-anchorage resisted the stresses that resulted in cover separation failure.

Most of the previous experimental studies were carried out on the strengthened RC beams with various anchorage systems. The location of cracks which formed the concrete teeth were not pre-determined and thus the effect of geometry of concrete teeth remained unclear and measurement of FRP strain exact at the cracked section through strain gage was difficult. Therefore, a clear and comprehensive understanding of mechanism of U-anchorage and the effect of its designing parameter has not been reached yet.

The authors are conducting a series of studies with the aim at development of an analytical approach for flexural strengthening of an existing structure with external FRP composites with various anchorage systems. The present work concentrates specifically on the use of end U-shape anchorage system and its influence on the mechanism of...
EXPERIMENT PROGRAM

Testing specimens

Seven specimens with different width and height of U-shape end anchorage were prepared. Specimens’ geometry and reinforcement arrangement are shown in Figure 11. The test specimens were 1500 mm long with a rectangular cross section of $150 \times 200$ mm. All specimens had a clear span of 1300 mm, and employed two deformed bars of diameter 10 mm as respective compression and tension reinforcement. 8 mm diameter steel stirrups spaced at 100 mm were placed along the entire length of the beam and the concrete cover thickness at tension and compression side was 46 and 21 mm, respectively, and the side concrete cover was 22. The former value was larger to force the concrete cover separation to initiate. The cantilever sections formed between two adjacent 10 mm wide artificial cracks were 100 mm in length, 150 mm in width and 55 mm in height. The specimens were symmetrical about centre line.

As shown in Table 1, the specimens were divided into three groups by the width of U anchorage, namely, L50 group, L100 group, and control group. The specimens of L50 group were denoted as L50-60, L50-80 and L50-180, and those of group L100 were labelled L100-60, L100-80 and L100-180. The first number appearing after L represents the width of U anchorage ($b_{uf}$) and the following number indicates the height ($L$) as shown in Figure 11. Specimen L0-0 was a non-anchorage control beam.

Materials

The average compressive strength ($f_{cu}$) of three 150 mm concrete cubes was 26.42 MPa after 28 days of curing. Table 4 shows the mechanical properties of tension and shear reinforcement, where $D$, $E$, $f_y$, $f_u$ denote the unit diameter, the modulus of elasticity, yielding strength and ultimate strength, respectively.

One layer of CFRP consisted of unidirectional textile with a width of 130 mm, length of 900 mm and a dry fibre thickness of 0.111 mm. The elastic modulus and tensile strength of the CFRP laminate was 241 GPa and 3696
MPa, respectively. Adhesive used was a thixotropic epoxy resin with elastic modulus and tensile strength being equal to 2.83 GPa and 52 MPa, respectively.

The following procedure was adopted for specimen preparation. Artificial cracks of 10 mm wide and of height up to the centroid of tension reinforcement was made by four wood plates at casting to form cantilever sections at both sides of specimens. Special attention was paid to make sure one stirrup existing above the centre of cantilever session. All specimens were extracted from the moulds 24 hrs after casting and then cured for 28 days. Three layers of CFRP laminates were then bonded to the soffit of the specimens in a wet-layup procedure after sandblasting, brushing and cleaning of the concrete surface, which was to guarantee an ideal bond between the CFRP and the concrete. Two layers of CFRP U-anchorage were then bonded to the cantilever session in a similar procedure. As indicated in Figure 1, 70mm and 100mm wide CFRP full wrapping was used to prevent fully development of intermediate crack-induced interfacial (IC) debonding before the failure of cantilever. All the specimens were then placed in room environment for seven day for the adhesive curing before testing.

Testing apparatus

The strengthened beam was firstly given a four-point monotonic loading with a shear span of 500mm as indicated in Figure 1. Several strain gages were glued to CFRP laminate (Figure 12) to measure the strain distribution. The deflection was measured by means of LVDTs placed at loading points and supports of the specimens, respectively. Specimens were tested monotonically to failure by a load controlled hydraulic jack at a constant loading rate of 2 kN/min.

Though the parameters of two “teeth” (left and right cantilever) in the same specimen are the same, they may not always fail together due to the scatter. In this case, when the cantilever failed in one side first, the support close to the failed cantilever was moved towards the beam centre and a three-point bending test was conducted as shown in Figure 13 until the failure of cantilever in another side. The locations of LVDTs at two loading points were changed correspondingly.

RESULTS AND DISCUSSIONS

Failure mode

The typical crack distribution of some specimens was recorded as shown in Figure 14.

Two kinds of failure modes, failure of cantilever (concrete cover separation) and flexural failure of beam without cantilever failure were observed for all the specimens. As the load increased, the diagonal shear crack occurred from the top of artificial crack which was nearer to the support, and then horizontal crack appeared and propagated along the level of the steel reinforcement (top line of the cantilever). For control specimen, the cantilever failed in a brittle manner soon after the initiation of horizontal crack, while the load can still increase till the flexure failure of beam. For specimens with U-anchorage height less than 180 mm, the U-anchorage debonded followed by fully separation of cantilever. Instead, for specimens L50-180 and L100-180, neither debonding of U anchorage nor the failure of cantilever was observed, the specimens finally failed in flexure with concrete crushing after the yielding.
of tension reinforcement. As indicated in Figure 4, diagonal crack (No. ③) of concrete cantilever was observed for both L50-180 and 100-180 due to the tensile stress generated by the pull-off force of CFRP laminate.

![Figure 14 Typical cracks distribution (unit: kN)](image)

**Load-strain response (CFRP)**

In order to clarify the failure mechanism of beam-type cantilever with different size of U anchorage, the typical load-strain relationship of CFRP laminate at the cracked section of some specimens is plotted in Figure 15.

As the load increased, the CFRP strain increased linearly followed by some sudden drops which may attribute to the initiation of cracks, cantilever separation or U anchorage debonding. The CFRP strain at the knee point reached the maximum in case of cantilever’s full separation, while the knee point could be surpassed in other possible cases. This knee point was regarded as the judgement of fully separation status of cantilever for all the specimens except specimens L50-180 and L100-180, for which no debonding of U-anchorage and separation of cantilever occurred, and therefore no rapid reduction in CFRP strain was recorded (Figure 5).

![Figure 15 Load-CFRP’s strain correlation curve](image)

**Debonding load**

Both four-point and three-point bending test were conducted for all specimens except L50-80 and L100-180. The corresponding failed cantilever sections and debonding load deduced from load strain curve are listed in Table 5. \( P_{exp} \) represents the average debonding load of four-point and three-point test results. Note that based on the study of Zhang et al. (2011), the load corresponding the concrete cover separation depended upon the distance between the support and the end of CFRP laminate (or location of cantilever in this study), therefore the cantilever failure load (or the moment at the cracked section of cantilever) was considered the same for both A and B side although the shear span was a bit different.

Note: The value with "*" means ultimate load without cantilever failure.

Figure 16 shows the comparison of debonding load between different specimens. For specimens L50-180 and L100-180, the values represent the ultimate load. For the same height of anchorage, the increase in anchorage width did not increase the debonding load. Actually it was even smaller for anchorage width of 100mm when anchorage height was 60mm. When the anchorage width was 50mm, the debonding load decreased with the increase of anchorage height, while opposite tendency was observed for specimens with anchorage width of 100mm. The debonding load had no clear relationship with the width and height of U-anchorage for those specimens failed in cantilever separation, maybe due to scatter of the test results or insufficient number of test specimens. However, both 50 mm and 100mm wide but 180mm high anchorages can efficiently prevent premature cantilever failure and increase the ultimate load. More tests are expected to be conducted with more options of height of U-anchorage to investigate clearly the effect of U-anchorage after the initiation of cantilever separation.

![Comparison of debonding load](image)

Figure 16 Comparison of debonding load

Mechanism of anchorage

As shown in Figure 7, each concrete tooth acted as a cantilever and the concrete cover separation corresponded to the failure of this cantilever. The load $\sigma_f$ exerted by the longitudinal CFRP is limited by the following factors: (1) the flexural strength of plain concrete: cantilever separates when the concrete tensile stress generates at point A for the section of top end of cantilever reaches the flexural strength. (2) The effect of U-anchorage: the U-anchorage acts as a reinforcement. When the U-anchorage was applied, it prevents the separation from further propagating once it is initiated while the diagonal shear cracks passing through U-anchorage affects the bond strength of U-anchorage and concrete. And the debonding load of anchorage is the maximum “pull out force” at the cantilever section. If this force is larger than the concrete tensile stress generates at point A, the U-anchorage debonds after the initiation of cantilever separation, else the U-anchorage debonds first. With small height of U-
anchorage, the anchorage effect keeps the same since the anchorage debonds right after cantilever separation. Instead, if the height of the anchorage is sufficient, the anchorage strips will not debond and effectively prevent the progress of the cantilever separation. As for different width of U-anchorage with same anchorage height, if the U-anchorage covers the concrete tensile zone, the width of U-anchorage has no obvious difference on the mechanics. Due to the page limitation, the detailed analytical model for prediction of cantilever separation together with Finite Element simulation and experimental verification are not presented here.

CONCLUSIONS

The behaviors of CFRP laminates strengthened beam-type cantilever with or without U-shape CFRP anchorages were experimentally investigated. Several conclusions can be made based on the test results:

1. The load at the fully separation of cantilever can be determined by the key point in the load-strain response curves of CFRP laminate at the end cracked section of the cantilevers.
2. When the height of U anchorage is small, the anchorage debonded before the initiation of concrete cover separation; and the peak load with concrete cover separation kept unchanged. The width of U anchorage had little effect on the concrete cover separation, but greater width of U anchorage can more efficiently prevent the initiation of IC debonding.
3. With sufficient height of U-anchorage, cantilever separation can be prevented, and the peak load was improved.

ABSTRACT

CFRP (Carbon fibre reinforced polymers) systems have been used to strengthen concrete structures during several decades. Especially CFRP plates and rods are used successfully to upgrade existing concrete structures to a required capacity level. Although most of the systems work quite well, several challenges still exist, since the systems show little ductility and the failure modes normally occur through initiation of cracks in the concrete (such as intermediate crack de-bonding). As a consequence the CFRP material is not utilized fully and failure occurs suddenly without sufficient warning. Consequently the de-bonding leaves the concrete beam with a capacity which is of the same magnitude as before strengthening was conducted. This paper presents a strengthening system which improves the utilization of Ø8 and Ø10 CFRP circular rods, increases the ductility by means of a ductile anchorage system and at the same time ensures the required strengthening effect. The initial result shows ductility equal to or larger than the reference T-section beam. The strengthening effect is up to 107%. Extensive research, at the Technical University of Denmark, is ongoing at present time to further verify the results through testing and applied theory.

CFRP, RC beams, strengthening, ductility, anchorage.

INTRODUCTION

Strengthening of RC (Reinforced concrete) beams using NSMR (Near surface mounted reinforcement) CFRP (Carbon fibre reinforced polymer) strengthening has been used extensively during the recent years (Mohamed et al. 2008, Rashid et al. 2008, El-Harcha and Rizkalla 2004, Serancino et al. 2007), typically resulting in a significant strengthening effect of the RC structure. However, besides of a susceptibility to fire a major disadvantage related to these strengthening systems is the brittle failure mode and resulting lack of ductility. These failure modes normally initiate as IC (Intermediate crack) de-bonding, (Triantafillou and Antonoplos 2000, Smith 2007, Teng 2003 and Said and Wu 2008), end peeling (Täljsten 1997), concrete cover separation (Gao 2005 et al., Cordon et al. 2008) and sometimes delamination of the fibre material (Cuntze et al. 2004, Schmidt et al., 2012). Investigating these failure modes show that it seems difficult to utilize the full tension capacity of the CFRP material and that the failure is, in addition to this, very dependent on the concrete strength.

Consequently, several efforts to investigate anchoring of the CFRP strengthening system have been going on during the last decade, especially in the field of CFRP plate strengthening, where increased strengthening effects is seen along with an amplified ductility. It is generally accepted that FRP anchoring provides increased efficiency of FRP systems (Smith et al. 2011, Kalfat et al. 2013 and Hansen et al. 2011). However the documentation is still based on limited test results and different test procedures (Kalfat et al. 2013). Anchorage of plates have been used with CFRP dowel anchorages (Smith et al. 2011). This research showed the effect on strength and ductility when placing CFRP dowels in different configurations along the CFRP plate. It showed also that the mid span deflection during loading was significantly affected by the location of the dowels. However it was generally observed that the ductility and strength was increased where the CFRP plate failed in IC de-bonding and shear failure of the CFRP dowel anchors. Also anchoring using steel anchors of multi directional CFRPs is used (Brunckhorst et al. 2007) and patch anchors were seen to increase the ultimate failure load by 39-43% (Kalfat et al. 2013).

The plated systems are relatively easy to anchor in different ways using dowels, concrete steel anchors and nails (Yun et al. 2008), but only limited research have been conducted on anchoring of circular CFRP NSMR systems. The anchoring of such rods often relates to the field of anchorage of tendons for pre- and post-tensioning but these
are also expected to be very efficient for NSMR strengthening. Anchorage of circular CFRP rods remains a challenge, as premature failure modes can occur and cumbersome installation seems to be a common problem (Schmidt et al 2011) compared to conventional methods used for steel rods or cables.

Research at DTU in the field of CFRP anchorage of circular rods during recent years has established an important step towards designing an easy to mount anchorage for CFRP rods (Schmidt et al 2010, 2011). This research has mainly focused on the development of anchorage mechanisms, which utilize the full capacity of the CFRP rods (and plates), but has by now reached the next stage, where the focus is to create an increased ductility of the system, when applied to the RC structures.

The research presented in this paper shows the initial step of this research, where a specially developed ductile end anchorage for 8mm and 10mm circular CFRP rods is applied to T-section RC beams to establish a significantly increased anchoring effect and ductility. The ductile end anchorage system is expected to lead to a more controlled ductile deformation and force transfer, where a contribution from aggregate interlocking from intermediate crack debonding (IC-debonding) can be incorporated.

**EXPERIMENTAL PROGRAM**

The NSMR CFRP circular rod strengthening system was mounted on a T-section RC beam with a total height of 350mm, a flange width of 300mm and a length of 2200mm, Figure 1. 2Ø16 deformed steel bars were used as tension reinforcement and 2Ø8 was placed in the compression zone. Ø8 deformed steel bars was used as shear stirrup reinforcement and placed with a distance of 200mm. The concrete tested according to DS/EN 12390-3 had an average compression strength of 49MPa. The deformed steel reinforcement was tested to have an average yield strength of 569MPa and an E-modulus of 179GPa.

![Figure 1 RC test beam and applied reinforcement.](image1.png)

Figure 2 and Figure 3 shows the location of the 8mm and 10mm circular CFRP rods. The tensile capacity of the CFRP rods was 2500 MPa with an E-modulus of 165GPa according to the manufacturers values. The test configurations are shown in the Table 1.

ANCHOR MOUNTING

Anchoring of the CFRP NSMR rod is shown in Figure 4, where a specially designed anchor configuration is mounted to the RC beam ends. The mounting procedure was as follows: 1) mounting of thread M24 bars into the RC beam, 2) pre-mounting of mechanical anchor on the CFRP rod (The CFRP rod was already glued into the RC beam leaving the ends exposed for the anchor installation), 3) mounting of anchor block, 4) applying fast curing glue (to ensure sufficient CFRP/wedge contact between CFRP and inner wedge surface) and 5) pre-setting of wedge into the barrel. The mounting procedure of the anchored strengthening system lasted approximately 10 min.

Figure 4 Installation of the specially designed anchor system.

TEST SETUP AND MONITORING

The beams were loaded using deformation controlled actuators (2mm/min) in a four point bending setup, Figure 5, where strain gauges (SG) were applied on the CFRP rods, deformed steel reinforcement and concrete. Also LVDT transducers (DF) were added to investigate the beam deformations during loading. All RC beams were designed to fail in bending, in order to ensure sufficient activation of the ductile anchorage system and thus enable optimal verification of the system response.

Figure 5 Test setup and applied monitoring equipment (view from side and below).

RESULTS AND DISCUSSION

Figure 6a shows the failure mode of the un-anchored NSMR CFRP rods, where IC-debonding failure was experienced for all beams. Such a failure mode is typically obtained when using these strengthening systems and occurs suddenly without much warning. As seen from Figure 6b, where the anchored beams are shown, a different
failure mode was obtained, which is characterised by significant cracking and concrete peeling, and an increased deformation before concrete crushing occurs.

Using one and two 10mm rods without anchors, resulted in a maximal deflection (at the loading points) of 19mm and 12mm respectively. However, when anchoring the 10mm rods, the maximal deflection was increased to 46mm (287% increase). Figure 7 shows representative beam deflection shapes at different load steps for an un-anchored system (Figure 7a) and an anchored system (Figure 7b), both with 10mm CFRP rods. It is seen how the anchored configurations have a symmetrical deflection, which is significantly larger than the obtained in the un-anchored configurations. This correspond to the authors expectations of developing a sustained- and controlled failure mechanism with increased ductile behaviour, just as the aggregate interlocking seems to contribute to the beam improved performance.

When evaluating the strain development in the CFRP rods, the un-anchored CFRP rods showed an un-symmetrical development of strains during loading when delamination initiate, Figure 8a. However, when the CFRP rods were anchored the strain development continued to be symmetrical throughout the loading regime, Figure 8b, indicating the desired activation of the ductile anchors.

The load/moment - deformation curve for each configuration is depicted on Figure 9. A significant strengthening effect is generally obtained by using the NSMR CFRP rods. The un-anchored configurations, however, show an almost linear response until a sudden failure occurs and consequently a low ductility. When the ductile anchors are applied to the NSMR CFRP rods, a significant increase of the capacity was obtained, but with substantial ductility as the outcome as well. The linear response ends at a moment of approximately
100kNm (approximately 70kNm for the reference beam) where a horizontal regime, with a small inclination starts to develop. This regime stays almost stable until concrete failure occurs. The load/moment versus deflection are shown in Figure 9a. Figure 9b shows an example of the ductile beam response when anchoring two 8mm NSMR CFRP rods. At a deflection of approximately 20mm and 35mm sudden reductions of loads occurred. Generally, these reductions are dedicated to the intended movements in the ductile anchor setup and concrete cracking (aggregate interlocking failure), where sliding of the anchorage parts occur during loading in the horizontal deformation regime.

**Figure 9**

a) Representative load/moment – deformation curves for the test configurations. b) Example of sudden sliding in the ductile anchor system.

The ductile anchor setup behaviour in combination with aggregate interlocking seems to provide the full ductile beam response. Consequently, this mechanism offers substantial warning and ductility. An overview of the results is seen in Table 2. The theoretical moment capacity of the T-section RC reference beam is calculated to be 64.3 kNm and ACI (ACI 2008) is used to calculate the strengthening magnitude.

**B-2Ø10M-2 failed initially at the support. The beam was then tested further as v2 (second version) to examine the final bending capacity

**CONCLUSIONS**

Four test series were investigated using ductile anchored and un-anchored 8mm and 10mm CFRP NSMR circular rods. The research is the first step in a large research program aiming at developing a strengthening system with a controlled ductile deformation, increased warning, and a higher strengthening effect. The following can be concluded from the test programme.

- The developed ductile anchor setup was relatively easy to apply to the RC T-section beams. This opens a realistic opportunity of mounting the system on real life structures.
- Using the anchored NSMR lead to a different failure mode, where significantly increased ductility and warning is obtained, compared to the un-anchored NSMR configurations.
- The CFRP material was activated equally well in both ends when the anchor setup was applied. This enabled a better utilization of the rod.
- It seems possible to secure a controlled ductile behaviour by using the developed anchor setup
- Generally, the anchor setup worked as required in the test programme.
The result shows an increased capacity of 132% and a maximal deformation increase of up to 287% when using anchored 10mm NSMR CFRP circular rods compared to un-anchored rods. Additional research is required in order to investigate the failure mechanisms, optimize the anchor setup, apply the system to longer beams, etc. and is presently ongoing at DTU.

ABSTRACT

This paper presents the research activities performed within a Polish-Swiss Research Program between EMPA (Switzerland) and Lodz University of Technology (TUL, Poland) on two large-scale post-tensioned concrete girders. The main aim of the project was a pioneer application of an innovative strengthening system with pre-tensioned carbon fibre reinforced polymer (CFRP) strips on an existing bridge over the Pilsia River in Szczercowska Wieś (central Poland). The project consisted of the laboratory tests of two post-tensioned concrete beams, which were performed as the exact copies of the original bridge girders. The first of them served as a reference member, while the second one was strengthened for flexure and for shear with pre-tensioned externally bonded CFRP reinforcement. The paper presents the main test results and the numerical model created in a commercial FEM software Atena, considered one half of the symmetrical girder, with a step by step analysis of several loading phases of the tested girder referring to the self-weight of the girder, post-tensioning, slab casting, strengthening, and external loading until failure. The comparison of the test and numerical load-deflection response shows a very good agreement and promising results for both flexure and shear.

INTRODUCTION

Flexural strengthening of RC structures with CFRP laminates is actually a well-recognised technique of improving load capacity, although this method does not fulfil the serviceability limit state (SLS) of the strengthened structures. In order to improve this condition, pre-tensioning of CFRP reinforcement is recommended. In case of pre-stressed or post-tensioned (PT) concrete structures the only effective strengthening technique is the application of the pre-tensioned CFRP laminates. Due to the fact that pre-stressed tendons are located near the bottom surface, such structures cannot be strengthened with the use of steel plates anchored with mechanical anchors because they could cut the pre-stressing steel reinforcement during the mounting of the anchors on the post-tensioned beam. To solve this problem a unique gradient strengthening method has been proposed (Meier et al. 2001, Czaderski et al. 2012, Michels et al. 2013). Prior to the first application of this technique on the bridge over the Pilsia River in Poland (Kotynia et al. 2015), an extensive experimental research program had been conducted within the Polish-Swiss Tulcoempa project (Michels et al. 2016). The main aim of the paper is to present a new FE-model using ATENA software and to apply it for an analysis of the behaviour of the PT girders tested in this project, both in terms of flexure and shear. The results of the experimental tests of two PT girders, strengthened with pre-tensioned laminates were used to verify the proposed MES model.

EXPERIMENTAL PROGRAM

Two full-scale I-shaped girders 18.4m in length and 1.0m in height were reconstructed according to the original bridge drawings and then cast of class C35/45 concrete (of 61.4MPa and 62.1 MPa compressive concrete cube strength of girders 1 and 2, respectively). Then girders were post-tensioned with three parabolic and two straight steel pre-stressing tendons with a total cross section of 345 mm² (each tendon pre-stressed with the pre-stressing force of 363 kN, the average yield and ultimate strength of 1.660 MPa and 1.810 MPa and the ultimate strain of 4.8%).
The last stage of prefabrication of the girders was casting the new upper concrete deck (125 cm wide and 21 cm deep, with the compressive concrete cube strength of 47.5 MPa and 51.1 MPa in girder 1 and 2, respectively) that finally gave the T-section PT concrete girder shown in Figure 1.

The first girder served as a reference, while the second one was strengthened in flexure with two pre-tensioned CFRP laminates (100 mm wide, 1.2 mm thick, with the modulus of elasticity equal to 165 GPa), with a gradient anchorage method (without mechanical anchors applied with three consecutive force releases equal to 50 kN (over the first of 300 mm bond length) and two next releases of 35 kN (each over 200 mm bond lengths)). After the flexural strengthening, the shear strengthening was applied. The shear region was strengthened with 14 vertical wrappings of CFRP sheet (of 75 mm width and about 0.9 mm mm thick, with spacing of 150 mm, with the modulus of elasticity equal to 240 GPa) applied with the wet lay-up technique (Figure 2). A detailed description of the reconstruction of the girders and the strengthening process is presented in (Michels et al. 2016).

Experimental tests

In order to investigate the strengthening efficiency, the girders were tested in a 6-point bending set-up. The supports were set at 18.0 m span and four actuators were situated symmetrically in the midspan of the beam at 1.2 m spacing. The loading configuration was selected so as to be compatible with the adequate Polish Standard (PN-85/S-10030 code for bridge design) for the calculation of the designed loads for concrete bridges. The loading was controlled by displacement of the hydraulic jacks and set to 3.5 mm/min. In the first phase the girders were preloaded with 4 x 100 kN force, then unloaded and loaded again until failure (Figure 3).

The reference girder reached its ultimate load of 4 x 193 kN and failed due to extensive yielding of the prestressing tendons. The actual failure (concrete crushing or rupture of the reinforcement) was not reached, but the tests had to be stopped due to very high deflections. However, the load-deflection response obtained from the test (Figure 4) allowed to assume that the ultimate load was not likely to increase significantly, should the test be continued. The strengthened girder failed due to the rupture of both longitudinal CFRP laminates. The ultimate load was equal to 4 x 240 kN and the strain in the CFRP reinforcement reached 1.6% at rupture (including pre-strain). The complete results of the experimental tests are presented in Table 1.

Shear tests

No signs of shear failure have been observed during flexural tests, even though the loads and deflections were extremely high. For a direct verification of the girders’ shear behaviour, an additional experimental test was conducted, in which the strengthened girder was stripped of all the CFRP reinforcement and subjected to high shear loads. The goal of the tests was to confirm that, contrary to traditional strut-and-tie approach (chapter numerical model), a direct transfer of the compressive concrete stresses due to the arch effect from the loading point to the support prevented the shear failure and provided the girders to carry much higher loads, even without any shear strengthening.

For the purpose of the extended tests of the strengthened girder (previously tested for flexure), all the CFRP reinforcement had been removed and the loading points were moved as close to one of the supports as it was possible due to the loading setup. The spacing between loading points was the same as in the flexural tests (4 x 1.2m) and the shear span of 2.2 m (Figure 4).

![Figure 4 Shear test scheme](image)

Even in the second test the girder did not fail in shear. The maximum load applied reached 4 x 268 kN, which corresponded to the highest shear force in the shear span equal to 938kN. The test was stopped due to high deflections and yielding of the longitudinal reinforcement. The deflection in the girder’s midspan reached 185 mm (not including permanent deformation resulting from the flexural test). The highest diagonal compressive strain in concrete registered with digital image correlation system Aramis reached 0.6%. The results of the shear test are shown in Table 1.

NUMERICAL ANALYSIS

An exact model of the laboratory girders was created in the FEM software Atena 2D. The constitutive laws of the model comprised: a non-linear behaviour of concrete in compression, non-linear fracture mechanics, Kupfler biaxial failure criterion, the reduction of concrete compressive strength, shear stiffness after cracking and fixed crack direction (compatible with principal stresses direction). Real mechanical properties of all constitutive materials (concrete, pre-stressing and mild steel, CFRP reinforcement) were implemented in the model, based on laboratory tests or manufacturer’s data. One half of the girder was modelled for the simulation of flexural tests, with appropriate symmetry boundary conditions in the middle. For the simulation of the shear test, the whole girder was modelled due to lack of symmetry in the loading pattern (Figure 5).
To reproduce the internal stresses in the girder correctly, multiple loading cases and steps were incorporated in the model. Initially, during the post-tensioning, the girder lied on its formwork. That boundary condition was also given in the simulation in order to avoid bending moment and premature bending cracks caused by the self-weight of the girder. However, for the external loading that line support had to disappear. Since the line supports incorporated in the program cannot be removed during the simulation, a non-linear contact spring was modeled as line support instead. That contact spring was ineffective for tensile forces and compressive forces higher than those due to self-weight. Therefore the girder could deflect freely upwards during post-tensioning (later during external loading the contact spring was switched off). To simulate the post-tensioning, an adequate tensile force was introduced in each tendon. At that time, the weight and modulus of elasticity of concrete in the upper slab in the model was reduced to 0, as the slab of the laboratory girder cast after the post-tensioning. In the second phase the actual weight and stiffness of the concrete slab was applied, which corresponded to its casting. In further steps the girder was externally loaded by prescribed displacement of a mass-less load distribution beam with two contact points with the girder (representing two loading jacks). The displacement was increased by 5 mm (and later 10 mm) in each step.

The comparison of experimental and numerical load-deflection and load-strain curves shows an excellent compatibility of laboratory tests and FEM simulations (Figure 6). The numerical models of both girders showed behaviour identical with the behaviour of the tested members, up to the point where the failure occurred or the tests were stopped. In the simulation of the reference girder’s flexural test, at 260 mm midspan deflection the applied external load was an equivalent of $4 \times 190$ kN, which was almost exactly the same as in the laboratory test.
The simulation of further loading made it possible to obtain a failure due to concrete crushing under the load of 4 \times 196 \text{kN} and midspan deflection equal to 437 \text{mm}. In case of the strengthened girder’s flexural simulation, the load corresponding to CFRP laminates’ rupture (\(\varepsilon_{\text{f,test}} = 1.0\%\)) was equal to 231\text{kN} (at 203 \text{mm deflection}), which corresponds very well with the ultimate load of 4 \times 240 \text{kN} (at 210 \text{mm deflection}) obtained in the laboratory test. Similar consistency was also achieved in terms of internal strains and stresses in the girders, as well as cracking pattern and inclinations of cracks (see Table 1, Figure 6).

The simulation of the shear test confirmed very high shear load capacity of the girder. The applied loads reached similar levels as in laboratory test. Maximum external load in the model was equal to 4 \times 270 \text{kN}, which corresponded to support reaction equal to 938 \text{kN}. The directions and values of principal stresses (Figure 7) show the phenomena of direct transfer of compressive loads from loading points to the supports and pre-stressing cables anchors via concrete compressed diagonally. The average compressive stress in concrete diagonal was equal to about 21 \text{MPa} and the principal compressive strain reached 0.057\%. The simulation also showed that even though almost all the stirrups in the shear span were yielded, the shear stresses were effectively transferred via compressed

Figure 7 a) Stress pattern in girder 1, b) cracking pattern in flexural test of girder 1, c) cracking pattern in the flexural test of girder 2, d) cracking pattern in shear test of girder 2.
concrete diagonal and pre-stressed cables. Similarly to the results of flexural simulations, almost identical cracking patterns were obtained in the real shear test and simulation (Figures 7b and 7c).

**CONCLUSIONS**

On the basis of a comparative analysis of the test and numerical results, the following conclusions can be drawn:
- Very good compatibility of flexural test and numerical results
- Excellent consistency of the MES model and test results in terms of the ultimate loads, midspan deflection, concrete strain, and the cracking pattern.
- The proposed FE model successfully predicts enhancing effects in the ULS and SLS in the full range of loading.
- The proposed model can be used for parametric simulations considering the following investigated parameters: variable pre-stressing force in the internal pre-stressing tendons; variable pre-stressing level of the externally bonded pre-stressed laminates; variable elasticity modulus of FRP laminates and concrete strength; flexural behavior of PC girder strengthened with CFRP laminates without pre-stressing; flexural behavior considering the shrinkage in the slab (top deck); shear behavior without concrete filling elements.

ABSTRACT

Masonry walls have failed out of plane much more frequently than they have in plane; however, more research and investigations have aimed to improving in plane capacity. The objective of this study is to investigate the out-of-plane flexural performance of reinforced masonry walls and evaluate the contribution of externally bonded fiber-reinforced polymer (FRP) sheets and strips to flexural capacity. Nine fully grouted reinforced masonry walls were built using concrete masonry units and type S mortar. The out-of-plane loading was simulated by four-point bending with an effective span of 1.12 m (44 in.) between the supports. The reinforced walls subjected to cyclic load at a rate 1.27 mm/min (0.05in./min). The reference masonry wall was in running bond pattern and reinforced with 2 No. 4 steel bars. The following experimental parameters were investigated: the type and amount of FRP composite, steel reinforcement ratio, and the effect of surface preparation. The test setup, instrumentation of the specimens and the discussion for the results and modes of failure are described in this study. The general behavior of the reference and strengthened specimens are characterized by load–deflection curve responses. Different modes of failure, including compressive concrete crushing failure, FRP rupture, and FRP reinforcement debonding from the masonry substrate occurred in the strengthened reinforced walls.

Reinforced masonry walls, Strengthening, FRP, EB, out-of-plane, cyclic load.

INTRODUCTION

There is a lot of existing masonry structures that do not satisfy design and structure lifetime requirements due to aging, change in use and corrosion. For these reasons, masonry walls that have an insufficient out-of-plane strength to resist the forces generated by seismic events, wind, or lateral earth pressure are in need of an upgrading capacity to extend their lifetime. Fiber reinforced polymer (FRP) has become an attractive method for strengthening masonry structures. (Al-Jaberi et al., 2015) evaluates the behavior of reinforced masonry wall strengthened with NSM-FRP bars. The results of this study showed that the NSM technique affects the flexure strength and mode of failure for the tested specimens. This technique is affected by FRP properties, FRP surface treatment, groove size and geometry, bar size and adhesive agent (Sharaky et al., 2014). Significant research has focused on improving out of plane behavior of unreinforced masonry wall system by using external bonded FRP. Unreinforced masonry walls strengthened using GFRP strip and subjected to out of plane cyclic load was investigated by (Velazquez-Dimas et al., 2000). This study showed that the Strength and deformation capacity of the retrofitted wall were significantly enhanced, retrofitted wall resisted pressure was approximately five times the wall weight and the deflection as much as 5% of the wall height. The results of experimental research on brick masonry vaults strengthened by fiber-reinforced polymer (FRP) strips are presented (Valluzzi et al., 2001). The presence of the fibers prevents the typical brittle collapse of brick masonry. Three failure mechanisms are possible depending on the position and amount of the reinforcement in the strengthened masonry structure: (1) masonry crushing, (2) detachment of the fibers; and (3) sliding along a mortar joint due to the shear stresses. The cyclic behavior of unreinforced brick walls, before and after retrofitting using Glass Fiber Reinforced Polymers (GFRPs) was investigated (Kalali and Kabir, 2012). These experimental tests demonstrate the ability of GFRPs to keep the bricks together and maintain the specimens integrity in addition to prove that GFRP provide an effective technique for improving the seismic resistance of unreinforced brick walls.
The vast majority of previous studies have focused on the behavior of unreinforced masonry walls. The research reported here extended the previous studies by considering the behavior of fully grouted reinforced masonry walls strengthened with different types of FRP under half reversed cyclic loading. Nine reinforced masonry walls were strengthened externally using GFRP sheets and CFRP laminate. The parameters considered were the type and amount of FRP composite, steel reinforcement ratio, and the effect of surface preparation.

**EXPERIMENTAL PROGRAM**

**External Strengthening System**

The procedures for installing FRP systems may differ slightly depending on manufacturers that developed the system. Temperature and surface moisture in addition to surface preparation of substrate at the time of installation are the effective parameters on performance of FRP systems.

The GFRP sheet to be glued on the surface is 200 mm (8 in) width and 0.36 mm (0.014in) thick in size. Prior to attaching FRP sheet to the tension surface of reinforced masonry walls, a primer coat of epoxy was applied to the specimen in the regions where the GFRP sheets were to be bonded. The GFRP sheets was saturated in epoxy and then positioned by hand on the prepared surface and a paint roller was used to release trapped air below the fiber sheet. This process of strengthening named wet lay-up method can be seen in “Figure 1” below.

---

**Test Specimens**

Nine reinforced masonry specimens were constructed using standard masonry blocks 152.5 mm (6 in.) and type S mortar. The nominal dimensions of these walls were 1220 mm (48 in.) six course length by 610 mm (24 in.) one and a half course width as shown in “Figure 2”. The specimens were constructed in a running bond and reinforced with different of vertical steel reinforcement ratio. The walls were. They were grouted four days after construction to ensure stability during the vibration process. After a curing period, the walls were strengthened using a GFRP composite (unidirectional E- glass fabric with an epoxy matrix) and a CFRP laminate. The primary variables for this study are listed in Table 1.

**Specimen Designation**

(a) Masonry walls before strengthening  (b) Eternally bonded specimen

Figure 2 Masonry Specimens
The specimen ID consisted of three parts as shown in Table 1. The first part represented FRP information (type, thickness, and width). The first character identified the FRP type: namely “C400” for carbon FRP laminate and “G” for SHE-51 composite (E-glass). The second and third characters referenced the cross-section thickness and width in mm, respectively. The second part of the ID identified the bonding adhesive type, number of FRP strips in the tension face, and the wall bond pattern. The first character represented the bonding adhesive type: E (for Tyfo S Epoxy) and S (for SikaDur 30). The second character identified the number of strips in the tension face. The third character referred to the wall bond pattern applied: “R” for running bond. For specimen No.2, the letter W refers to the specimen without surface preparation. The third part of ID represents the main steel reinforcement.

Specimen Surface Preparation and FRP Installation

The surface was cleaned manually with a wire brush to remove all excessive mortar from the walls joints that left from the construction process. The prepared surfaces were vacuumed after brushing to remove the residual dust. Tyfo S epoxy resin mixed with silica fume to provide a putty filler layer that smoothed and leveled the prepared surface before composite material was installed. The SEH51 fabric was saturated with Tyfo S epoxy resin before it was applied to the wall. The saturation process ensured good bonding with the substrate. The Tyfo S epoxy resin was mixed at a volume ratio of 100 parts A to 42 parts B. The curing period for Tyfo S epoxy resin is three days at 60o C. SikaDur 30 adhesive used to bond the Aslan 400 CFRP strip. SikaDur30 mixed with a volume proportion of one part of component B to three parts of component A. The FRP sheet or laminate bonded to the tension face of the wall so that the fiber was perpendicular to the bed joints.

Material Properties

A series of tests was performed to determine each material’s mechanical properties. The properties of the materials that were used to construct the specimens are summarized in Table 2. The manufacturing properties of FRP and its bonding adhesive are presented in Table 3.

Test Setup and Loading System

Four-point line loading with simply supported boundaries can be used to conduct out-of-plane testing of reinforced masonry walls as shown in “Figure 3”. An MTS double-acting hydraulic jack with a push-pull capacity of 965 MPa (140 kips) was used to apply the load. The specimens subjected to out of plane loading without any consideration to normal (vertical) load that available in case of bearing walls, so the behavior doesn’t include such effect. This load was transferred to the masonry specimen by means of continuous steel plates and bars along the full width of the external face of reinforced walls to provide two equal line loads. The distance between these two lines was 200 mm. (8 in.). The load was applied in half-cycles of loading and unloading, as a displacement control at a rate of 1.27 mm/min (0.05 in./min). The displacement amplitude increment was 6.35 mm (0.25 in.), double half loading cycle was applied for each amplitude level as illustrated in “Figure 4”. Deflections at mid and third span were measured using three (LVDTs) at each side. FRP and steel bars strain are recorded during the loading using strain gauges placed on the FRP and steel bars.

EXPERIMENTAL OBSERVATIONS

Reinforced concrete masonry walls generally behave in a flexural ductile mode due to steel reinforcement. The first flexural tensile crack initiated at the block mortar in the maximum moment region (between two line loads). Further flexural tensile cracks in the block mortar and within the CMU developed beyond the cracking load. The FRP sheets that attached to the masonry caused cracks to propagate in the masonry units. The masonry cracks were oriented parallel to the bed joints. Cracks also extended along the FRP sides due to high stress in this region. The cracks also moved vertically toward the compression face in a straight line, as illustrated in “Figure 5”. Flexural shear cracks outside the constant moment region generated in the later stages of loading. A number of distinct failure modes of reinforced masonry walls strengthened externally by FRP observed in this experimental study. The first mode was flexural failure (FRP rupture or concrete crushing) and the second mode was the FRP debonding from the masonry wall. The composite action between the masonry wall and FRP ended at the failure. The debonding failure in all its forms, whether intermediate crack (IC) or plate end-debonding failure generally happened in the masonry substrate. A strong adhesive between the GFRP and masonry would prevent
the debonding failure between the adhesive and concrete masonry or between the adhesive and FRP. Pictures of typical modes of failure are shown in “Figure 6”.

![Image of typical modes of failure]

---

### EXPERIMENTAL RESULTS AND COMPARISON

The load vs. deflection curves envelopes are illustrated in “Figure 7”. The moment capacity and stiffness of the reinforced walls were increased for specimens externally strengthened with FRP (compared to the control specimen). Interestingly, the flexural capacity of walls strengthened with one strip of FRP composite dropped to approximately the same capacity of the control specimen when the failure (debonding) occurred. On the other hand, the flexural capacity of walls strengthened with two strips of FRP dropped below the control specimen capacity. This is due to existing of block unit cracking and damage that accumulated after failure occurred.

It is worthwhile to point out that in a general sense, using putty filler layer lead to increase the shear capacity for the walls, which can be attributed to the improvement of masonry unit as a result of absorption of epoxy.

The load-deflection responses for the specimens strengthened with GFRP composite and CFRP laminate are illustrated in “Figure 7 a and b”, respectively. Strengthening the specimens with GFRP composite is increased load carrying capacity by 300%, while the CFRP increased the specimen’s capacity by 81%. The reason for this difference is the bonding material. Using silica fume mixed with Tyfo S epoxy resin in specimens with GFRP reduced the porosity of the concrete unit and increased its compressive strength. The specimens with GFRP and epoxy resin showed a better behavior than the specimens with CFRP and SikaDur30 due to the epoxy’s high debonding strain compared with SikaDur30, as shown in “Figure 7 c and d”. It’s very limited experimental studies have considered the effect of varying longitudinal steel ratio on the behavior of upgraded masonry walls. “Figure 7 e” shows this effect, the control capacity and the initial stiffness affected by the longitudinal reinforcement. The stiffness depend on external strengthening and the internal reinforcement ratio, so the stiffness of specimen reinforced with 2#4 more than other reinforced with 2#3 bars. The ultimate load and post peak behavior depend on controlling mode of failure which is independent of the steel reinforcement ratio. The specimen reinforced with 2#4 failed by rupture of FRP followed by masonry crushing that lead to post peak ductile behavior. On the other hand, the specimen reinforced with 2#3 failed by plate end debonding followed by flexure shear failure that’s lead to brittle failure. The effect of surface preparation is illustrated in “Figure 7 f”. The mode of failure changed from FRP rupture (for specimen with putty filler layer) to the plate end debonding (for specimen without surface preparation). The flexural capacity was improved by 10% by adding a putty filler layer as a base layer for GFRP sheet.
Figure 7 Load verses mid span deflection curves for test specimens

CONCLUSIONS

It was determined that one or two strips of GFRP (200 mm wide) (8 in.) attached on the exterior surface of the reinforced wall improves the out-of-plane strength significantly by (230 to 300 %) compared to the control specimen. The strength was increased by about (40 to 80 %) when one or two strips of the CFRP laminate were used. This improvement in capacity is equivalent to (3-5) g of acceleration and the deflection at the order of L/30. In terms of strength and ductility, the specimens with GFRP displayed better behavior than the specimens with CFRP. This behavior is due to the existing of silica fume and epoxy as a filler layer and the high debonding strain for epoxy compared to SikaDur30 in addition to high stiffness of CFRP. Also the existing of this layer improved the flexural capacity and changed the mode of failure compare with the same strengthened specimen without filler layer. The stiffness of the strengthened wall depend on external FRP and the internal steel reinforcement, while the ultimate load capacity and post peak behavior depend on controlling mode of failure which is independent of the steel reinforcement ratio. The test results indicated that the flexural behavior of reinforced masonry walls strengthened externally by FRP may be controlled by FRP fracture, debonding (intermediate crack or plate end debonding failure), or compressive concrete crushing failure.

ABSTRACT

An increasing research trend is to improve the structural performance of existing structures with new generation high performance materials. Among those, advanced composite materials have been significantly used as means of innovative solutions to strengthen existing structures. The most common usage of these materials is the external strengthening applications on structural components. The main objective of this study is to investigate the behaviour of prepreg strengthened semicircular masonry arches, and to highlight the effect of strengthening configurations on the structural performance of the arches. For this purpose, a series of masonry brick arches were prepared and strengthened by using unidirectional monolayer prepreg composites, which were produced in a prepreg machine. In the study, three different strengthening configurations were investigated, namely the Continuous Strengthening at the Intrados surface (CSI), Continuous Strengthening at the Extrados surface (CSE) and Localized Strengthening at the Intrados and Extrados surfaces (LSIE). The findings show that the monolayer prepreg composites play an important role in the strengthening of the masonry arches and the composites significantly enhance the load carrying capacity of the arches.

INTRODUCTION

Masonry materials have been used in the construction industry for centuries and masonry structures still represent a considerable portion of the building stock in the world. Although many masonry structures are currently kept in service, the majority of these structures are not quite able to resist large seismic forces. Therefore, development of effective strengthening methods for these existing structures is important for resilient communities and the preservation of these structures is still challenging in the structural engineering community. Restoration, strengthening and reinforcement of masonry structures have recently seen heightened interest in structural engineering. As a response to this challenge, using composites as strengthening materials can be made very effective. There is strong evidence that such materials have been used in different applications lately. In the last few decades, several composite materials have come to the forefront of strengthening due to their proven effectiveness for the structural and seismic retrofitting of existing structures. There are several research studies, which highlighted the common use of composite materials in different applications (Staab, 2015; Wang et al., 2011; Ye, 2003). A major portion of the studies focused on carbon fibre reinforced polymer (CFRP) and glass fibre reinforced polymer (GFRP) composites and their contributions to the structural performance (Grande and Milani, 2016; Mazzotti et al., 2015; Reboul and Ferrier, 2015; Milani and Lourenço, 2013; Lorenzis et al., 2013; Fedele and Milani, 2012; Witzany et al., 2011; Mosalam et al., 2007; Mosallam and Mosalam, 2003). Moreover, a considerable portion of the past research focused on the use of CFRP and GFRP composites in the masonry arches (Pintucchi and Zani, 2016; Castori et al., 2016; Caporale et al., 2014; Borri et al., 2011; Cancelliere et al., 2010; Lorenzis et al., 2007).

Although significant research has been conducted on strengthening masonry components with CFRP and GFRP composites, the application of prepreg composites for strengthening of masonry structures is relatively limited.
Therefore, this study focuses on the monolayer prepreg composites and their effects on the structural behaviour of the masonry arches. In the scope of this study, three different strengthening configurations, namely Continuous Strengthening at the Intrados surface (CSI), Continuous Strengthening at the Extrados surface (CSE), and Localized Strengthening at the Intrados and Extrados surfaces (LSIE), are experimentally investigated.

**MATERIALS AND METHODS**

**Manufacturing of Monolayer Prepreg Composite**

Prepreg is short for “pre-impregnated” fibre-reinforced composites. Prepreg composite is a multi-phase material that is composed of resin matrix and fibre reinforcement. In this study, the used resin matrix was composed of Araldite®LY 1564 SP epoxy resin and Aradur®XB 3486 hardener, which were weightily mixed in the ratio of 100:34, respectively. Furthermore, 12 K A-42 carbon fibre was used as a reinforcement material and the carbon fibres were supplied by DowAksa Advanced Composites Holdings BV (Turkey). In the production phase, all composites were manufactured in a unidirectional monolayer form (one direction of reinforcement) by using a special prepreg machine (Figure 1).

![Prepreg machine components](image1.png)

**Figure 1 Prepreg machine components**

After production of the composites, the monolayer prepreg composites were observed using Scanning Electron Microscopy (SEM) technology (Figure 2). SEM observations were conducted with a JEOL 6510-LV JSM SEM equipment of the laboratories of Marmara Research Centre of the Scientific and Technological Research Council of Turkey (TUBITAK MAM).

![SEM images of the prepreg composite](image2.png)

**Figure 2 SEM images of the prepreg composite**

**Preparation of Lime-based Mortar**

Lime-based mortar was produced by six principal components: hydraulic lime, stone and brick powder, fine sand, lime paste and water, and cement-free natural hydraulic lime (Albaria Calce Albazzana®) obtained from BASF Chemical Company and used as a binder material. Other components were locally selected for the mortar. The components were mixed in equal proportion by weight to prepare the lime-based mortar. To obtain good quality mortar, the mixture was blended by Steel Drum Mortar Mixer.
Preparation of the Masonry Arches

In the experiments, the arches were built of 29 standard hollow bricks, which had sizes of 90×190×50 mm (Figure 3). The clay bricks were obtained from a local brick company in Erzurum, Turkey. In the first step, the bricks were cleaned with water to remove any contamination and dust from the surfaces, and to enable an effective adherence between the brick and the mortar. After surface cleaning, masonry bricks were dried at room temperature for two days. The arches were constructed on a wood scaffolding with the desired geometrical properties. The internal diameter, internal rise and thickness of the arches were 1000 mm, 500 mm and 90 mm, respectively. The joints between the bricks were filled with the prepared lime-based mortar and the mortar joints were kept with a constant thickness of almost 5 mm.

CHARACTERIZATION OF THE MATERIALS

Mechanical Properties of the Composite

The tensile strengths of the prepreg composites were assessed by taking five representative specimens having dimensions of 25×250 mm. ASTM D 3039 standard was followed for the determination of the tensile strength of the prepreg composite using a Shimadzu universal tensile testing machine. All tensile tests were conducted considering the same conditions. The tensile strengths of the prepreg composites are given in Table 1.

Mechanical Properties of the Masonry Materials

Masonry materials used in the arches were tested to determine their mechanical characteristics. Therefore, clay bricks and mortar samples were tested in compression and three-point bending (Figure 4). These tests were performed based on the Turkish Building Codes (TS 699; TS EN 1467; TS EN 1469). In the mechanical tests, mortar samples at 7 and 28 days were used in order to obtain the mechanical properties (Tables 2 and 3).

Strengthening Procedure

All masonry arches were strengthened using three different combinations, i.e. CSI, CSE, and LSIE. Before the application of the prepreg composites, the rough surfaces of the masonry arches were grinded and cleaned in order to remove any contaminations. Subsequently, the adhesive material used between the composites and arch surfaces was prepared by using Araldite AV 138 M-1 epoxy and HV 998 hardener and applied on the arch surface as a putty layer using a spatula (Figure 5). Finally, the prepreg composites were carefully applied to the arch surfaces and the strengthened arches were cured for ten weeks. The strengthening configurations investigated in this study are schematically presented in Figure 6.
TESTING PROCEDURE AND OBSERVATIONS OF THE MASONRY ARCHES

A series of experimental investigations were conducted to determine the maximum load bearing capacity and failure mechanisms. The arches were tested while rigidly attached in a reinforced concrete rigid platform. In the experimental study, each of the arches was subjected to gradually increasing concentrated vertical force applied at the mid-span until failure. The load was applied by a hydraulic jack and it was measured by a 250 kN capacity HBM load cell. The horizontal and vertical displacements were acquired by seven displacement transducers (LVDTs). Furthermore, five strain gauges (STRG) were used to measure the strains of the prepreg composites. The test setup and position of the loading and measuring devices are shown in Figure 7.

Unstrengthened Arch

The unstrengthened arch was first tested in the experimental study. During the test, the first hinge took place at the keystone when external load was 1.5 kN. After the load reached 2 kN, the second hinge occurred between the 7th and 8th bricks, then the unstrengthened arch failed when the load of the arch reached $F = 2.39$ kN. The unstrengthened arch experienced brittle failure due to formation of a three-hinge mechanism and all separations occurred in the interfaces between mortar joints and the bricks (Figure 8). Figure 9 shows the load-displacement curve corresponding to the loading point and the energy absorption capacity of the unstrengthened arch.
Continuously Strengthened at the Intrados surface (CSI)

In the CSI arch test, when the load reached 5.5 kN, debonding mechanism was observed at the prepreg-masonry arch interface. Subsequently, the eight bricks, numbered 14 to 21 became vulnerable and the first crack initiated between the 15th and 16th bricks. As a result, the ultimate load value of the CSI arch was 6.37 kN. Figure 10 shows the failure mechanism of the CSI arch. Figure 11 shows the load-displacement curve corresponding to the loading point and the energy absorption capacity of the CSI arch.

Continuously Strengthened at the Extrados surface (CSE)

The first debonding of the prepreg composite appeared during testing the CSE arch after reaching the load value of 5.20 kN. The prepreg was totally debonded between the 1st and 5th bricks, when the loading reached 9 kN.
first crack appeared between the 4th and 5th bricks at a load of 10.71 kN. As for the failure mode, the CSE arch collapsed due to the separation between the 14th and 15th bricks (Figure 12). Figure 13 shows the load-displacement curve corresponding to the loading point and the energy absorption capacity of the CSE arch.

![Figure 12 The failure mechanism of the CSE arch](image1)

Figure 12 The failure mechanism of the CSE arch

![Figure 13 CSE test results (a) Load-displacement curve, (b) Energy absorption capacity](image2)

Figure 13 CSE test results (a) Load-displacement curve, (b) Energy absorption capacity

Locally Strengthened at the Intrados and Extrados surface (LSIE)

In the LSIE arch test, the first crack became visible between the 4th and 5th bricks at the load of 1.5 kN. Next crack appeared between the 11th and 12th bricks at the external load of 2 kN. At a load of 2.5 kN, the third crack appeared in the arch. Finally, the LSIE arch failed in the mode of three-hinged collapse mechanism with an ultimate load of 4.56 kN. The collapse mechanism is presented in Figure 14. Figure 15 shows the load-displacement curve corresponding to the loading point and the energy absorption capacity of the LSIE arch.

DISCUSSION OF RESULTS

The main focus of this study was to examine the semicircular masonry arches, which were constructed using bricks and hydraulic lime-based mortar. They were also strengthened using monolayer prepreg composites with three different strengthening configurations on the extrados and intrados surfaces of the arches. In the study, the arches were loaded by incremental load at the mid-span and the structural behaviour of the arches and the prepreg composites were investigated from the experimental measurements. The experimental results showed that the load carrying capacity of the unstrengthened arch was 2.39 kN. The strengthened CSI arch had higher load carrying capacity as 6.37 kN. For the strengthened CSE and LSIE arches, the load carrying capacity reached values of 10.71 kN and 4.56 kN, respectively (Figure 16). Thus, the prepreg composites clearly contributed to the load carrying capacity, which compared to the load carrying capacity of the unstrengthened arch, was 266% for the CSI arch, 448% for the CSE arch, and 190% for the LSIE arch.
When the displacements of the arches were examined, the maximum displacement was calculated in the unstrengthened arch that was about 50 mm at the quarter point of the span. With respect to the strengthened arches, the maximum displacements were measured in the range of 10 mm and 15 mm at mid-spans. When the results of the energy absorption capacity of the arches were examined, the CSE arch had the maximum energy absorption capacity and it was almost two times higher than that of the unstrengthened arch (Figure 17).
When the results of the strain gauges on the prepreg composites were examined, small strains of the prepreg composites were observed. During the experimental study, the prepreg composites frequently debonded from the arch surfaces. Therefore, the prepreg did not provide the desired contribution as explained by the low values of the measured strains on the prepreg composites (Figure 18). The discrepancy for STRG3 (CSI) and STRG2 and STRG4 (CSE) in Figure 18 is attributed to debonding of the composite material at very early stages of loading.

**CONCLUSIONS**

Composite materials continue to remain popular in various engineering applications, including providing innovative and efficient solutions as strengthening materials for the construction industry. Considering easy installation, low weight, and high strength, composite materials have been used as strengthening materials for many existing structures. Therefore, strengthening of existing structures with composite materials has been a popular research area. This study mainly focused on masonry brick arches and investigated the structural strengthening of the arches with monolayer prepreg composites.

The examination of the experimental results showed that the monolayer prepreg composites have a considerable effect on enhancing the load carrying capacity and other structural properties of the arches. The prepreg composites clearly contributed to the load carrying capacity, which compared to the load carrying capacity of the unstrengthened arch, was 266% for the CSI arch, 448% for the CSE arch, and 190% for the LSIE arch. Moreover, the experimental study showed that the prepreg composites generally improve the energy absorption capacity of the brick masonry arches. When the results of the energy absorption capacity of the arches were examined, the energy absorption capacity of the CSI and CSE arches enhanced 130% and 194%, respectively. In addition, the structural interaction at the interfaces between the masonry arches and the prepreg composites plays an important role in the structural behaviour and the effectiveness of the strengthening of the arches. Therefore, the successful application of the prepreg composites heavily relies on better understanding of the debonding mechanism. It is emphasized that the monolayer prepreg composites provide excellent and versatile solutions for strengthening masonry structures.

ABSTRACT

Reinforced concrete bridge deck slabs without shear reinforcement need to resist high magnitude concentrated loads. The governing failure mechanism of reinforced concrete bridge deck slabs is commonly shear, as it has been shown in experimental tests in the literatures. However, the existing shear strengthening methods, such as Externally Bonded (EB) FRP technique and Near Surface Mounted (NSM) FRP technique, are unavailable to apply in the shear damaged concrete bridge deck slabs. Embedded Through-Section (ETS) strengthening method is a relatively recent shear strengthening strategy for reinforced concrete components and consists of the opening holes across the structural thickness, where FRP bars are introduced and bonded to the concrete substrate with adhesive materials. Therefore, the ETS strengthening method could be suitable to improve the shear behaviour of concrete bridge deck slabs. To assess the effectiveness of this technique used in concrete slabs, a comprehensive experimental programme was carried out. In this test, the types of embedded materials and spacing of embedded rods were varied to investigate the behaviour of ETS FRP bar strengthening concrete slabs. The test results illustrated that the failure mode of concrete slabs were varied from shear failure to flexural failure by the application of ETS strengthening method and the ultimate strengths were also enhanced by this strengthening strategy. The results of this works show that the ETS strengthening scheme is effective and provides significant improvement in the shear behaviour of concrete slabs.

KEYWORDS

FRP, ETS strengthening, concrete slabs, shear behaviour, experimental test.

INTRODUCTION

Reinforced concrete slabs subjected to concentrated loads near linear supports are commonly found in practice, such as bridge deck slabs (Natário et al. 2014). The structural elements are characterized by high shear forces concentrated in the region between the concentrated loads and the linear support. Due to the increasing traffic loads and heavy truck load close to supports, the existing bridge deck slabs could fail in shear. Thus, more massive construction or shear reinforcement are now required in bridge deck slabs, whereas this formerly the case (Rombach and Latte 2008). To assess the question whether the lack of safety for existing bridge deck slabs that have been built mainly without shear reinforcement, or whether deck slabs under concentrated wheel loads exhibit reserves of shear capacity which have been neglected in current design codes (Rombach and Kohl 2013).

Currently, the shear strengthening techniques based on the use of fibre reinforced polymer (FRP) materials have been proposed and developed in the past thirty years (Teng et al. 2003; Lorenzis and Teng 2007). Externally bonded (EB) FRP is the most commonly used method for strengthening concrete structures using FRP material. To increase the shear behaviour of reinforced concrete structures, FRP sheets are generally applied on the side surface of concrete elements. Additionally, the near-surface-mounted (NSM) FRP rod method is another technique used to increase the shear resistance. In the NSM method, FRP rods were embedded grooves intentionally prepared on the concrete cover of the side faces of concrete structures. The efficiency of these strengthening schemes relies on the bond performance of concrete-adhesive-FRP interfaces. However, those two strengthening methods cannot be applied to increase the shear capacity of concrete deck slabs, due to inaccessible web of structures. Therefore, a
new strengthening approach is adopted (see Figure 1): vertical holes are drilled into the deck slabs upwards from the soffit in the shear zones, high-viscosity epoxy resin is injected and then FRP bars are embedded in to place. This strengthening method is called deep embedment strengthening (Valerio et al. 2009) or embedded through-section (ETS) strengthening (Mofidi et al. 2012). The research works in the literatures (Valerio et al. 2005; Chaallalet al. 2011; Barros et al. 2008) revealed that this strengthening technique provided higher strengthening efficiency compared to the EB and NSM strengthening method. In addition, the shear capacity of strengthened concrete beams was enhanced by this strengthening method.

![Figure 1 ETS strengthening process](image1)

The objective of this research study is to investigate the effect of the following variables on concrete slabs strengthened in shear using the ETS methods: (1) material type of strengthening materials; (2) spacing of FRP rods; (3) FRP rod diameters; (4) Damage of drilling holes. In addition, an experimental campaign of pull-out tests on carbon, glass, basalt and steel bars embedded into concrete is also presented, which defines the parameters for the design of strengthening scheme.

**EXPERIMENTAL PROGRAM**

**Bond Test**

![Figure 2 Test specimens for bond test](image2)

![Figure 3 Bond-slip behaviour of ETS strengthened test specimens](image3)

To assess the bond properties and optimise the choice of the strengthening rods for the ETS technique for concrete slabs, a series of pull-out tests on different strengthening rods epoxy-resined into 150x150x150mm concrete cubes were performed (see Figure 2). In this study, four types of strengthening materials, such as CFRP, GFRP, BFRP and steel, were adopted to investigate the bonding-slip behaviour of strengthening rods embedded through concrete
materials. As shown in Table 1, the failure mode of steel embedded specimens was debonding failure. On the other hand, all the test specimens embedded by FRP rods failed in concrete cracking, see Table 1. This could be due to the better compatibility between FRP and concrete compared to steel. In addition, the bond test results indicated that the bond strength and bond-slip behaviour could not be affected by the variation of strengthening materials, see Figure 3. The mechanical properties of embedded bar and adhesive were shown in Table 2.

Slab test programme

The experimental programme (see Table 3) involves eight tests performed on full-scale concrete slabs. Figure 4 presents the geometry and the reinforcement arrangement of the eight concrete slabs of the experimental programme. The reinforcement percentage and loading position (see Figure 4) was designed according to the current design code, which was adopted to force the occurrence of shear failure mode for the unstrengthened concrete slabs under a three-point load configuration. As shown in Table 3, some structural parameters were varied to investigate the shear strengthening effect of ETS scheme for concrete slabs, which included the strengthening materials, spacing of FRP strengthening rods and diameter of FRP strengthening rods. In addition, a test specimen was drilled but no strengthened was conducted to investigate the damage of drilling process.

Figure 4 Dimension of strengthened test specimens

The experimental programme (see Table 3) involves eight tests performed on full-scale concrete slabs. Figure 4 presents the geometry and the reinforcement arrangement of the eight concrete slabs of the experimental programme. The reinforcement percentage and loading position (see Figure 4) was designed according to the current design code, which was adopted to force the occurrence of shear failure mode for the unstrengthened concrete slabs under a three-point load configuration. As shown in Table 3, some structural parameters were varied to investigate the shear strengthening effect of ETS scheme for concrete slabs, which included the strengthening materials, spacing of FRP strengthening rods and diameter of FRP strengthening rods. In addition, a test specimen was drilled but no strengthened was conducted to investigate the damage of drilling process.
The vertical displacement was measured at the position under the applied load using linear variable displacement transducers (LVDTs) as shown in Figure 5a. The strain values of strengthening rods and steel reinforcement was measured by the electronic strain gauges and the locations of those strain gauges were shown in Figure 5b. The strain values of concrete slabs through the depth were measured by the vibrating-wire strain gauges, see Figure 5c.

Table 4 shows the cracking loads, the loading-carrying capacity, the vertical deflection under the loading point at failure and the failure mode of all the test slabs. All the test slabs cracked in flexure around 30kN. Those test slabs strengthened in shear with steel or FRP bars in shear span attained full ductile flexural response. The unstrengthened test slabs failed in brittle shear, see Table 4 and Figure 6. As shown in Figure 6, the shear discontinuity was constrained to occur between the ETS bars and loading point. Therefore, the loading capacity was enhanced by around 10% with the ETS strengthening method, as seen in Table 4. However, the increasing degree of this test slabs was smaller than that obtained in the test results of the ETS strengthened beams (Valerio et al.2005), because the flexural capacity of the unstrengthened test slab is a bit larger than shear capacity of that specimens. In addition, no debonding failure occurred in all the strengthened slabs, which is attributed to the increased bonding effect of ETS method. In the comparison of test results from models coded as B-con and BD1-16, it was found that the drilling process would influence the structural behaviour of concrete slabs. The test results indicated that the material type of embedded bars could not influence the behaviour of strengthened test slabs significantly, which is attributed to the good bond behaviour of ETS bars and concrete. In addition, it was shown in the test that failure mode of test slabs was varied from flexural failure to shear-flexural failure by reducing the
number of embedded bars. Interestingly, increasing the diameter of embedded bars resulted in a bit larger ultimate capacity and vertical deflections.

Figure 6 Cracking patterns of test specimens

Figure 7 shows the load-deflection at loading point for all the test specimens, clearly demonstrating the flexural ductility that exhibited those specimens containing sufficient shear strengthening. To investigate the effect of ETS strengthening method on the ductility of concrete slabs, a deformability factor (DF) (Vijay and GangaRao 2001) defined as the ratio of energy absorption at ultimate (area under load-deflection curve up to the failure load) to the energy absorption at service load (at serviceability deflection limit of span/250) was used in this paper. As shown in Table 5, the ductility of concrete slabs was enhanced by more than 200% in the comparison between unstrengthened and strengthened slabs. The ductility of strengthened concrete slabs could be enhanced by increasing the stiffness of ETS bars.

CONCLUSION

This study presents the relevant results of experimental programme for assessment of the effectiveness of the ETS FRP technique for the shear strengthening of reinforced concrete slabs. The following conclusions can be drawn from this experimental investigation.

(1) The system effectiveness relies on the bond between the ETS bars and the concrete. A series of pull-out tests has shown that the bond-slip response of the system is robust and ductile. Due to the good compatibility between FRP and concrete, no debonding failure occurred in the test specimen embedded by FRP bars.

(2) No major differences were noticed between the slabs strengthened with steel bars and those strengthened with FRP bars, but the use of FRP is suggested for such strengthening, due to its lightness and corrosion resistance.

(3) Due to the loading location close to the support, shear failure occurred in the unstrengthened test slabs. The failure mode is brittle and sudden. The ETS shear strengthening technique can be used to avoid the occurrence of shear failure of concrete slabs subjected to the load close to supports. It was found that failure mode of concrete slabs were varied from brittle shear failure to ductile flexural failure. It is due to the continuity of shear cracking development was broken by the ETS strengthening method.

(4) In this study, it was found that the material type of ETS strengthening materials cannot influence the behaviour of strengthened test slabs. Interestingly, increasing the diameter of ETS FRP bars resulted in larger ultimate capacity and higher ductility.

(5) Due to the small flexural stiffness of test slabs, the ultimate capacity was enhanced by around 10%. However, the ductility of test slabs was improved significantly. The vertical deflection at the failure was increased by more than 100% and the ductility was increased by more than 200%.

ABSTRACT

The shear span/depth ratio is known to affect the behavior of reinforced concrete (RC) beams. However, for RC beams shear-strengthened with fiber-reinforced polymer (FRP), due to insufficient understanding of its effect, the shear span/depth ratio is not considered in existing design guidelines. This paper focuses on the effect of shear span/depth ratio on the behavior of RC beams shear-strengthened in full-wrapping and U-wrapping CFRP configurations. In total, twelve strengthened beams and six normal beams are tested with shear span/depth ratios from 1.0 to 3.5. The experimental results indicate that the shear span/depth ratio can significantly affect the shear behavior of strengthened RC beams, but in different ways for the two FRP strengthening configurations, especially in the FRP shear contribution and distribution of FRP strain along a critical shear crack. Furthermore, the authors’ experimental results, as well as test results from the literature, are compared to predictions from various design guidelines. For both full-wrapping and U-wrapping configurations, the results show the same trend for our tests and those from the literature.

INTRODUCTION

Full-wrapping and U-wrapping fiber-reinforced polymer (FRP) configurations are two major shear-strengthening schemes in externally bonding (EB-) FRP composites for improving the shear resistance of deteriorated RC beams. In the literature, there are a lot of research results (e.g., Pellegrino and Modena 2002; Chen and Teng 2003a, b; Leung et al. 2007; Chen et al. 2010) showing that the shear strength of reinforced concrete (RC) beams can be substantially increased by full-wrapping or U-wrapping FRP composites working as external stirrups. Both experimental investigations and theoretical analyses have been carried out to explore various issues of RC beams strengthened in shear with EB-FRP. However, a comprehensive investigation covering a wide range of shear span-to-effective depth ratio (also called the shear span/depth ratio, or \(a_v/d\) ratio, where \(a_v\) and \(d\) are respectively the length of shear span and the effective length of a RC beam) is yet to be reported. Although shear span/depth ratio is a very important factor on the shear behavior of RC beams whether they are strengthened or not, only few investigations in the literature (e.g., Khalifa et al. 2000; Boussellam and Chaallal 2006) have tested shear-strengthened members with two or more shear span/depth ratios. Even in these experimental investigations, the effect of shear span/depth ratio was not the major focus. This paper will therefore focus on the effect of the shear span/depth ratio on the shear performances of RC beams strengthened with full-wrapping and U-wrapping CFRP strips. To study the strengthening effect for beams exhibiting various shear failure modes, a wide range of shear span/depth ratios from 1.0 to 3.5 at 0.5 intervals will be considered. After a description of the experimental program, the test results will be presented and discussed. Then, the effects of shear span/depth ratio for the two FRP configurations are compared. Furthermore, our own test results, as well as collected data from the literature, are compared to predictions from various design guidelines.

EXPERIMENTAL DESIGN

A total of eighteen RC beams were tested in the experimental investigation. Six normal RC beams, not strengthened with FRP, were used as control. Six RC members were shear-strengthened with U-wrapping CFRP strips while another six specimens were strengthened in shear with full-wrapping CFRP strips. The RC beams
were either 2,000 or 2,400 mm long. Shorter specimens were prepared for \(a/v > 2.5\), while longer beams were employed for \(a/v < 2.5\). All specimens were designed to fail in shear even after they have been strengthened in shear with CFRP strengthening configuration. The longitudinal steel reinforcement consisted of four reinforcing bars (diameter = 28 mm, yield strength = 450 MPa) at the bottom and two reinforcing bars (diameter = 32 mm, yield strength = 470 MPa) at the top. All specimens were tested under four point bending. One side of the beam (as the un-strengthened zone) was heavily reinforced in shear with stirrups (12-mm diameter at 85-mm spacing, yield strength = 390 MPa), whereas the other side (as the strengthened zone) was reinforced with 6.5-mm diameter stirrup (yield strength = 310 MPa) at 160-mm spacing. Experimental investigations would focus on the weaker side, which was expected to undergo shear failure even after strengthening with CFRP strips. In the un-strengthened zone, the shear span \(a_s\) is equal to \(a\) for beams with \(a/v \leq 2.0\); for beams with \(a/v > 2.5\), \(a_s\) will be fixed at 2\(d\). The CFRP strips were bonded discretely over the strengthened zone in a full-wrapping or U-wrapping strengthening configuration, where all strips were 60-mm wide and applied at 150-mm spacing (center-to-center). The effective thickness of CFRP layer was 0.11 mm. The tension strength of CFRP sheet is 4200 MPa, the tensile modulus is 235 GPa, and the elongation is 1.8%. The concrete for casting the beams was supplied by a local ready-mix producer. The shorter and longer beams were cast separately, and the average compressive strength from concrete cubes was 47 and 55 MPa, respectively. Strain gauges were glued on the longitudinal/transverse steel reinforcements and the concrete surface. To have good estimates of the effective strains of CFRP strips, which govern their resistance to shear failure, a series of strain gauges were installed on each CFRP strip to record, as accurately as possible, the strain level at the point intersected by the major shear crack. The load was applied by a hydraulic testing machine with the loading speed rate maintained at 0.01 mm/s. During testing, a data logger was used to record and store the test data, which were later transmitted to a computer for further processing.

**TEST RESULTS AND ANALYSIS**

**Overview of Experimental Observation**

In the four-point bending test, the twelve RC beams shear-strengthened with full-wrapping and U-wrapping CFRP strips were observed to fail in different shear failure modes with increasing the shear span/depth ratio, which can be classified into deep-beam failure, shear-compression failure, and shear-tension failure according to conventional reinforced concrete theory. The variation of shear failure mode with shear span/depth ratio is similar to that of the corresponding control specimens. Generally speaking, most of the FRP strips failed in debonding for U-wrapping FRP configuration, and in rupture for full-wrapping strengthening configuration. FRP strips not intersected by the critical shear crack (e.g., the strips close to the support) might not be damaged at the ultimate state of RC beams. Also, in the U-wrapping FRP configuration, a small number of strips close to the support might fail in complete/partial rupture as shear cracks intersect with the strip at a position near the bottom of the beam, where the FRP is effectively anchored through U-wrapping.

![Figure 1 Shear capacity and FRP shear contribution of all specimens](image_url)

**Shear Capacity and FRP Shear Contribution**

In previous experimental investigations, FRP strip were often considered as external stirrups in shear-strengthened beams (Khalifa et al. 2000; Triantafillou and Antonopoulos 2000), where the FRP shear contribution is obtained by subtracting the results for the control beam from the corresponding strengthened beam. Based on this approach,
the FRP shear contributions of all specimens are calculated and shown in Figure 1. For convenience of analysis, the corresponding strengthening percentage increments are also presented in Figure 1.

As shown in Figure 1, both U-wrapping and full-wrapping FRP strips can improve the shear resistance of RC beams, but the effectiveness varies with shear span/depth ratio. Furthermore, the full-wrapping configuration is more effective than the U-wrapping configuration for a given shear span/depth ratio. Although the improvements of shear capacities for the two FRP strengthening configurations are different, the trends of FRP shear contributions in both cases show a similar parabolic shape, increasing from the minimum value for the deep beam to a maximum value for a beam with medium span/depth ratio before decreasing with further increase in span/depth. This trend indicates that FRP shear contribution for both U-wrapping and full-wrapping configuration will vary while the shear failure mode changes with shear span/depth ratios.

The trend of FRP shear contribution with increasing shear span/depth ratio could be explained by considering three major aspects. First, as FRP strips play different roles in resisting shear under various shear failure modes, the FRP shear contribution varies with shear span/depth ratio. For a deep beam, the concrete arch carries most of the applied load and FRP strips act as hoops to restrict the deformation of the beam web in the vertical direction. FRP strips are hence not contributing much to the shear resistance. Second, the angle of the critical shear crack can affect the effectiveness of FRP strips in shear resistance. For a smaller shear span/depth ratio, the angle of the critical shear crack with respect to the fiber orientation is smaller, so the stress along the fiber direction is less effective in controlling the opening of the crack. Third, the FRP strips intersected by the critical shear crack will provide most of the FRP shear contribution, whereas the strips outside the critical shear crack should play an insignificant role in resisting shear. A similar explanation has been provided by Cao et al. (2005) and Li and Leung (2016).

**COMPARISON BETWEEN TEST RESULTS AND DIFFERENT DESIGN GUIDELINES**

The accurate prediction of the FRP shear contribution $V_f$ is a key issue for the development of design guidelines. In this paper, five existing design guidelines, i.e. ACI 440.2R (2008), FIB-TG 9.3 (2001), JSCE (2001), GB 50608 (2010), and CSA S806 (2012), are employed to obtain the FRP shear contribution for comparison with our own results, as well as the collected data from the literature. In the calculations, all safety factors will be taken out of the design equations because different design guidelines have different underlying theories and different ways of including safety factors. Apart from the safety factors, other limits on the strengthening effect will still be maintained.

**Comparison between Our Results and Predictions from Design Guidelines**

The experimental results (**abbr. Exp**) and predicting values (**abbr. Pre**) from the five design guidelines for the full-wrapping and U-wrapping configuration are shown in Figure 2. As shown in Figure 2, regardless of the design guideline adopted, the Pre/Exp ratio of FRP shear contribution $V_f$ is clearly dependent on the shear span/depth ratio, especially when $a_v/d \leq 1.5$ and $a_v/d \geq 3.0$. For both FRP configurations, the distribution trend of Pre/Exp ratios always decreases from the higher values for deep beams to the minimum values for medium shear spans before increasing with the shear span/depth ratio, but the curvatures of fitting lines are different for the two FRP configurations. For U-wrapping configuration, all the design guidelines severely overestimate the shear resistance of FRP strip for the deep beam. In the high shear span/depth ratios ($a_v/d \geq 3.0$), there is still a potential risk of overestimating the FRP shear contribution with the JSCE, FIB and GB design guidelines, where the Pre/Exp ratio is very close to or over 1.0. For full-wrapping FRP configuration, for $a_v/d = 1.0$, the FRP shear contributions predicted from two design guidelines, ACI and CSA, are conservative, whereas the other three design guidelines overestimate the experimental results. For shear span/depth ratio $a_v/d$ not less than 1.5, all the five design guidelines can predict conservatively the FRP shear contributions. However, the predicted $V_f$ from ACI and CSA guidelines seem to be overly conservative due to the individual limitations, such as limiting of effective FRP strain to 0.004 in ACI 440.2R and the limiting of FRP tensile strength to 0.005$E_f$ in CSA S806.

The above comparative analysis indicates that the predictions of the FRP shear contribution $V_f$ from existing design guidelines are affected strongly by the shear span/depth ratio, so the shear span/depth ratio shall be taken into account in design equations. Furthermore, there will be a potential risk in overestimating the FRP shear contribution for beams with low $a_v/d$ ratios (especially for deep beams) from existing design equations. Such a trend of the predicted FRP shear contribution from the five design guidelines can be explained by the following two major reasons. First, the shear strength models of these five design guidelines are all based on the traditional truss model, which is suitable for slender RC beams rather than for deep beams. As the diagonal tension reinforcement (which is provided by steel stirrups and FRP strips) has a relatively small effect on the concrete arch action for a deep beam, its contribution could be very low. Second, in these design guidelines (except for CSA
design guideline), the inclination angle of critical shear crack $\theta$ is assumed equal to 45°. Actually, the angle $\theta$ changes with the shear span/depth ratio, which is a function of section depth, reinforcement properties, and the internal forces (e.g., moment, shear and axial force) acting on it according to the modified compression field theory (MCFT) (Razaqpur and Spada 2015). Specifically, with changing shear span/depth ratio, the angle $\theta$ can be below or above 45°, which would lead to higher or lower prediction of the FRP shear contribution $V_f$.

**Comparison between Collected Data and Predictions from Design Guidelines**

To better understand the effect of shear span/depth ratio on the differences between predictions from existing design guidelines and collected data from the literature. Fifty-two test results ($1.50 \leq a_v/d \leq 3.80$) are chosen for U-wrapping configuration, while forty-three data ($1.43 \leq a_v/d \leq 3.00$) are chosen for the full-wrapping case.

For U-wrapping FRP configuration, the trend of the Pre/Exp ratio of $V_f$ between predictions from the five design guidelines and collected data shows high variations as FRP debonding failure is also sensitive to other factors such as member size, properties of materials and bond-slip behavior between FRP and concrete. For the FIB, JSCE and GB design guidelines, most of the Pre/Exp ratios are over 1.0 [Figures 3(b) - (d)]. The other two design guidelines often overestimate the shear resistance of FRP for $a_v/d \leq 2.0$ and $a_v/d \geq 3.00$ [Figures 3(a) and (e)]. For full-wrapping FRP configuration, as shown in Figure 4, both the ACI and CSA design guidelines can provide conservative predictions for most of the experimental data over the range of shear span/depth ratios considered. However, the predicted $V_f$ from these guidelines seem to be overly conservative especially in the range of $a_v/d$ ratio from 2.5 to 3.0. The predictions from the FIB, GB and JSCE guidelines overestimate the FRP shear contributions in many of the forty-three experimental results, especially for $a_v/d \leq 2.0$ and $a_v/d \geq 2.7$ [Figures 4(b) - (d)]. This clearly indicates a potential risk of overestimating the FRP shear contributions for both lower and higher $a_v/d$ ratios with these guidelines.

![Figure 2 Comparison of $V_f$ between our test results and predictions from design guidelines](image-url)
Figure 3 Comparison of $V_f$ between collected data and predictions from design guidelines (U-wrapping sheets)

Figure 4 Comparison of $V_f$ between collected data and predictions from design guidelines (full-wrapping sheets)
CONCLUSIONS

The experimental investigation in this thesis focuses on the effect of shear span/depth ratio on the mechanical behavior of RC beams shear strengthened with both U-wrapping and full-wrapping FRP configurations. The following conclusions can be drawn from the test results and experimental analysis:

1. EB-FRP strengthening technique can improve effectively the shear behavior of RC beams, especially the shear capacity. The improvement of shear capacity in the full-wrapping configuration is more significant than that in U-wrapping configuration.
2. The FRP shear contribution is significantly affected by the shear span/depth ratio not only in U-wrapping but also in full-wrapping configurations. The trend of FRP shear contribution shows a near-parabolic shape with increasing shear span/depth ratio from 1.0 to 3.5, which increases from the minimum value for a deep beam to the maximum value for the beam with medium span/depth ratio before decreasing with further increase in shear span/depth ratio.
3. For both FRP configurations, the predicted shear capacity from five existing design guidelines is all affected strongly by the shear span/depth ratio. In all five design guidelines, there is a potential risk in overestimating the FRP shear contribution for beams with lower a/d ratios (especially in deep beams).

ABSTRACT
This paper presents the results of an experimental campaign carried out to investigate the behavior of reinforced concrete (RC) beams strengthened in shear using externally bonded advanced composite materials. In order to compare their performance, two different types of composite materials were used to strengthen the beams: fiber reinforced polymer (FRP) and fiber reinforced cementitious matrix (FRCM) composites. The beams were then tested in four-point bending scheme, and measurements regarding applied load and mid-span displacements were acquired. Observations regarding the gain in shear strength, influence on mid-span deflection and ductility, and comparison of the performance of the two strengthening systems are provided. For specimens strengthened with FRCM composite, the contribution to the shear strength provided by the FRCM strengthening system is compared with the value predicted by an analytical model found in the available literature.

KEYWORDS
FRP, FRCM, reinforced concrete, shear, strengthening.

INTRODUCTION
The growing necessity of strengthening existing reinforced concrete (RC) structures due to their deterioration with age or change in applied loads due to use modification or upgrading to currently available design codes has generated a great interest in researchers to develop time/cost efficient strengthening techniques. Among these techniques, Fiber Reinforced Polymer (FRP) composites have proven to be an adequate solution, providing additional strength for flexural, shear, and confinement applications while minimizing some disadvantages associated with traditional strengthening techniques such as increase in self weight of the structure, undesirable change in stiffness, and handling of heavy steel parts. However, some drawbacks of the use of FRP composites, linked mainly to the use of the epoxy resins, have been reported (Al-Salloum et al. 2012). For this reason, advanced composites in which the resin matrix is replaced by a cementitious matrix, known as Fiber Reinforced Cementitious Matrix (FRCM) composites, have recently raised interest in researchers worldwide. Although research performed on the topic is still scarce, the effectiveness of this technique for flexural and shear strengthening and confinement of axially/eccentrically loaded RC elements is confirmed by the available experimental evidence (e.g., Triantafillou et al. 2006; Bruckner et al. 2006, 2008; Blanksvard et al. 2009; Pellegrino and D’Antino 2013; and Ombres 2015).

This paper presents the preliminary results obtained from an on-going experimental investigation carried out at the University of Padua (Italy) on the behavior of RC beams strengthened in shear using externally bonded FRCM composites. The effectiveness of the FRCM composites in providing additional shear strength to RC beams is discussed and also compared with the effectiveness of FRP composites. Furthermore, the predicted contribution to the shear strength by the FRCM strengthening system computed by the model proposed by Triantafillou and Papanicolaou (2006) is compared to the experimental results.
EXPERIMENTAL PROGRAM

The experimental program carried out at the Construction Materials Testing Laboratory of the University of Padua (Italy) included the testing of six RC beams with the geometry and configuration of internal longitudinal and transverse reinforcement presented in Figure 1a. The longitudinal reinforcement ratio \( \rho_l = A_s / b w \) (\( A_s \)=longitudinal reinforcement area, \( b_w \)=beam width, \( d \)=beam effective depth) was 0.057. The beams were cast in two different batches. The average concrete compressive strength for the different batches, determined by testing 3 cylinders with dimensions \( \phi 100 \times 200 \) mm in accordance with EN 12390-3 (2009) within +/- 4 days of the day of testing, was 23.3 MPa and 21.3 MPa. The \( \phi 8 \) mm, \( \phi 16 \) mm, and \( \phi 26 \) mm deformed reinforcing steel bars had a measured yield strength (average of three specimens for each diameter) of 527 MPa, 535 MPa, and 545 MPa, respectively. The beams were tested using a four-point bending scheme with a total span length of 2.70 m, as shown in Figure 1. The shear span-to-depth ratio (\( a/d \)) was equal to 3.0. The test was controlled by slowly increasing the force. The loading was paused at different increments to mark cracks and take photographs.

The beams were designated according to the following convention:

\[ S1 - XXXX - F# - UY \]

where \( S1 \) corresponds to the stirrup spacing in the tested shear span (300 mm, center to center), \( XXXX \) defines the type of strengthening system (control, FRP, or FRCM), \( # \) is the type of fiber (1=carbon mesh, 3=carbon net, and 4=steel net), \( U \) indicates U-wrapped composite configuration, and \( Y \) is related to the use of composite anchors (N=no anchors, A=anchors). Table 1 presents the characteristics of the beams tested.

The beams were strengthened with a U-wrapped configuration with one layer of fibers. Before installing the FRP/FRCM system, the beam surface was subjected to mechanical grinding, the corners of the specimens were rounded to a radius of approximately 20 mm, and any loose sand grains were removed. For the FRCM system, the concrete surface was wetted and the first layer of cementitious matrix was immediately applied. The beams were strengthened in shear within just one of the shear spans, with a continuous strip (see Figure 1b). In order to force the shear failure in the designated span, the opposite shear span of the beam had steel stirrups spaced 75 mm (see Figure 1a).

The elastic modulus, ultimate tensile strength, overall area weight, and thickness of the fibers reported by the manufacturer are presented in Table 2 (G&PIntech 2016). For specimens strengthened with FRCM composite, the cementitious matrix was applied in layers of approximately 2 mm thickness. Three 40x40x160 mm samples taken from the cementitious matrix were tested +/- 4 days from the day of testing of the beams. The average flexural strength $f_{cf}$ (EN 12390-5 2009) and average compressive strength $f_{cm}$ (EN 12390-3 2009) were equal to 6.33 MPa (COV=0.15) and 45.2 MPa (CoV=0.039), respectively.

*Equivalent nominal thickness (mm/m)

For beams S1-FRCM-F3-UA and S1-FRCM-F4-UA, spike anchors comprised of dry aramid fibers were used to in an attempt to anchor the composite to the beam side faces. The anchors were placed in holes drilled through the entire cross section of the beam located 100 mm from the top of the beam. After placing the anchors, the holes were filled with epoxy resin, and the anchors were fanned out and attached to the FRCM system using epoxy resin.

**RESULTS AND DISCUSSION**

Figure 2 shows the applied load (P) versus mid-span displacement ($\Delta$) curves for all specimens. The maximum load ($P_{max}$), the nominal shear strength ($V_n=0.5P_{max}$, neglecting the effects of self weight), the displacement at mid-span corresponding to $P_{max}$ ($\Delta P_{max}$), and the failure mode of each beam are summarized in Table 3. The additional shear strength provided by the strengthening system ($V_f$) and its efficiency relative to the nominal shear strength of the control beam ($V_f/V_{n,control}$) are also included in Table 3. $V_f$ is computed as the total shear strength of a given strengthened specimen minus the shear strength of the control specimen (S1-Control).

The initial stiffness of the six beams was similar as shown in Figure 2. However, for the control beam, there is a reduction of the stiffness after a level of load associated with cracking of the concrete ($P=150$ kN) that is not noticeable in the other beams. Irrespective of the composite system (FRP, carbon-FRCM, or steel-FRCM), the curves for the strengthened specimens are similar up to failure, with a significant reduction of the stiffness close to $P_{\text{max}}$.

**Additional shear strength provided by the strengthening system**

From Table 3, it can be seen that using FRP composite the failure mode of S1-CONTROL was transformed from shear to flexure, with an increase in strength of $V_f/V_{n\text{-control}}=0.47$. All specimens strengthened with FRCM jackets failed in shear and had an increase in shear capacity ranging from 24% to 30%. Specimens with steel fibers had a slightly larger increase of $V_f$ than specimens with carbon fibers. In addition to the increase in shear strength, all strengthened beams had an increase of $\Delta P_{\text{max}}$ relative to the control beam.

The use of anchors resulted in a negligible increase of the shear strength for strengthened beams for both types of fibers, but allowed for attaining larger values of $\Delta P_{\text{max}}$ when compared with the corresponding beams without anchors. These observations are in agreement with the results of Baggio et al. (2014), who utilized anchors similar to those used in this study and witnessed a 3% increase in the strength when comparing FRCM strengthened beams with and without anchors. This behavior can be explained by the fact that some FRCM composites exhibit slippage of the fibers relative to the cementitious matrix during the debonding process (D’Antino et al. 2015; Tetta et al. 2015).

**Failure mode and cracking pattern**

Beam S1-CONTROL presented a typical beam shear failure characterized by the formation of a main diagonal crack as shown in Figure 3. It is important to notice that besides the main crack, minor diagonal cracks distributed along the shear span also formed. For beam S1-FRP-F1-UN, flexural failure caused by concrete crushing was observed. For this specimen, it was not possible to identify cracks in the strengthened shear span, although some shear cracks were recognized in the unstrengthened shear span of the beam.

In Figure 3, the cracking patterns for the beams strengthened with FRCM composites are also included. Unlike beam S1-FRP-F1-UN, cracking was visible on the surface of the FRCM jackets. This is an advantage of the FRCM system over the FRP system because it allows for immediate and easy inspection of damaged regions (Triantafillou and Papanicolaou 2006).
Beam S1-FRCM-F3-UN failed by diagonal tension. Local detachment of the entire thickness of the jacket close to the point of application of the load and fiber slippage along the main crack were observed. The inclination of the main diagonal crack was less steep than that of the control beam, and the distribution of the cracking was located in a smaller area. For beam S1-FRCM-F3-UA, the diagonal crack formed around the anchors, and composite detachment was precluded. Although there was not a significant increase in the shear strength, the width of the cracks was larger than those observed in the corresponding beam without anchors, which might explain the larger value of $\Delta P_{\text{max}}$ attained.

For beam S1-FRCM-F4-UN, failure was caused by detachment of the composite system. It is important to notice that the cracking pattern reflected in the steel FRCM jacket is different than those observed by the control specimen and the beams strengthened with carbon FRCM composite. However, after the FRCM jacket was removed, it was observed that diagonal cracks formed in the beam beneath the composite (see Figure 4). In Figure 4, it is also observed that above the diagonal crack, the fibers and the external matrix layer debonded from the internal matrix layer. However, below the diagonal crack, the entire FRCM jacket detached from the concrete substrate. Beam S1-FRCM-F4-UA failed by diagonal tension and local detachment of the FRCM system between the anchors.

![Figure 4 Cracking pattern for beam S1-FRCM-F4-UN](image)

**COMPARISON BETWEEN EXPERIMENTAL AND ANALYTICAL RESULTS**

The model proposed by Triantafillou and Papanicolaou (2006) to predict the additional shear strength provided by the FRCM system ($V_{f\text{-pred}}$, see Eq. 1) was first presented for fully wrapped rectangular beams without anchors and then extended for U-wrapped elements (Tzoura and Triantafillou, 2015). The effective stress in the FRCM system ($\sigma_{\text{eff}}$) is computed based on the average strain reached across the shear crack, taken as 50% of the ultimate strain of the bare fibers, $\varepsilon_{fu}$:

$$
V_{f\text{-pred}} = \rho_f \sigma_{\text{eff}} b_w d_f; \quad \sigma_{\text{eff}} = 0.5E_f \varepsilon_{fu}
$$

where $d_f$ is the effective depth of the jacket, taken as 0.9d, and $\rho_f$ is FRCM reinforcement ratio ($2t_f/b_w$, $t_f$= nominal fiber thickness). In Table 4, the values of $V_{f\text{-pred}}$ computed with Eq. 1 for the strengthened beams without anchors are presented along with the variables used for their calculation:

<table>
<thead>
<tr>
<th>Beam</th>
<th>$b_w$ (mm)</th>
<th>$d$ (mm)</th>
<th>$d_f$ (mm)</th>
<th>$t_r$ (mm)</th>
<th>$\rho_f$</th>
<th>$\sigma_{\text{eff}}$ (MPa)</th>
<th>$V_{f\text{-pred}}$ (kN)</th>
<th>$V_d/V_{f\text{-pred}}$</th>
</tr>
</thead>
<tbody>
<tr>
<td>S1-FRCM-F3-UN</td>
<td>150</td>
<td>250</td>
<td>225</td>
<td>0.047</td>
<td>0.0006</td>

<td>145.8</td>
<td>0.24</td>
</tr>
</tbody>
</table>

It can be seen that the model overestimates the additional shear strength provided by the system, which indicates that the level of strain/stress predicted by the model is overestimated. The overestimation is higher for the beam strengthened with steel fibers. At this point, it is important to point out that the model was developed for FRCM composite with carbon fibers, and therefore, its applicability for other fibers needs to be studied and validated.
CONCLUSIONS

- Using FRP composites was able to change the shear failure of the control beam into a flexural failure for the strengthened beam, providing an increase in the beam capacity of 47%. There was also an increase in the displacement at mid-span corresponding to maximum load.
- Beams strengthened with carbon-FRCM composites showed an increase in shear strength of 24% and 26% for specimens without and with anchors, respectively. For beams strengthened with steel-FRCM composites, the increase was 30% irrespective of the use of anchors.
- The use of anchors did not result in a significant increase in the shear strength for either type of FRCM composites. However, strengthened beams with anchors showed larger displacements at mid-span.
- Unlike with FRP composites, cracking was visible on the surface of the FRCM jackets. However, for the case of steel-FRCM composites, after the removal of the jacket, it was observed that the cracking pattern on the surface of the jacket was different from that observed in the concrete beneath it.
- For FRCM strengthened beams without anchors, the type of failure was different depending on the type of fiber used. For carbon fibers, local detachment of the entire thickness of the jacket from the concrete substrate was observed. For steel fibers, detachment of the fibers and external matrix layer or of the entire composite from the substrate was witnessed.
- The model by Triantafillou and Papanicolaou (2006) overestimated the additional shear strength provided by the FRCM system for the beams presented in this paper. A larger overestimation was observed for steel FRCM than carbon FRCM, which might be related to the different debonding failure modes observed.

ABSTRACT

Many existing reinforced concrete (RC) deep beams have been found to be shear-deficient due to insufficient shear reinforcement, substantial increment in service load, and severe environmental conditions, and thus need to be repaired. And externally bonded fiber reinforced polymer (FRP) provides an excellent solution. However, up to date, limited studies have been carried out to investigate the shear behavior of deep beams strengthened in shear with FRP composites. This paper presents a new analytical model based on strut-and-tie method for the shear strength prediction of FRP-strengthened RC deep beams. In the proposed model, the Kupfer-Gerstle biaxial failure envelope is adopted to predict shear failure of the shear span region under a stress state of biaxial tension and compression by either the compressive crushing of the strut or the diagonal tensile cracking of concrete. And the contribution of the FRP composite and the shear reinforcement in the deep beam are taken into account by increasing the nominal tensile strength of the concrete. A test database is also assembled to verify the proposed model, which demonstrates its simplicity and effectiveness.

Fiber-reinforced polymer (FRP), RC deep beams, strengthening, shear strength, biaxial compression-tension failure envelope.

INTRODUCTION

Deep beams are those members whose clear spans do not exceed four times the overall member depth, or regions of beams with concentrated loads within twice the member depth from the support (ACI-318 2008). There are several applications of RC deep beams, such as transfer girders in tall buildings, wall of water tanks, offshore structures and foundations (Zhang et al. 2004). Many existing RC deep beams have been found to be shear-deficient due to insufficient shear reinforcement, substantial increment in service load, and severe environmental conditions, and thus need to be repaired.

Externally bonded fiber reinforced polymer (FRP) composites provides an excellent solution for such an issue, due to their high strength-to-weight ratio, excellent corrosion resistance, and ease for installation. Up to date, however, most research on FRP shear strengthening has been focused on regular beams (Lee et al. 2011), and limited studies have been carried out on FRP-strengthened deep beams in shear (Zhang et al. 2004; Islam et a. 2005; Lee et al. 2011), especially for the theoretical research based on rational models. A series of experimental tests carried out by Zhang et al. (2004) to demonstrate the feasibility of using an externally bonded CFRP system for increasing the shear strength of deep beams and a corresponding design method was also developed. Islam et al. (2005) also carried out a series of experimental tests to improve shear behaviour of deficient deep beams using an externally bonded FRP system and found that the shear strength of the deep beam was enhanced. Recently, Lee et al. (2011) also investigate the performance of shear-deficient RC T-section deep beams strengthened with CFRP sheets through tests, and concluded from the test results that the key variables of strengthening length, fiber direction combination, and anchorage have significant influence on the shear performance of strengthened deep beams. Code design methods were also adopted to evaluate the shear strengths.

This paper presents a new analytical model based on strut-and-tie model (STM) for the shear strength prediction of FRP-strengthened RC deep beams. In the proposed model, the Kupfer-Gerstle biaxial failure envelope (Kupfer and Gerstle, 1973) is adopted to predict shear failure of the shear span region under a stress state of biaxial tension and compression by either the compressive crushing of the strut or the diagonal tensile cracking of concrete. And the contribution of the FRP composite and the shear reinforcement in the deep beam are taken into account by
increasing the nominal tensile strength of the concrete. A test database is also assembled to verify the proposed model.

**STRUT-AND-TIE MODEL FOR RC DEEP BEAMS**

A STM for simply supported RC deep beams under two-point symmetrical top loading is given in Fig. 1, modified from STM for pre-tensioned concrete (PC) deep beams (Wang and Meng 2008), which consists of the upper nodal zone A, the bottom nodal zone B, the strut AB, the concrete horizontal strut and the tension tie. The failure of the strut AB is identified as the ultimate limit state of the model. In the model, \( h_0 \) is the effective depth of the beam; \( a \) is the shear span measured between the concentrated load and the support centre; \( e \) is the distance from the support centre to the beam end (Fig. 1).

**Basic Assumptions and Failure Criterion**

The bottom nodal zone B suffers the greatest compressive and tensile stresses simultaneously, and thus it would determine the shear strength of the model. Therefore, in the proposed model, it is also assumed that the shear strength of the FRP-strengthened RC deep beams is reached when the stresses of concrete at the nodal zone B reach the failure envelope, as previously adopted for PC deep beams (Wang and Meng 2008). Besides, the reinforced concrete in the deep beam is idealized as an equivalent homogenous material in a biaxial plane stress state and the contribution of the FRP and web steel reinforcement is accounted for by increasing the nominal tensile strength of the idealized homogenous material. This approach has been used to predict the shear strength of PC deep beams and RC beam-column joints (Wang et al. 2012).

It is well known that for concrete in a biaxial stress state, the appearance and widening of tensile cracks in concrete lead to deteriorations of its compressive strength along the crack direction. To account for the softening effect, Kupfer and Gerstle (1973) proposed the Kupfer-Gerstle’s biaxial compression-tension failure criterion (Fig. 2), which seems either more convenient than the principal tensile strain methods, or more theoretical than the efficiency factor methods. Considering the fact that the tensile stress is great enough at shear failure, the small curved segment, AC, (Fig. 2) of the failure criterion is ignored, while the BC segment (Fig. 2) is utilized to account for the effect of tension on the compressive strength of concrete in the nodal zone B in the proposed model, just expressed as below.

\[
f_{t,i} - 0.8 \frac{f_{c}}{f_{c}^{'}} = 1
\]

(1)

where \( f_i \) and \( f_c \) are respective the principal tensile and compressive stresses, acting perpendicular and along to the axis of the diagonal strut AB, respectively, and the tensile stress is taken as positive; \( f_c^{'} \) is the concrete compressive strength of cylinder, representing the maximum compressive strength in the \( f_i \) direction; \( f_{t,i} \) is the nominal tensile strength of concrete considering both contributions from the steel shear reinforcements and the FRP composite in the \( f_i \) direction (Fig. 3). Detailed derivation information for each term will be given in the following text.
Determination of Terms $f_1$, $f_2$ and $f_{t,n}$

From the equilibrium of forces at the nodal zone $B$ (Fig. 1),

$$F_c = V_n \sin \theta$$  \hspace{1cm} (2)

$$T = F_c \cos \theta = V_n \tan \theta$$  \hspace{1cm} (3)

where $F_c$ and $T$ are the forces in the strut and bottom tension tie, respectively; $\theta$ is the inclined angle of the strut (Fig. 1).

Thus, from Eq. (2), the principal compressive stress, $f_2$, in the direction of the strut at the bottom nodal zone $B$ (Fig. 3) can be computed by

$$f_2 = \frac{F_c}{A_{str}}$$  \hspace{1cm} (4)

where $A_{str}$ is the cross-sectional area of the strut at the nodal zone $B$ and is defined as

$$A_{str} = b_w (l_a \cos \theta_s + l_b \sin \theta_s)$$  \hspace{1cm} (5)

where $b_w$ is the width of the web; $l_a$ is the depth of the bottom nodal zone $B$; $l_b$ is the width of the support-bearing plates (Fig. 1).

As for the principal tensile stress, $f_1$, at the bottom nodal zone $B$ (Fig. 3), it was calculated as follows, as adopted for PC deep beams (Wang et al. 2008)

$$f_1 = \frac{kT \sin \theta_s}{A_c / \sin \theta_s} = kp$$  \hspace{1cm} (6)

where $p$ is the average equivalent tensile stress across the strut and $A_c$ is the cross-sectional area of beam. $k = 4$ for the case of bottom longitudinal reinforcement which induces a linear stress distribution along the strut (Wang et al. 2008). As for web steel reinforcement and FRP composites, which is commonly uniformly distributed, it is noteworthy that the rectangular stress block will be induced along the strut, that is, $k = 1$ can be obtained without any stress distribution assumption.

In a similar fashion as Eq. (6), the combined tensile capacity, $f_{t,n}$, at the bottom nodal zone $B$ (Fig. 3) can be expressed as below, in which the first, second, third and fourth terms are respectively the contributions of the
bottom longitudinal reinforcement, \( f_{ls} \), web steel reinforcements (horizontal, vertical or inclined), \( f_{ws} \), the FRP, \( f_{frp} \), and the concrete, \( f_{cu} \),

\[
f_{tu} = f_{ls} + f_{ws} + f_{frp} + f_{tc}
\]

\[
f_{tu} = \frac{kA_{j}f_{j} \sin \theta_{j}}{\sum_{i} A_{i} / \sin \theta_{i}} + \frac{A_{w}f_{yw} \sin (\theta_{w} + \theta_{n})}{A_{w} / \sin \theta_{i}} + \sum_{i} A_{j}E_{ij} \epsilon_{le,i} \sin (\theta_{j} + \theta_{i}) + f_{ct}
\]

where \( A_{i} \) and \( A_{w} \) are the respective total areas of longitudinal and web reinforcement crossing the strut; \( f_{j} \) and \( f_{yw} \) are the respective yield strengths of longitudinal and web reinforcement; \( \theta_{e} \) is the angle of the direction of the resultant force of all web reinforcement (vertical, horizontal or inclined) crossing the strut to the horizontal axis (Fig. 1); the contribution of concrete to the nominal tensile strength, \( f_{cu} \), is given by ACI318 (2008):

\[
f_{cu} = 0.556 \sqrt{f_{c}^{0}}
\]

In Eq. (7), \( A_{ij} \) and \( E_{ij} \) is the cross-sectional area and elastic modulus of the FRP strips crossing the strut at an angle \( \theta_{ij} \) with respect to the horizontal axis, respectively. The FRP contribution, \( f_{frp} \), can be estimated as the sum of the contributions of the strips in different directions. As shown in Fig. 3, the total tension force in the generic direction can be expressed by

\[
F_{ij} = A_{ij}E_{ij} \epsilon_{le,ij}
\]

where \( A_{ij} \) can be expressed by Eq.(10),

\[
A_{ij} = 2 \frac{h_{le,i} (\cot \theta_{e} + \cot \theta_{ij})}{s_{ij}} w_{ij} F_{ij}
\]

Where \( h_{le,i} \) is effective height of the strip bonded on the web at ultimate; \( w_{ij} \) is the strip width; \( s_{ij} \) is the distance between two strips; \( t_{ij} \) is the equivalent thickness of strips (Fig. 4).

In Eq. (7), \( \epsilon_{le,ij} \) is the effective FRP strain at ultimate and can be computed by Eq. (11), which was originally developed for intermediate crack debonding in FRP-strengthened RC beams (Teng et al. 2004).

\[
\epsilon_{le,ij} = 0.36 \tau_{max,i} / \sqrt{t_{ij} E_{ij}}
\]

\[
\tau_{max,i} = 1.5 \beta_{w,i} f_{cu}
\]

\[
\beta_{w,i} = \frac{2.25 - w_{ij} / (s_{ij} \sin \phi_{ij})}{1.25 + w_{ij} / (s_{ij} \sin \phi_{ij})}
\]

In the case of continuous FRP composite (i.e. sheet), it can be taken to be composed of strips with no space between them, and thus the above same derivation can be applicable just with \( s_{ij} \) equal to \( w_{ij} \).

In Eq. (7), it is assumed that the web steel reinforcements have reached their respective yield stresses in calculating the nominal tensile strength of concrete. The simple summation of the four components as proposed herein leads to only slight underestimation with an acceptable overall accuracy as shown later in the paper.

**Shear Strength of FRP-Strengthened RC Deep Beams**

From Eqs. (1) ~ (11), the following expression can be derived for \( V_s \):

\[
V_s = \frac{1}{k \sin 2\theta_{k} + 0.8 \frac{2f_{tu} A_{k}}{f_{c} A_{w} \sin \theta_{i}}}
\]
Besides, from the equilibrium of forces at the nodal zone A (Fig. 1),

\[ b_n f_c' = F_c \cos \theta_s \] (13)

Substituting for \( F_c \) from Eq. (2), the depth of the nodal zone A, \( l_c \), can be derived:

\[ l_c = \frac{V_n}{b_n f_c' \tan \theta_s} \] (14)

\( \theta_s \) can be computed from

\[ \tan \theta_s = \frac{h - \frac{l_a}{2} - \frac{l_c}{2}}{a} \] (15)

From Eqs. (14) and (15), the term \( l_c \) cannot be determined initially, so an iterative procedure is required. For convenience and simplicity, the interactive procedure can be simplified by assuming \( l_c = l_a \), and the error introduced in \( V_n \) is generally less than 2%, which is in accordance with the findings of previous researchers [Wang and Meng 2008].

From above all, the steps for determining the nominal shear strength, \( V_n \), can be summarized as follows:

Step 1. Determine \( \theta_s \) from Eq. (15), assuming \( l_c = l_a \), where \( l_a = 2(h - h_0) \).

Step 2. Determine \( f_{ts} \) from Eq. (7).

Step 3. Calculate \( V_n \) from Eqs. (12).

**VERIFICATION OF THE PROPOSED SHEAR STRENGTH MODEL**

The proposed model was validated using 20 simply supported FRP-strengthened RC deep beams from the literature (Zhang et al. 2004; Islam et al. 2005). All specimens have a rectangular cross-section, and eventually failed in shear with or without FRP debonding. They had a compressive cylinder strength varying from 38MPa to 43 MPa, an overall depth between 229 mm and 800 mm, and a shear span to depth ratio, \( a/h_0 \), from 0.81 to 1.88. The vertical and horizontal web reinforcement ratios ranged from zero to 0.2%, and zero to 0.2%, respectively. Different CFRP systems have been used to strengthen the deep beams, such as fibre wrap, strips and grids.

The test shear force, \( V_{n, test} \), and the model prediction, \( V_{n, model} \), are shown in Fig. 5 for the proposed model. The test-to-predicted average strength ratio (AVG) and its coefficient of variation (COV) are 1.08 and 0.119, respectively, which indicates that the prediction is not only accurate, consistent, but also safe. And it further indicated that the assumptions adopted for them are sufficiently accurate for the model predictions.

![Figure 5 V_n, test vs. V_n, model for proposed model](image-url)
CONCLUSIONS

This paper has proposed a modified strut-and-tie model for predicting shear strength of FRP-strengthened RC deep beams. A simple and reasonable formula has also been derived based on the Kupfer-Gerstle biaxial failure envelope. The contribution of the external bonded FRP composites is taken into account by increasing the nominal tensile strength of the concrete. And the effective FRP strain is accounted using the approach originally developed for the intermediate crack debonding in FRP-strengthened RC beams. The predictions of the proposed model were evaluated with of 20 test results, which demonstrated that the predictions are accurate, consistent and conservative and further indicated that the assumptions adopted for them are sufficiently accurate for the model predictions.

SHEAR STRENGTHENING OF CONTINUOUS REINFORCED CONCRETE
T-BEAMS USING DEEP EMBEDMENT TECHNIQUE

ABSTRACT

Despite numerous studies, shear behaviour before or after strengthening is still not fully understood, particularly in continuous concrete structures which are the norm. Upgrading shear resistance is altogether more difficult since Externally Bonded Reinforcement (EBR) or Near Surface Mounted (NSM) techniques do not allow the FRP material to be anchored into the compression zone of the T-beams and they cannot be used in cases where the sides of the beams are inaccessible. An innovative retrofit technique, named Deep Embedment (DE) or Embedded Through Section (ETS) technique involves the insertion of FRP/steel bars upwards into vertical or inclined holes which have been drilled from the soffit of concrete beams. In this way, the tension and compression chords of the beams are directly connected while the bars are bonded to the concrete core through adhesives. With this technique strengthening can be done in cases where the webs are inaccessible. Thus the main focus of this study is to significantly contribute to the current knowledge on the behaviour of Reinforced Concrete continuous T-beams strengthened in shear using the DE technique where large shear forces are combined with large negative bending moments. An experimental program consisting of ten two-span continuous T-beams designed to fail in shear was carried out in order to significantly contribute to the current knowledge on the behaviour of RC continuous T-beams strengthened in shear using this technique. Therefore, this paper reports on the test results and on their significance in being able to apply this technique on concrete structures by validating them through adequate analytical models.

INTRODUCTION

Strengthening and rehabilitation of reinforced concrete (RC) structures has become an important part of civil engineering. Gold and Martin (1999) emphasised the significant redundant building space in the UK to be strengthened, much of which was constructed in the 1960s and 1970s. Majority of the buildings from 1980s, 1990s and pre-and-post World War II need to be adapted to meet the requirements of the 21st century. Shortage of structural ductility can be the cause of the brittle and catastrophic failure of a structure. To date recent codes, require a high amount of shear reinforcement which differs from previous codes that did not obtain strict rules for the increased ductility (spacing and lack of concrete cover, irregular stirrups). Triantafillou 1998; Khalifa et al. 1998; Pellegrino and Modena 2002; Chaallal et al. 2011, have shown shear capacity of RC beams can be considerably enhanced by using the Externally Bonded technique (EB). (De Lorenzis and Nanni 2001; Barros and Dias 2005; Chaallal et al. 2011, have presented results in Near Surface Mounted (NSM) technique. These techniques have been developed due to the dangerous and sudden shear failure within reinforced concrete (RC) structures. Lack of understanding concerning the shear behaviour before and after strengthening still exists within research, even though use of FRP reinforcement on the basis of experimental research on simply supported beams is defined by the International and national guidelines and codes (Concrete Society Technical Report 55, ACI, etc.). This is prominent for continuous concrete structures, which have been disregarded in the previous studies. Improvement of shear resistance is altogether more challenging by using Near Surface Mounted (NSM) and Externally Bonded Reinforcement (EBR) techniques which are broadly used for flexural strengthening. It is not realistic choice to full FRP wrapping of beams as they are frequently cast monolithically with the top slab. So, U-wrapping or side-wrapping is sometimes used. It is important to acknowledge truss action may not be mobilised.
due to these methods as FRP material cannot be anchored into compression zones; similarly, the impact of debonding of FRP laminates within low strains raises additional problems. In scenarios were sides of beams are unreachable the external bonding techniques cannot be used. The behaviour within FRP shear reinforcement in the negative moment region in continuous structures has not yet been fully understood; more research has been conducted on simply supported beams employing FRP shear strengthening in the positive moment regions. Large shear forces co-exist with large negative bending moments at the same location; as shown in Figure 1.

An alternative strategy for shear strengthening of reinforced concrete beams with FRP/steel bars, Deep Embedment (DE) or Embedded Through Section (ETS) has been developed (Valerio and Ibell, 2003; Valerio et al. 2009; Chaallal et al. 2011; Mofidi et al. 2012). In this technique, DE bars are epoxy bonded into previously drilled holes (vertical or inclined) through the cross section of the RC beams. In this way, tension and compression chords are directly connected and bond between FRP bars and concrete is much better, which makes this technique superior in comparison with Externally Bonded (EB) and Near Surface Mounted (NSM) methods (Valerio et al. 2009), (Figure 2). The novelty of this research is focused on how the deep embedment technique can be extended in scope by considering strengthening materials other than CFRP (GFRP and steel are being considered), angles of drilling other than vertical (angles at 45 degrees are being considered), and the effects of continuity on shear strengthening. An experimental program consisting of ten RC continuous beams has been conducted in order to provide useful data for a deeper understanding of failure mechanisms in DE strengthened continuous beams as well as the contribution of FRP/steel bars to its total shear capacity. This experimental program will be followed by the development of an analytical model for the calculation of the shear contribution of DE bars. The experimental program will be described in detail and obtained results presented.

**TEST PROGRAM**

The experimental program involves tests performed on ten full-scale reinforced concrete continuous T-beams. They were all designed according to the British Standards (BS 8110-1). Average geometry of typical continuous reinforced concrete beams in buildings was considered while adopting dimensions of the specimens. All test beams have the same dimensions and internal reinforcement as shown in Figure 3 and Figure 4. Their characteristics are summarised in the Table 1. Reinforcement ratios in hogging and sagging zones were kept constant at 1.31% in all beams. Stirrups were spaced at a distance, s=d/2 which corresponds to a shear reinforcement ratio $\rho_{sw} = 0.1\%$.

Materials

The concrete grade was standard C40 grade with water-to-cement ratio of 0.53 and coarse aggregate less than or equal to 20 mm. The average values from the standard cube and tensile splitting tests have shown \( f_{cu} = 60 \) MPa for the concrete compressive strength and \( f_{ct} = 4.86 \) MPa for the concrete tensile strength. Spirally wound sand-coated FRP bars and steel bars have been used for specimen strengthening together with two-component adhesive. Their properties are given in Table 2.

Strengthening of the beams

As illustrated in the Table 3 and Figure 5, all the beams are divided into three groups (I, II and III). The control specimen, not strengthened with Deep Embedded bars, is labelled as CON. Each group consists of three beams strengthened in the shear zone using three different configurations: a) vertical bars spaced at 150 mm (C150, G150 and S150 - one bar between two shear links), b) vertical bars spaced at 75 mm (C75, G75 and S75 - two bars between two shear links) and c) inclined bars (45°) at 150 mm (C150∠, G150∠ and S150∠ - each bar crossing two shear links).

PRESENTATION AND DISCUSSION OF EXPERIMENTAL RESULTS

Table 4 summarizes the experimental results obtained from the tests for all the test groups. The results are presented in terms of the loads attained at failure, experimental shear resistance, deflection at load point and the type of the failure. A simplified methodology accepted in the TR55 (Design guidance for strengthening concrete structures using fibre composite materials) was adopted in order to calculate the contributions of Deep Embedded bars to the shear resistance of the beams. ACI318 (Building Code Requirements for Structural Concrete and Commentary) and BD44 (The assessment of concrete highway bridges and structures) gave the closest predictions for the shear capacities of the beams.

Table 4 shows that the shear-strengthened beams experienced significant increase in capacity with respect to the control beam. In this experimental program, the average increase in shear capacity reached around 55%. Deep Embedment strengthening system can significantly enhance the shear capacity of RC beams even in presence of a minimum amount of transverse steel reinforcement. Decreasing the DE bar spacing resulted in a higher contribution to shear resistance (specimens C75 and G75 failed in flexure). Specimens strengthened with inclined DE bars reached similar ultimate capacities as those strengthened with DE bars spaced at 75mm.

Figure 6 Shear cracks in specimen CON

Figure 7 Shear cracks in specimen C150∠

Figure 8 Shear cracks in specimen G150∠

Figure 9 Shear cracks in specimen S75
Specimens CON, C150, C150\(\angle\), G150, G150\(\angle\) and S75 failed in shear whereas specimens C75 and G75 failed in flexure. The load at which the first diagonal cracks appeared was of a similar level for all beams. Diagonal cracks first started to develop on the left side of the load and then followed by parallel crack formation on the right side of the beam middle support (pin). Characteristic shear crack patterns are shown in the Figures 6, 7, 8 and 9.

Figures 10, 11 and 12 show the curves for applied load versus maximum displacement at the point load for the control and strengthened beams. They represent typical behaviour during a shear test. A loss of a beam’s stiffness caused a redistribution of internal stresses and activated shear links and DE bars to increase shear resistance.

![Figure 10 Load versus displacement – group I](image1)

![Figure 11 Load versus displacement – group II](image2)

![Figure 12 Load versus displacement – group III](image3)

DE technique showed to be very efficient in developing high strains in DE bars before the final failure happens, some of the DE bars experienced very high strains during the tests. Characteristic are samples G150, G150\(\angle\) and C150\(\angle\) where DE bars almost reached their ultimate tensile capacities. Following figures represent some of the damaged bars (Figures 13, 14 and 15).

**CONCLUSIONS**

This paper presents the results of an experimental investigation involving nine tests on RC T-beams strengthened in shear using the Deep Embedment technique. On the basis of the results of the present research, the following main conclusions can be drawn:

- DE technique has been demonstrated to be effective and reliable for enhancing the shear capacity of continuous concrete beams.
The DE technique is very promising; therefore, further data analysis is needed to address other important effects along with the development of suitable analytical models for safe use of this retrofit technique.

ABSTRACT

Existing research has shown that externally bonded fibre-reinforced polymer (FRP) reinforcement is an effective shear strengthening technique for reinforced concrete (RC) beams. One issue that has not been properly clarified by existing research is the size effect in RC beams shear-strengthened with FRP. Most of the existing experimental studies have been carried out on beams of small/medium size (e.g., with a beam height < 0.45m) and most of the existing shear strength models have been developed and substantiated using the test results of such small/medium-size beams. This paper presents the test results of 18 beams in 3 series corresponding to three different beam heights respectively: 300 mm, 600mm and 900 mm. Each series consisted of 6 beams, including a group of 3 beams with steel stirrups and another group of 3 beams without steel stirrups. Each group had 3 beams: an RC beam without strengthening (control specimen), a beam shear-strengthened with FRP U-strips, and a beam shear-strengthened with FRP full wraps. All the 18 beams had a shear span-to-depth ratio of 3.0. The test results showed that a significant size effect exists in RC beams shear-strengthened with FRP U-strips while the size effect is minimal when FRP full wraps are used. The test results also demonstrated that significant shear interactions exist among the different components (concrete, steel and FRP) of an FRP-strengthened RC beam.

KEYWORDS

FRP, RC beams, strengthening, shear strength, size effect, shear interaction, U-strips, full wraps.

INTRODUCTION

Extensive research has shown that externally bonded (EB) fibre-reinforced polymer (FRP) reinforcement provides an effective method for the shear strengthening of a reinforced concrete (RC) beam (Teng et al. 2002). It is also well-known that concrete is a quasi-brittle material in which localized cracking/damage associated with material softening is a common phenomenon; as a result, the size effect exists in the shear strength of RC beams: the nominal shear strength \(\tau\), defined as the ultimate shear force in the beam divided by its effective sectional area (= beam width \(b\) x effective beam height \(h_0\)), decreases with an increase in beam height (Bazant 1999). Steel reinforcements (e.g. stirrups) can substantially mitigate but cannot eliminate the size effect (Yu and Bazant 2011). In an RC beam shear-strengthened with an EB FRP system, the FRP-to-concrete bonded interface is the weakest link and its behaviour has a major effect on the shear strength of the strengthened beam. It is well known that for an FRP-to-concrete bonded interface, an effective bond length exists beyond which the force transfer by the interface does not increase (Chen and Teng 2001). Because of the existence of an effective bond length, the force transfer between concrete and EB FRP is limited to a localized zone, which is initially within a mobilized zone near the most stressed part of the FRP and then propagates towards its less stressed part (Yuan et al. 2004). This force transfer mechanism between FRP and concrete is another source of size effect in RC beams shear-strengthened with EB FRP. As a result, the size effect in RC beams shear-strengthened with EB FRP is complex and of great importance to structural safety.

Despite the obvious importance of size effect in RC beams shear-strengthened with EB FRP as explained above, most of the existing experimental studies on the subject have been conducted on small-size beams (i.e. with a
beam highest not exceeding 450 mm), and most of the existing shear strength models have been developed on the basis of small-size beam tests (Bousselham and Challall 2013). Very few studies have been carried out on size effect in FRP shear-strengthened RC beams. Although these studies have clearly shown the existence of a significant size effect in RC beams shear-strengthened FRP U-strips (Leung et al. 2007; Godat et al. 2007; Bae et al. 2012; Bousselham and Challall 2013; Long and Rovnak 2015) and a marginal size effect in RC beams shear-strengthened with FRP wraps (Leung et al. 2007), they suffer from two main limitations: 1) the beam sizes investigated do not cover the wide range of practical beam dimensions well, with the largest effective height investigated being 660 mm (beam height 720 mm) (Leung et al. 2007); 2) there is a lack of systematic, in-depth research into the mechanism behind this size effect.

To correct the deficiencies in existing knowledge, a large experimental programme has been undertaken by the authors’ research group over the past four years: a total of 30 beams were tested to examine the effects of the following parameters in depth: beam height (300mm, 600mm or 900mm), shear span-to-depth ratio (1.5 or 3.0), strengthening configuration (FRP U-strips or FRP full wraps), and presence of steel stirrups (with or without stirrups). Of these 30 test beams, 12 beams had a shear span-to-depth ratio of 1.5 while 18 beams had a shear span-to-depth ratio of 3.0. Due the limited space, only the main results of the latter beams are presented in the present paper, but readers can refer to Chen et al. (2016a) for the results of the former beams. An additional merit of the present experimental study is that the strains in both the FRP reinforcement and the steel stirrups were measured using a large number of strain gauges to allow an accurate, quantitative assessment of the contributions to shear resistance by the different components (FRP, concrete and steel stirrups) of the strengthened beam. These strain data provide useful insight into shear interactions among the three components, allowing the mechanism of size effect in RC beams shear-strengthened with EB FRP to be clarified.

**EXPERIMENTAL PROGRAMME**

**Test Specimens**

The main details and results of the beams with a shear span-to-depth ratio equal to 3 are listed in Table 1; further details can be found elsewhere (Chen et al. 2016b, 2016c). The 18 test beams are divided into 3 series in terms of beam heights: 300 mm, 600mm and 900 mm, corresponding to effective beam heights of 250 mm, 515 mm and 800 mm respectively. Each series included 6 beams, which can be further divided into 2 groups of beams with and without steel stirrups. Each group comprised 3 beams: an RC beam without FRP strengthening (control specimen), an RC beam shear-strengthened with FRP U-strips, and an RC beam shear-strengthened with FRP full wraps (also referred to simply as “FRP wraps” for brevity). The beams with and without steel stirrups were cast at two different times using commercial concrete available from a local concrete provider; the average concrete cylinder (150 mm x 300 mm) strengths tested at 28 days and on the days of testing the beams were 35.9 MPa and 45.3 MPa respectively for beams without stirrups and 36.9 MPa and 55.4 MPa respectively for beams with stirrups. To ensure that shear failure would be critical, all the beams were over-reinforced in flexure, leading to longitudinal tension steel bar ratios of 4.29%(2D32, i.e., two bars with a diameter of 32 mm), 4.12%(8D32) and 3.91%(14D36) for the beams with a height of 300 mm, 600mm and 900mm, respectively. To allow better observations of failure modes and crack patterns, horizontally discrete U strips or full wraps were bonded on the RC beam following a typical wet lay-up procedure at least 7 days before testing; careful surface preparation was adopted to ensure a good-quality bond between concrete and FRP (i.e., debonding of EB FRP occurred only in the concrete adjacent to the bonded interface, see Figure 3). The sectional corners of all the beams were rounded to a radius of around 25 mm to preclude premature FRP rupture there. To study the size effect, all the other geometrical parameters of the beams, including the thickness, width and spacing of the FRP strips, were proportional to the beams size.

**Test Set-up and Instrumentation**

All beam specimens were subjected to two concentrated loads (i.e., 4-point bending) and tested in the structural laboratory of Guangdong University of Technology using a 5,000 kN-capacity loading frame (Figure 1). Loading was applied using a manually operated actuator together with a hydraulic jack with a load capacity of 3,200 kN. During the loading process, the forces at the two loading points were each recorded by a load cell with a load capacity of 3,000 kN. Five LVDTs were installed at mid-span, the two loading points and the two supporting points respectively to measure displacements. A large number of strain gauges were used to measure strains in the FRP strips and the steel bars (see Figure 2 for their locations). Additional strain gauges were used to monitor concrete strains on the beam compression face and the strains in the tension steel bars. Furthermore, a crack meter was used to record the widths of main shear cracks at a number of locations. To exclude local compression failure at both the loading points and the supporting points, tailored-made steel loading pads [see Chen et al. (2016a, 2016b, 2016c) for details] were deployed at these locations. Of the two shear spans of a
beam, only one shear span was the target of the experimental study, while the other shear span was heavily strengthened to avoid failure. All discussions in the present paper are concerned with the test shear span with the non-test shear span basically ignored.

Figure 1 Test set-up

TEST RESULTS AND DISCUSSIONS

Failure Modes and Shear Capacities

As detailed in Table 1, all control RC beams failed by the typical shear tension failure mode, governed by the development of a critical shear crack in the shear span. Results reported in Chen et al. (2016b, c) showed that in RC beams with steel stirrups, an apparent secondary shear crack also appeared in the shear span. The beams strengthened with FRP U-strips failed by FRP debonding (Figure 3a) while those strengthened with FRP wraps failed by FRP rupture (Figure 3b) (Table 1). It can be seen in Figure 3 that although the dominant shear cracks in beams MB-S-UF and MB-S-WF respectively are quite similar in term of crack location and angle, the crack
width of the former is much smaller than that of the latter, being 2.7 mm and 5.1 mm respectively at the ultimate state (Chen et al. 2016b, c). The smaller maximum shear crack width in RC beams strengthened with FRP U-strips implies the brittle nature of the FRP debonding failure. Furthermore, an apparent secondary shear crack appeared in the beams strengthened with FRP wraps (i.e. MB-S-WF) but not in the beam strengthened with FRP U-strips.

![Locations of strain gauges in large beams (all units in mm)](image)

(a) FRP strips  
(b) Steel stirrups

Figure 2 Locations of strain gauges in large beams (all units in mm)

Table 1 shows that the beam size affects the shear enhancement effect differently for RC beams with FRP U-strips and those with FRP wraps: for the former, the shear enhancement effect has a clear tendency to decrease with an increase in beam height, while for the latter, such a tendency does not appear to exist. It is worth noting that in medium-size beams and large beams strengthened with FRP U-strips, the shear enhancement effect became quite marginal (no more than 10%), which is in line with the results reported by Leung et al. (2007).

Figure 3 Failure modes

![Nominal shear strength versus beam effective depth (size effect)](image)

Figure 4 Nominal shear strength versus beam effective depth (size effect)
Size Effect

It is a common practice to assess the size effect using the nominal strength (i.e., $v$) (Bazant 2000). The nominal shear strength of a beam is defined as the shear force at ultimate state divided by the beam effective sectional area ($= \text{beam width} \times \text{effective beam height} \times h_0$), following Bazant (2000). Figure 4 shows the nominal shear strength versus the effective beam height curves. It can be seen that the size effect is significant in RC beams without steel stirrups, which becomes less significant in RC beams with steel stirrups as expected (Yu and Bazant 2011). For both RC beams with and without steel stirrups, the FRP wraps can effectively mitigate the size effect; as a result, the size effect in RC beams strengthened with FRP wraps is insignificant or much reduced. For RC beams strengthened with FRP U-strips, however, the size effect is significant; for those RC beams without steel stirrups, the slopes of the $v$ vs. $h_0$ curves are nearly the same for the control beams and for the FRP-strengthened beams, implying that the size effect is nearly the same for these two types of beams; for RC beams with steel stirrups, the FRP U-strips appear to have substantially increased the size effect.

Shear Interactions

Using the extensive strain data obtained in the present study, the shear contributions of the different components (FRP, concrete and steel stirrups) during the loading process can be quantitatively evaluated. In the present study, the method employed by Teng et al. (2009) was adopted in calculating the shear contributions of FRP strips and steel stirrups, and only those FRP strips and steel stirrups intersected by the critical shear crack were deemed to have contributed to the shear resistance of the beam. After the shear contributions of FRP strips ($V_f$) and/or steel stirrups ($V_s$) were determined using the above method, the shear contribution of concrete can be deduced by subtracting $V_s$ (for beams without steel stirrups) or the sum of $V_f$ and $V_s$ (for beams with steel stirrups) from the total shear force. The shear interaction among the different components of FRP-strengthened RC beams can then be analysed using the results.

![Figure 5 Development of shear contributions by different components in FRP-strengthened RC beams](image)

Figure 5 shows the shear interaction process for medium-size beams without steel stirrups. It should be noted that in Figure 5, points M, N and H stand respectively for the ultimate states of control beam and FRP-strengthened beam as well as the state at which $V_f$ peaks. From Figure 5 it can be seen that important shear interactions exist between $V_f$ and $V_s$ after point M: $V_f$ increases while $V_s$ generally decreases. In RC beams strengthened with FRP wraps, this interaction is a long process that ends when the ultimate state of the strengthened beam (point N) is reached, due to the relatively large rupture strain of FRP; as a result, the total shear force increases continuously after point M, which is in sharp contrast to the immediate decrease of the shear force in the control beam. It is well established that the degradation of concrete shear resistance is associated with localized concrete cracking/damage due to material softening of concrete, which is also the source of size effect in the shear strength of RC beams. From the present test results, it can be concluded that the detrimental size effect on the shear strength can be well counteracted by the linear elastic nature of FRP as well as its large rupture strain, which explains why the FRP wraps can mitigate the size effect. In RC beams strengthened with FRP U-strips, even though such beneficial shear interactions exist in the short stage immediately after point M, $V_f$ soon starts to decrease after an initial increase due to the brittleness nature of debonding failure (i.e. debonding occurs at relatively small shear crack widths as mentioned above). In other words, the detrimental size effect associated with the material softening of concrete cannot be effectively counteracted by FRP U-strips failing by FRP debonding, which is why FRP U-strips cannot mitigate the size effect in shear-critical RC beams.
CONCLUSIONS

This paper has presented the main results of an experimental study on the size effect in RC beams shear-strengthened with either FRP U-strips or FRP full wraps. These beams all had a shear span-to-depth ratio of 3.0, which means that the behaviour of the RC beams is dominated by the formation of a major shear tension crack. From the results and discussions presented in the paper, the follow important conclusions can be obtained:

1) FRP full wraps can effectively mitigate the size effect in shear-critical RC beams, and as a result, the size effect in RC beams shear-strengthened with FRP full wraps is much reduced and can become insignificant; the relative magnitudes of shear contributions by the concrete and the FRP have a significant influence on the size effect via shear interactions;

2) FRP U strips are incapable of mitigating the size effect and may in fact significantly increase the size effect in shear-critical RC beams; as a result, the size effect of RC beams shear-strengthened with FRP U strips is significant.

ABSTRACT

The objective of this study is to present a new strengthening method that prevents premature debonding of externally bonded (EB) carbon fiber-reinforced polymer (CFRP). The new method reproduces the technical advantages of full-wrap strengthening configuration, using a newly developed anchorage system. To that end, an experimental investigation on RC T-beams shear-strengthened with a new closed-stirrup technology is conducted. The closed-stirrup is made of prefabricated CFRP L-shape laminates and a CFRP rope as a closure. This application method does not use mechanical anchors and is fast and easy to install, providing a viable and cost-effective solution. It can also be useful for concrete members located in seismic regions where closed-stirrups are required for confinement purposes. The investigation involved laboratory tests performed on full-size RC T-beams. Among the features studied, the feasibility of the CFRP closed-stirrup shear strengthening technique and the influence of internal steel-stirrup ratio on the performance of EB-CFRP were examined. The test results demonstrated the effectiveness of using the closed-stirrup anchorage system in increasing the shear resistance of strengthened RC T-beams. The results also confirmed the existence of an interaction between the internal transverse steel reinforcement and the EB-CFRP composites.

KEYWORDS

RC T-beams, carbon fiber-reinforced polymer (CFRP), shear strengthening, anchorage, closed-stirrup, L-shape laminate, CFRP rope.

INTRODUCTION

The use of externally bonded (EB) carbon fiber-reinforced polymer (CFRP) to strengthen RC beams in shear is well-documented for both experimental and design aspects (e.g., Chaallal et al. 1998, Mofidi and Chaallal 2014). However, premature failure by FRP debonding due to lack of effective bond length and anchorage is still a major concern.

It is well established that shear strengthening using a full-wrap configuration offers a better behavior compared to side bonding or U-wrap schemes. However, up to date, the full-wrap technique can only be used for rectangular beams when accessible. This is obviously a serious limitation since most beams are monolithically cast with slabs and therefore have a T section. This observation has been the main impetus to conduct this experimental research study, which investigates the feasibility of shear-strengthened RC T-beams using closed-stirrups made of CFRP L-shape laminates and a CFRP rope as a closure for anchorage. Prefabricated CFRP L-shape laminates are well documented (e.g., Czaderski and Motavalli 2002, Chen and Robertson 2004, Mofidi et al. 2014). The rope is a bundle of flexible CFRP strands held together using a thin tissue net, inserted through the flange of the beam and bonded to the free ends of the L-shape laminates in a flared shape, forming a full-wrap configuration (CFRP closed-stirrup). This application method does not use mechanical anchors and is fast and easy to install, providing a viable and cost-effective solution. It considers a situation in which the CFRP is intended to increase the original shear resistance of deficient RC T-beams, to enhance anchorage and prevent premature debonding, which is a major issue particularly in shear. Moreover, such a technique will improve the confinement of concrete taking into account the whole effective depth of the beam. It can also be useful for seismic regions where closed-stirrups are required for confinement purposes.
EXPERIMENTAL INVESTIGATION

Description of specimens

A total of six tests were performed in this research study. The specimens consist of full-size RC T-beams with a total length of 4520 mm, a height of 406 mm and a shear span of 1050 mm. The details of specimens are presented in Figure 1. Table 1 presents the experimental program matrix for the test specimens. The control specimens, not strengthened with CFRP, were labeled CON, whereas the specimens retrofitted with CFRP L-shaped laminates were labeled LS-RF for the rope anchorage passing through the flange. Three different ratios of internal transverse steel were examined for each category of specimens: S0 series represents the beams with no transverse steel, whereas S3 and S1 series represent respectively the specimens with steel stirrup spaced at $s = 3d/4$ (260 mm) and $s = d/2$ (175 mm). The longitudinal tension steel reinforcement consisted of four M25 (area of 500 mm²) distributed in two layers. The compression bars consisted of six M10 (area of 100 mm²) in one layer into the flange. The transverse steel reinforcement consisted of 8 mm diameter (area of 50 mm²) for both S3 and S1 series.

Materials

The average 28 days concrete compressive strength ($f'_c$) was 28 MPa. The longitudinal steel reinforcement has average yield strength of 470 and 540 MPa for M25 and M10 rebars, respectively. The transverse steel yield strength was 580 MPa. These values were based on tension tests performed in the laboratory according to ASTM A370-12a standard.

The CFRP closed-stirrup technique used in this study consisted of: (i) unidirectional CFRP L-shaped laminates prefabricated by pultrusion in an epoxy matrix with 0-degree orientation; and (ii) unidirectional CFRP ropes, a bundle of flexible strands held together using a thin tissue net, used as an anchorage system. The L-shaped laminates had a 90 degree bend with 25 mm inner radius, 300 longer leg x 125 mm shorter leg x 20 mm width and 2 mm thickness. They were characterized by an ultimate tensile strength of 1350 MPa, 90 GPa modulus of elasticity and 1.3% elongation at break. The CFRP ropes had a cross section area of 25.27 mm² before saturation, and were cut at 625 mm length each. They had an ultimate tensile strength of 1590 MPa, 215 GPa modulus of elasticity and 0.74% elongation at break. The CFRP L-shaped laminates were bonded to the beam surface and the ropes using a two-component adhesive, made of resin and hardener, mainly engineered for structural applications. The epoxy’s mechanical properties were: 24.8 MPa bond strength, 4.5 GPa tensile modulus of elasticity and 1% ultimate elongation.

Strengthening procedure and test setup

The CFRP closed-stirrups were distributed along the shear span in intermittent strips spaced at 175 mm (Figure 2a). The CFRP L-shape laminates were bonded transversally to the bottom and lateral faces of the web to form a U-wrap scheme, where the shorter legs of two opposite L-shape laminates were overlapped and bonded to the soffit of the beam. Afterwards, the CFRP rope was inserted through the drilled holes on both sides of the flange, at the intersection with the web, and bonded to the free ends of the L laminates as a closure to establish a full-wrap configuration, as shown in Figure 2b.
The RC T-beams were tested in three-point loading flexure. The load was applied at a distance 3d from the support to ensure a slender type beam. The tests were performed under displacement control conditions at a rate of 2 mm/min. Strain gauges were affixed to the steel-stirrups located in the loading zone along the expected plane of shear failure. The longitudinal steel rebars were also instrumented with strain gauges at the location where the load was applied. Deflections of the beams were measured using linear vertical displacement transducers installed under the load application point. The CFRP deformations were measured using strain gauges installed vertically onto each L-shaped laminate.

EXPERIMENTAL TEST RESULTS

The experimental results are summarized in Table 2. They are presented in terms of the loads reached at failure; the shear resistance due to concrete (V_c), steel stirrups (V_s), and CFRP (V_{frp}); the shear resistance gain due to CFRP; as well as the deflections at ultimate loads.

The shear resistance was derived experimentally from the ultimate load of the specimen measured at failure. V_{frp} was obtained by subtracting the total shear resistance from that of the control specimens (V_c+V_s). The gain in shear resistance due to CFRP was calculated as a percentage of the shear capacity of the corresponding control specimens (gain = V_{frp} / (V_c+V_s)). V_c and V_s were calculated based on the results achieved from the control test specimens (S0-CON, S3-CON and S1-CON). The values provided in Table 2 are calculated based on the following assumptions implicitly admitted in the design guidelines: a) the shear resistance due to concrete is the same whether the beam is reinforced with transverse steel reinforcement or not and whether the beam is strengthened with CFRP or not; and b) the shear resistance due to steel is the same whether the beam is strengthened with CFRP or not.

Cracking patterns and failure mode

All specimens exhibited a shear failure mode by crushing of concrete (S0 series) or yielding of steel-stirrups followed by concrete crushing and CFRP debonding (S3 and S1 specimens), as shown in Figure 3. Specimen S0-LS-RF ruptured with one principal diagonal shear crack, whereas distributed shear cracks formed around the main shear crack in the specimens with steel stirrups. Strengthened specimens with steel stirrups exhibited a considerable strain beyond the yielding point of longitudinal steel, particularly in specimen S1-LS-RF, allowing therefore a more ductile behavior of the shear-strengthened RC T-beams before reaching their ultimate failure.
The load corresponding to initiation and propagation of shear cracks was similar in all specimens; the cracks initiated at mid-height of the web and propagated towards the support and the load application point. The number of distributed shear cracks increased with the steel-stirrup ratio along the shear span, whereas thinner cracks were obtained accordingly. In specimen S0-LS-RF, the shear-crack angle was flat and almost connected the loading point to the support, with an angle of 28 degree. It became steeper in specimens S3-LS-RF and S1-LS-RF with 35 degree and 40 degree, respectively. With the presence of transverse steel, the crack propagated along the flange for a longer distance, causing steeper angles compared to specimens of S0 series.

No debonding or slippage of CFRP L-shape laminates was observed before reaching ultimate loads, indicating that a more effective utilization of the CFRP can be achieved when preventing debonding failure. This demonstrates the effectiveness of using the CFRP closed-stirrups in shear strengthening of RC T-beams.

![Figure 3 Typical shear failure mode](image)

(a) concrete crushing of anchored specimens  
(b) rupture of steel stirrups

**Gain in shear resistance due to CFRP**

As shown in Table 2, the shear resistance of S0-LS-RF reached 204 kN compared to 84 kN in S0-CON, which represents a 143% gain in capacity due to CFRP with respect to the control specimen. In the S3 series, with four steel stirrups provided along the shear span, the gain in shear resistance due to CFRP was 47% in S3-LS-RF with respect to S3-CON, whereas for S1 series, with six steel stirrups along the shear span, the gain was 20% in S1-LS-RF compared to S1-CON. This can be attributed to the anchorage provided by the CFRP rope that prevented premature debonding failure, demonstrating the effectiveness of using the CFRP closed-stirrups in increasing the shear capacity of shear-strengthened RC T-beams. In the other hand, a comparison between the stirrup series revealed a substantial reduction in the resistance gain due to CFRP with the increase in steel-stirrup ratio. This confirms the findings of other researchers on the inverse interaction between internal transverse steel reinforcement and externally bonded CFRP composites (e.g., Bousselham and Chaallal 2004, Chaallal et al. 2002, Pellegrino and Modena 2002), but not yet captured in major current international design codes, such as ACI 440.2R-08 or CSA S806-12.

**Deflection response**

From the results presented in Table 2, it is clear that deflections at ultimate loads increased significantly in the CFRP rope-anchored specimens with respect to their corresponding control counterparts: from 2.6 mm to 11 mm in S0 series; 11.3 mm to 18 mm in S3 series; and 11.9 mm to 24.8 mm in S1 series. Similar results were obtained with the increase in steel-stirrup ratio for both control and strengthened specimens. Neither specimen in the S0 series reached its flexural elastic limit, despite the considerable increase in shear resistance due to CFRP in S0-LS-RF. However, CFRP rope-anchored specimens with steel-stirrups (S3-LS-RF and S1-LS-RF) experienced a ductile behavior due to yielding of the longitudinal steel before ultimate failure by shear. Overall, the CFRP closed-stirrup strengthening technique greatly enhanced the ductility performance of RC T-beams.

**Strain response in CFRP**

The CFRP closed-stirrups greatly contributed to shear resistance. In fact, all strengthened specimens exhibited a significant increase in CFRP strains after reaching the shear capacities of their corresponding control counterparts: the increase in CFRP strain in S0-LS-RF was about 5300 μstrains (i.e., for a shear resistance exceeding 84 kN up to ultimate load at 204 kN); in specimens with steel stirrups, the increase was about 3150 μstrains in S3-LS-RF and about 1400 μstrains in S1-LS-RF under the same conditions. These results revealed a substantial reduction in
the CFRP contribution to shear resistance with the increase in steel-stirrup ratio along the shear span. The maximum CFRP strains reached at ultimate were achieved by S0-LS-RF with a value of 5400 \( \mu \)strains, which represents 42% of its ultimate strain. This demonstrates the effectiveness of using such a strengthening technique and, at the same time, confirms once again the existence of an interaction, and hence a stress redistribution, between the internal transverse steel and the EB-CFRP composites.

CONCLUSIONS

Within the experimental scope of this investigation, the following conclusions related to the use of closed-stirrups can be drawn:

1. The increase in shear resistance of strengthened specimens was about 70% in average; the increase in the specimen without steel stirrups reached 143%. This demonstrates the effectiveness of using the CFRP closed-stirrups in increasing the shear capacity of shear-strengthened RC T-beams.
2. The abrupt debonding failure mode was prevented in all strengthened specimens, allowing a more effective utilization of the CFRP strengthening material and resulting thereby in a much enhanced shear capacity.
3. A substantial reduction in the CFRP contribution to shear resistance occurred with the increase in steel-stirrup ratio, confirming the existence of an interaction between the internal transverse steel and the CFRP.

ABSTRACT

The use of fiber-reinforced polymers (FRP) for the repair and seismic retrofit of existing concrete and masonry structures is continually growing. An integral part of the FRP solution is the use of FRP anchors as anchors can delay unwanted premature debonding failure. Anchors can also help to transfer forces from the FRP to adjacent structural elements. FRP anchors comprise two main components, namely (i) a portion embedded into the concrete or masonry member, and (ii) a splay portion that is connected to the FRP strengthening. It is the splay portion of the anchors which is considered in this paper as there has been very little research conducted to date in this area. A series of tests is therefore reported and a design formula is proposed.

KEYWORDS

Design, Fiber Reinforced Polymers (FRP), FRP anchors, strengthening.

INTRODUCTION

An inherent limitation of the repair and seismic retrofit of existing concrete and masonry structures with fiber reinforced polymer (FRP) composites is the propensity of the FRP to debond. Debonding can occur in a sudden manner and at FRP strains well below the ultimate strain capacity of the material. The addition of anchorage devices (i.e. FRP anchors) is becoming an integral part of FRP repair and retrofit solutions. Figures 1 and 2 show typical schematic configurations of embedded FRP tension anchors (herein FRP anchors) at walls and columns. The two distinctly different constituents of the FRP anchors shown in the figures are (i) embedded portion of the anchor, and (ii) anchor splay (or anchor fan) portion. As is clear from the details that the two anchor components exhibit very different behaviours. The embedded portion of the anchor performs in tensile pullout similar to an adhesive anchor with failure modes such as concrete cone failure or anchor pullout. Related experimental investigations have been reported to date (Ozdemir and Akyuz 2005, Kim and Smith 2009, Ozbakkaloglu and Saatcioglu 2009) as well as a design approach (Kim and Smith 2010). The splayed portion of the FRP anchor, which helps develop force transfer, depends on the shear strength of the adhesive used to bond the splay to the FRP, as well as the splay configuration. Research concerning the splay portion is most limited.

The splay end of the anchor is where the force transfer between the FRP strengthening and the anchor occurs. The fibers at the free end of the anchors are distributed in a splay over FRP plates and adhered to the FRP using the same epoxy used to apply the FRP. Sometimes a ‘patch’ of either bidirectional or unidirectional FRP is placed over the splay, unless the splay is placed between consecutive layers of FRP. Although such configurations are commonly used in practice, little information is available for the design of such splay connections. It is commonly assumed that the design basis for splays is the shear bond capacity of the epoxy although this remains to be confirmed to any great certainty.

Kobayashi et al (2001) investigated a variety of splay lengths and splay angles (i.e. the angle included between the outer edges of the splay). Their experiments concluded that such splay connections could be effective in transferring force between the FRP and the anchor if the anchor had adequate FRP material to exceed the tensile capacity of the fabric being developed. Also, they found that installing a layer of perpendicular FRP over the splay was effective in mobilizing the splays over their full width. However, their testing utilised smaller diameter anchors (approximately 6 mm) than are typically being specified in practice. While it is possible to make general performance observations from the Kobayashi results, it is not appropriate to extrapolate them to design recommendations for larger diameter anchors which will necessarily involve greater tensile demands and larger
splay sizes. In an attempt to gain more knowledge on the behavior of such splay connections for larger diameter anchors, a test program was conducted by KL Structures. A part of the results of this program are reported herein in addition to a design recommendation.

Figure 1 Detail of a typical embedded tension anchor

Figure 2 Typical use of embedded tension anchors
**EXPERIMENTAL PROGRAM**

In current practice the splay area is designed on the basis of the shear bond capacity of the epoxy used for adhering the splay to the FRP strengthening. The objective of this test program was therefore to develop guidance on how much of this shear bond capacity could be used in design. The test assembly utilised is shown in Figure 3 while Figure 4 shows a test in progress as well as a typical test specimen. The test parameters are provided in Table 1. Six nominally identical tests were conducted for each specimen group ID. All tests failed in the splay region except for three tests in Group 2 that failed in the grip region. These three undesirable results are therefore excluded herein. The bond strength of FRP to concrete and masonry is almost always governed by the tensile strength of the substrate. Since the objective of this test program was to solely test the bond between the FRP and the anchor splay, it was decided to use steel plates as the substrate material. The steel plates were sandblasted and solvent-wiped prior to installation of the base FRP. Pull-off tests showed the adhesion between the specially prepared steel plates and the base FRP to be well in excess of the anticipated shear bond stress between the FRP and the anchor splays.

![Figure 4 Test Setup for splay testing and typical specimen](image)
The tests were performed in a universal testing machine, wherein the tension load was applied to the specimen via the loading head while the plate with FRP was anchored to the base via a steel bracket. The main results extracted from the tests are the total tensile load and the total cross-head displacement. A typical result, in terms of the load-displacement relationship, is shown in Figure 5, for the set of 100mm long splay tests (i.e. specimen group 1). A horizontal line is drawn to show the mean minus one standard deviation strength result. The measured splay strengths and calculated shear bond stresses, based on the mean minus one standard deviation values, of all there sets of tests are presented in Table 2.

Table 2 Splay test results

It can be observed from Figure 5 that specimen 1 showed the lowest tension failure load. This particular specimen was dropped during fabrication resulting in the splay being separated from the base FRP prior to full cure of the epoxy. The FRP and the splays were allowed to cure, were mechanically abraded, solvent wiped and rebonded. The low tensile failure load is believed to be a result of this fabrication error. Specimen 2 exhibited a progressive debonding wherein the initial debonding was of an approximately 50mm wide strip of the base FRP from the steel plate followed by a partial debonding of the splay from the base FRP. Specimens 3 and 5 exhibited a similar behavior to that for specimen 2 with the exception that the failure of the base FRP from the plate was very limited. Specimen 4 failed by rupture in the neck region of the anchor, above the steel splay. This was attributed to inadequate saturation of the fibers which was observed in the failed region. Specimen 6 exhibited an almost complete shear failure between the splay and the FRP. Figure 6 shows a variety of failure modes observed in the tests, ranging from shear debonding of the splay from the base FRP (failure in the splay-FRP interface), to debonding of the splay and base FRP from the substrate (failure not just in the splay-FRP interface).
Figure 6 Different failure modes from splay testing

It can be seen from Figure 5 that there is significant variation in the maximum tensile strength, stiffness as well as the failure modes for the 100mm long splays. These were the first specimens fabricated for the tests and some of the inconsistency in the results may be a result of the evolving fabrication process which was well established for the larger splays. It was observed that for the 200mm long splays, the failure tended to either complete debonding of the splay from the FRP or complete debonding of the splay and base FRP from the steel plate. For the 150mm long splays the behavior was a mixture of that observed for the 100mm and 200mm long splays. This difference in behavior could be attributed to the inherent variability of the smaller splays which results from the smaller contact area between the splay and the FRP. As Table 2 clearly shows, the average failure shear bond stress decreased as the splay size increased but the failure mechanisms of the longer splay samples appear to indicated a more uniform distribution of the bond stress over the bonded area. The effect of a patch over the splay area was not studied in this effort, but it is believed that such a patch could only improve the behavior of the splay by distributing the forces across the splay and by providing local stability to the fibers.

During the testing, it was observed that the setup inherently created an eccentricity between the applied load and the resultant of the resistance at the base. Although small, this eccentricity created a peeling effect between the plate with the base FRP and the anchor splay, especially in the larger splay tests (See Figure 6(d)), and likely contributed to the lower tensile failure loads for the larger splay samples. It appears that the test may not have accurately simulated shear-only in the bonded area for all the specimens, because the tension/peeling force initiated a failure mode quite different from a pure shear condition. However, such eccentricities could exist when such anchors are installed in field conditions and so the tests are considered to still be appropriate for developing design guidance.

Figure 7 shows a plot of the measured bond stresses for all the different size splays. The lowest bond stress (corresponding to about 40% of the epoxy shear bond strength) was for a 200mm long splay where the failure was peeling off of the splay from the substrate FRP due to the eccentricity of the setup. A horizontal line, corresponding
to 35% of the shear bond strength of the epoxy, is drawn on the plot as a threshold value. It can be seen that all the measured values for bond stress are above this threshold.

Based on the above-described results of the splay tests, the following equation is proposed for splay capacity of the anchor:

$$F_S = 0.35V_{sb}A_S$$

where $V_{sb} =$ shear bond strength of epoxy as reported by manufacturer, $A_s =$ area of splay bonded to substrate FRP. This resulting bond stress value can be used to design anchor splays. All appropriate code specified strength reduction factors can be applied to the resulting splay capacity during design.

CONCLUSIONS

This paper has presented the details of an experimental program concerned with the splay portion of embedded FRP tension anchors. The specimens incorporated many of the fabrication issues associated with such anchors. In addition, a combination of shear and peeling stresses are simulated on the splay and this is representative of what can be experienced in the field. A design equation has been proposed based on the experimental results.

ACKNOWLEDGMENTS

KL Structures would like to thank Tim Ervin (Kulstoff Composite Products) for fabrication of the anchors as well as his invaluable assistance in the preparation of the specimens and the test setup.

ABSTRACT
The use of Fibre Reinforced Polymer (FRP) materials as Externally Bonded Reinforcements (EBR) is an established technique for structural improvement of existing buildings. Nevertheless, the technique features disadvantages, and premature FRP-to-concrete debonding has been commonly highlighted as one of the main problems, together with the difficulty to fully wrap the structural element when the structure presents complex geometries. FRP straight anchors are used to transfer the forces from the FRP sheet into the structural element, eliminating these two problems, but a comprehensive design method for FRP anchors has not yet been established despite the increased use and research on FRP anchors.
An extensive experimental programme has been carried out as part of an on-going research project with the ultimate goal being the development of a design methodology to enable engineers to efficiently and reliably design FRP anchors. The influence of a number of parameters on the capacity of straight FRP anchors has been investigated in the research, but only the anchor size and the fanning angle of the fan portion are reported here. The model that defines the relationship between anchor size, fanning angle and the capacity of the anchor exhibiting fibre rupture is described.

FRP, FRP anchor, EBR, fibre rupture, strengthening, retrofit, model

INTRODUCTION
Externally Bonded Fibre Reinforced Polymer Reinforcements (FRP-EBR) of Reinforced Concrete (RC) structures have been extensively investigated by the research community and widely used by practicing engineers. Two of the main problems of FRP-EBR systems reported in the literature and encountered by engineers are the premature FRP-to-concrete debonding (Chen & Teng 2001) and the presence of obstructions that prevent the RC structural member to be fully wrapped (Kim et al. 2009). Amongst the existing anchorage systems to overcome these problems FRP anchors have been highlighted in multiple occasions as the best solution, due mainly to the better properties of FRP materials when compared to more traditional materials such as steel, the high strength vs weight ratio and the better compatibility of FRP to FRP systems compared to FRP to other materials systems, as example given by Kalfat (2013). An FRP anchor consists of a bundle of fibres, or a rolled FRP sheet, that is soaked into epoxy resin before one end of the bundle (1) anchor dowel) is introduced into a hole that has been pre-drilled into the structural element and the other end is splayed into a fan shape ((2) fan component) and bonded with epoxy resin to the FRP sheet, with the fibres’ transition from the dowel to the fan through the small part of the anchor ((3) key portion), see Figure 19.

Figure 19 Straight anchor and main parts

The main problem for a wide implementation of FRP anchors is the absence of design guidelines that would enable engineers to reliably determine the anchor strength and predict its behaviour (Kim & Smith 2009; Kalfat et al. 2013).
Previous efforts have been undertaken to characterize the strength and behaviour of the anchor dowel, with a design model developed by Kim and Smith (2010) based on the failure modes related to the anchor dowel, but a thorough research has not yet been conducted on the behaviour of the key portion and the fan component. Reported herein are the results of 72 tests as part of an experimental campaign aimed to characterize the behaviour of the key and the fan components of straight anchors. Two main failure modes have been identified related to the dowel and fan components, fibre rupture and fan-to-sheet debonding respectively, with the tests reported here being focused on the fibre rupture failure mode, which all tests exhibited, and further research being continued in order to characterize the fan-to-sheet debonding failure mode.

TEST SET-UP, MATERIALS AND SPECIMEN PROPERTIES

An innovative test set-up unique for the on-going research programme was designed, with the main objective of replicating as close as possible a commonly used real application while aligning the applied load with the installed anchor and preventing induced moments or shear forces on the anchor, for more details of the test set-up the reader is referred to (del Rey Castillo et al. 2015). The applied tensile load was recorded with a load cell and displacements and strains were measured with the Digital Image Correlation (DIC) technique, but only loads are reported here.

The base material used to manufacture the FRP anchors was supplied as a bundle of fibres with a standard fibre content and the bundles were then combined and/or divided to manufacture anchors with different fibre contents. The manufacturer-specified material properties for the FRP products used in this research are given in Table 7. The properties are expressed as net-fibre laminate properties.

Concrete of two strengths were used but the influence of this property on the final strength of the anchor is negligible. The compressive and tensile strength reported in Table 8 of each concrete mix was determined using NZS 3112-2(1986).

Table 8 Concrete mechanical properties

Amongst the several parameters considered in the research two have been reported herein, the anchor size (how many bundles of fibres have been used to manufacture the anchor and the corresponding net cross section area) and the fanning angle α (angle from the middle to the end of the fan component, see Figure 19). The specimens and the parameters used in the construction of the anchors are listed in Table 9, with the names indicating the number of bundles used in the anchor assemble (0.5 to 6 bundles), which linearly correspond to the Net Cross Section Area in mm², and the intended fanning angle α (15, 27 and 60 degrees) at the time of the anchor construction. The intended angle did not always correspond with the final angle obtained, which was measured once the resin was cured and is reported in Table 9 as Fanning Angle α in Degrees. As can be observed in the table, anchors featuring 6 bundles and an angle α equal to 15 and 60 degrees were not tested, the reasons being the large strength of the 15 degrees 6-bundle anchors that prevented the specimen to be properly tested with the available equipment or the infrequently used angle of 60 degrees with big anchors.

RESULTS

The failure mode for all the tests reported herein is fibre Rupture of the anchor, either at the Key portion (Rk), at Middle length (Rm) or at the Top of the anchor (Rt) as shown in Figure 20. These three sub-failure modes did not have an influence on the final strength of the anchor but indicate that the fan-to-sheet debonding mechanism had
already commenced for the R\textsuperscript{m} and R\textsuperscript{t} modes. In 27 tests (37.5\% of 72 tests in total) this fibre rupture occurred after the FRP sheet had debonded from the concrete substrate, either completely (Complete Concrete Debonding or CCD) or partially (Partial Concrete Debonding or PCD) but the ultimate strength was not affected by the FRP-to-concrete debonding as already reported before, see (del Rey Castillo et al. 2015). Therefore 9 sub-Failure Modes (FM) exist and are reported in Table 10, R\textsuperscript{1} (40.3\% of 72 test), R\textsuperscript{m} (9.7\%), R\textsuperscript{t} (12.5\%), PCD+R\textsuperscript{m} (9.7\%), PCD+R\textsuperscript{t} (4.2\%), PCD+R\textsuperscript{1} (0.0\%), CCD+R\textsuperscript{m} (9.7\%), CCD+R\textsuperscript{t} (13.9\%) and CCD+R\textsuperscript{1} (0.0\%).

The Ultimate Tensile Load (UL) at failure is reported in kN in

Table 10, together with the Real Strength (RS) in MPa based on the ultimate load and the anchor net cross section area. The Efficiency (Eff) was obtained as the percentage ratio of the Real Strength to the manufacturer-specified strength as given in Table 7. The manufacturer specifies the strength of one bundle so the manufacturer strength of multiple bundle anchors was linearly calculated by multiplying the manufacturer strength of one bundle by the number of bundles used to manufacture the anchor.

1Ultimate Load in kN, 2Real Strength in MPa, 3Efficiency in %, and 4Failure Mode, see above for more details

422
FORCE TRANSFER MECHANISM AND TENSILE STRENGTH MODEL

The tensile force is transferred from the FRP sheet to the FRP anchor through the fan component and into the RC structure via the dowel, see Figure 21, with the force in the sheet being equal to the force in the dowel for the system to be in equilibrium, Eq 1a. By dividing the fan component into infinitesimal parts the infinitesimal force \( f_i \) is obtained, having this force two components being perpendicular and parallel to the force, as already hypothesized by Kobayashi (2001). Each of the parallel components can be calculated with the cosine of their corresponding fanning angle \( \alpha_i \), and the sum of all the \( f_i \) components equals the force transmitted to the dowel. Thus the Ultimate Load of the anchor exhibiting fibre rupture failure mode \( (N_{fr}) \) in N is equal to two times the cross sectional area in the dowel \((A_{dowel})\) multiplied by the tensile strength of the FRP \((S_{FRP})\) in MPa and by the sum of the parallel components of the force, reduced by a Efficiency Coefficient \( \psi_{eff} \), as shown in Eq 1b.

\[
\sum F = 0 \rightarrow F_{sheet} = F_{dowel} \tag{1a}
\]

\[
N_{fr} = \psi_{eff} S_{FRP} \sum \cos(\alpha_i) A_{dowel} \tag{1b}
\]

In order to calculate the sum of the \( \cos(\alpha_i) \) the integral between 0 and \( \alpha_0 \) (maximum angle \( \alpha \)) of the cosine function can be used, see Figure 22 and Eq 2a. However, the use of this equation would imply that for a fixed cross section area the quantity of fibres in the anchor increases as the angle increases. This behaviour does not represent the reality because the number of fibres remains constant for a constant cross sectional area although the fibres are less densely distributed in the anchor. To account for this effect an average value \( \alpha' \) has to be used, which is calculated by dividing the area by the maximum angle \( \alpha_0 \) and by substituting Eq 1b into equation 2b to obtain and expression for \( N_{fr} \).

\[
\int_0^{\alpha_0} \cos(\alpha) d\alpha = \left[ \sin(\alpha) \right]_0^{\alpha_0} = \sin(\alpha_0) - \sin(0) \rightarrow \alpha' = \frac{\sin(\alpha_0)}{\alpha_0} \rightarrow N_{fr} = \psi_{eff} S_{FRP} \frac{\sin(\alpha_0)}{\alpha_0} A_{dowel} \tag{2a}
\]

The efficiency coefficient for each test was then obtained dividing the ultimate load (UL) in Table 10 by the tensile strength \((S_{FRP})\) and the cross sectional area \((A_{dowel})\). This coefficient was then plotted against the angle \( \alpha \) for each anchor size, see Figure 23 (a) to (e) and the best fit obtained, see Eq 3 (a) to (e). The coefficients were correlated with their size as per Figure 23 (f) and the best fit again obtained for the efficiency factor as a function of the cross sectional area, see Eq 3f. Anchors featuring 6 bundles and an angle \( \alpha \) equal to 15 and 60 degrees were not tested, the reasons being the large strength of the 15 degrees six-bundle anchors that prevented the specimen to be properly tested with the available equipment and the infrequent use of angles of 60 degrees with such big anchors. The average efficiency

\[
\begin{align*}
\psi_{eff}^{14} &= 1.20 \frac{\sin(\alpha)}{\alpha} \tag{3a} \\
\psi_{eff}^{28} &= 0.99 \frac{\sin(\alpha)}{\alpha} \tag{3b} \\
\psi_{eff}^{42} &= 0.97 \frac{\sin(\alpha)}{\alpha} \tag{3c} \\
\psi_{eff}^{56} &= 0.80 \frac{\sin(\alpha)}{\alpha} \tag{3d} \\
\psi_{eff}^{84} &= 0.75 \frac{\sin(\alpha)}{\alpha} \tag{3e} \\
\psi_{dowel}^{14} &= 2.41 A_{dowel}^{-0.26} \tag{3f}
\end{align*}
\]
coefficient (0.4) for these tests was used in equation 3f.

Figure 23 Calibration of theoretical model with experimental results
For consistency with the equation described in Eq 1b the inverse of the cosine is applied to obtain a cosine function, Eq 4a, but for simplicity $0.57\alpha_0$ can be used for the range of angles under study (0 to 60 degrees), see Figure 24. By substituting this relationship into Eq 1b the governing equation 4b for $N_f$ is obtained, and by solving $y$ for Eq 3f the final equation is obtained, Eq 4c. The three dimensional surface describing Eq 4c can be seen in Figure 26, together with the experimental data points. For the biggest anchors made with six bundles the equation overestimated the strength and further research is needed in order to adjust these values. The influence of the fanning angle on the total capacity of the anchor is larger as the anchor increases its size and anchors with a more narrow angle $\alpha$ are more efficient than anchors with a more obtuse angle $\alpha$.

\[
\alpha' = \frac{\sin(\alpha_0)}{\alpha_0} \rightarrow \cos^{-1}(\alpha') = \cos^{-1}\left(\frac{\sin(\alpha_0)}{\alpha_0}\right) \equiv \cos(0.57\alpha_0)
\]

\[
\sum_i \cos(\alpha_i) = \cos(0.57\alpha_0) \rightarrow N_{fr} = \psi_{eff} \sigma_{FRP} \cos(0.57\alpha_0) A_{dowel}^{2/3}
\]

In order to obtain the lower bound equation for use in design the standard deviation was analysed for each group of data points with the same anchor size and fanning angle, but no trend was found within each anchor size, see Figure 25a. The standard deviation was then studied for the different anchor sizes, and, as can be observed in Figure 25b, it was established that the standard deviation increases as the anchors increased in size, following a power equation. By subtracting the standard deviation from the model the lower bound model can be found, see equation 4d, with the representation of this model being reported in Figure 26 together with the data from the experimental results. The ultimate force in kN as predicted by the model for each specimen is represented with a square and the recorded force is represented with a circle, with the difference between the two forces being represented with a solid line. As can be observed in Figure 26 the influence of the fanning angle on the total capacity of the anchor is larger as the anchor increases in size, and anchors with a narrower angle $\alpha$ are more efficient than anchors with a more obtuse angle $\alpha$. 

(a) Standard Deviation for each anchor size

(b) Standard Deviation for the test population
CONCLUSION AND FUTURE WORKS

Reported herein are the results of 72 tests on CFRP straight anchors that exhibited fibre rupture failure mode with varying anchor size and fanning angle $\alpha$. The sub-failure mode that the anchor exhibited did not affect the strength of the anchor, as long as the anchor could resist the energy released when the FRP-to-concrete debonding occurred. Anchors featuring an acute fanning angle generally behave better than anchors with a more obtuse angle, but this influence is almost negligible for small anchors and becomes more critical as the anchor size increases. Only ultimate loads are reported here, although strains and displacements were measured using the DIC technique. The force transfer mechanism between sheet, anchor and concrete substrate is analysed and a number of equations for different anchor sizes with a varying fanning angle $\alpha$ are reported (Eq 3a to f). A final equation and the corresponding lower bound equation are described, taking into consideration both anchor size and angle $\alpha$ to help engineers to calculate the final strength and anticipate the behaviour of straight CFRP anchors in a reliable way. Practicing engineers now have a tool to predict the maximum load that an FRP anchor is able to withstand for a given size and fanning angle $\alpha$.

However, the behaviour of the anchor is not yet fully understood, especially for big anchors that are difficult to test. A numerical model will help to understand the fracture mechanism and the influence of fanning angle $\alpha$ on the final strength of the anchor. A sensitivity analysis can be carried out to consider anchors with larger cross sectional areas and to increase the range of FRP and epoxy resin properties under study. Finally, a real case study application will be tested in order to verify the validity of the equations and investigate the influence of tensile-compression cycles on the anchor strength and behaviour.

ACKNOWLEDGEMENTS

The authors acknowledge the support of the technical staff of the Department of Civil and Environmental Engineering at the University of Auckland, as well as Contech Limited and Sika (NZ) for supplying the CFRP and epoxy resin used in the experimental campaign reported here. The funding support provided by the New Zealand Earthquake Commission is highly appreciated.

ABSTRACT

Recent studies have shown the efficiency of the application of Carbon Fibre Reinforced Polymer (CFRP) materials to reinforce cracked steel elements. Bonding CFRP materials on cracked steel plates leads to a significant reduction of the stress intensity factor (SIF) at the crack tip and thus to a significant increase of the fatigue life. This paper deals with the reinforcement of old steel plates (mild steel and puddled/wrought iron) by adhesively bonding CFRP laminates with Normal and Ultra High Modulus (NM and UHM, respectively). The chosen steel plate geometry is consistent with the one of old riveted connections. Steel plates with a single crack emanating from a centre hole are studied. Symmetrical and un-symmetrical reinforcement are considered as well as pre-stressing before application. Experimental results, showing efficiency of the different studied reinforcement configurations, are then used to determine the modified mode I SIF. Such a result could then be used in reinforcement operations to assess the provided increase of life expectancy.

INTRODUCTION

The preservation of historic metallic bridges is today a major challenge. The major causes of deterioration of these old structures are corrosion and fatigue phenomenon. Moreover, particular typologies of damage are recognized in these structures due to the used materials (wrought iron and mild steel) and the riveted connections. The traditional method of strengthening is based on the application of steel plates to the original structures that are welded, bolted or riveted. This traditional method shows some negative effects as the uses of welded, bolted or riveted plates may create residual stress and induce new stress concentration areas that are prone to fatigue. Moreover, the additional steel plates increase the permanent loads to the weakened structure and are prone to the same phenomena of corrosion and fatigue.

The use of CFRP in civil engineering is more developed in the case of concrete structures even if, for over ten years, the researchers have developed a greater interest for the case of metallic structures. Studies conducted on metallic structures reinforced by CFRP bonded have shown the possibility of enhancing the performance of structural members: increase of carrying capacity, stiffness, ductility, durability and fatigue resistance (Zhao et al. 2014). In addition, CFRP materials show some advantages in comparison to steel, such as high strength and rigidity for a low weight, no corrosion sensitivity and fatigue resistance. Moreover, FRP materials are easy to handle and their use in strengthening intervention may need shorter time. Consequently, it was decided with the collaboration of the French Railway Company to study the possibilities offered by such technology for the specific case of old riveted metallic assemblies. Previous studies consisted in analysing the behaviour of the riveted assembly (Lepretre et al. 2014) and the adhesively bonded joint (Chataigner et al. 2012; Lepretre et al. 2016). It was then decided to carry out investigations regarding the ability to increase life expectancy of cracked steel assemblies.

To investigate the efficiency of CFRP-reinforced steel elements in fatigue crack-growth behaviour, some research studies were led on various cracked steel plates configurations and for different CFRP materials. Liu et al. (2009) also studied the repair of cracked steel plates with centre hole by bonding NM CFRP sheets. The influence of some parameters such as bond length, bond width, double and single side repair was investigated. The fatigue life was increased for all reinforced specimens, and all the more in the case of double side repair. The experimental results showed that fatigue life could be extended by up to 7.9 times compared to the un-repaired specimens. Wu et al. (2012) adopted similar test specimen’s geometry to test Ultra High Modulus (UHM) CFRP laminates.
reinforcement. Five strengthening configurations with single and double side repair were investigated. The results show an increase of fatigue life by a factor ranging from 3.26 to 7.47.

Some researchers also investigated the pre-stressing technique of NM CFRP laminates (Bassetti et al. 2000; Colombi et al. 2003; Täljsten et al. 2009; Ye et al. 2010). Bassetti et al. (2000) and Colombi et al. (2003) used NM CFRP laminates (E=210 GPa and e= 1.2mm) pre-stressed up to 41.2 kN to reinforce steel plates with centre hole. An increase of 16 times the fatigue life was obtained for double side repair.

Thus, increasing the Young’s modulus or pre-stressing NM CFRP plates give the best results in terms of fatigue life extension of cracked steel elements. Nevertheless, today only few studies have investigated these two solutions. In this paper, non-pre-stressed and pre-stressed NM CFRP laminates as well as UHM CFRP laminates were used to reinforce metallic plates with one fatigue crack emanating from a centre hole. Single and double side repair and different initial crack lengths were studied. Two metallic materials were used for the metallic elements: S235 carbon steel and wrought iron. Experimental results, showing efficiency of the different studied reinforcement configurations, are then used to determine the modified mode I SIF.

EXPERIMENTAL STUDY

Experimental study on metallic plates with various degrees of initial damage has been conducted in order to investigate the efficiency of the different reinforcement process on fatigue crack-propagation. Two types of metallic materials were used as well as two types of CFRP reinforcement process.

Used materials and sample geometry

S235 carbon steel and wrought iron materials were used for the metallic plates. S235 carbon steel grade was chosen due to its mechanical behaviour similar to that of mild steel used in the metallic bridges of the first half of the 20th century (Bassetti et al. 2000). Wrought iron material originates from the dismantling of an old riveted bridge. Tensile test were carried out to assess the mechanical properties of the materials. The main yield stress, tensile strength and Young’s modulus of the steel and wrought iron (in rolling direction) plates are indicated in Table 1. Two types of laminates with their associated adhesive were selected. Reinforcement process A uses Normal Modulus (NM) CFRP with linear elastic adhesive, while reinforcement process B uses Ultra High Modulus (UHM) CFRP with no linear elasto-plastic adhesive. The selected materials for the two reinforcement processes and some of their mechanical properties are listed in Table 1.

The values correspond to an average values from three test results, the standard deviation is indicated in brackets.

Specimens consist in metallic plates reinforced with CFRP bonded on one side or both sides. The carbon steel plates are 510 mm-long, 90 mm-wide and 10 mm-thick with a 20 mm-diameter hole and one initial 0.6 mm-wide notch emerging from the hole, as shown in Figure 1. For wrought iron plates, the dimensions are the same except the thickness of 7 mm of the metallic plates. The geometry of the plates was chosen to represent a part of a riveted joint. Thus, the hole’s diameter represents the rivet hole and the thickness of the plates are convenient with those of old steel bridges members. The initial notch was made using the wire erosion technique. This allows to localize the crack initiation and to obtain a straight crack through thickness of the plates. From this initial notch, a fatigue crack is then initiated and propagated until a given length corresponding to the initial crack length a0 for which the plate is reinforced by bonding CFRP laminates.
Two different initial crack lengths were chosen for this study to simulate various stages of crack propagation when the strengthening is applied: \( a_0 = 6 \text{ mm} \) and \( a_0 = 13 \text{ mm} \). The first chosen length corresponds to a crack under rivet head, only detected using no destructive control technique. While the second initial length of the crack corresponds to a crack that has exceeded the rivet head and that can be detected by visual examination.

For all reinforced specimens, the CFRP plate is bonded on one side or both sides of the cracked plate and at a certain distance from the edge of the hole, taking into account the presence of the rivet head. For this reason, all CFRP plates were bonded at a distance of 10 mm from the edge of the hole. Geometry of repaired plates, initial crack length and repaired configuration are shown in Figure 1.

The specimens were tested under tensile cyclic loading with a stress ratio of 0.1 and a frequency of 10Hz, until complete failure of the specimens. The applied stress in the nominal section of the plates is similar for both carbon steel and wrought iron plates and varies from 100 MPa to 10 MPa.

Crack propagation for all S235 carbon steel specimens was recorded using the “beach marking” technique. The principle of this technique is to apply a reduced stress range for a short number of cycles during the propagation stage of the crack. The modification of applied stress range decreases crack growth rate and creates visible marks on the crack surface. It is thus possible to observe the real crack size and shape in the thickness of the steel specimens after complete failure of them and to relate it to the load history. For the wrought iron specimens, the “beach marking” technique cannot be applied due to the metallurgy of the materials. In fact, due to the manufacturing process, the microstructure is non homogeneus with a lot of inclusions of sulphides and oxides which have a brittle behaviour (Pipinato et al. 2012). This led to anisotropy of the material especially bad in the thickness direction due to the arrangement of the inclusions and the influence of the rolling process. After several tests, it was decided to adopt a specific crack propagation sensor bonded on the surface to record the crack length with time.

**EXPERIMENTAL RESULTS**

Fatigue life and failure modes

The tests results are summarized in Table 2 for carbon steel specimens and Table 3 for wrought iron specimens. Three identical specimens were done for each reinforcement configuration. For S235 carbon steel plates, the experimental results show good repeatability. Thus, the results indicated in Table 2 are an average value obtained for the three testing coupons corresponding to each reinforcement configuration. For wrought iron materials only UHM CFRP reinforcement was investigated. Moreover, the non-homogeneity of the materials leads to different results for testing specimens with the same reinforcement configuration. For this reason, the results indicated in Table 3 are for only one specimen labelled with “-1/-2/-3”.
The fatigue cycle number is counted until complete failure of the specimen and the fatigue life increase ratio corresponds to the ratio between the average fatigue life of CFRP-reinforced specimens and those of the reference specimens (un-reinforced).

Failure of all NM CFRP-reinforced specimens was caused by cohesive failure in the adhesive layer (see Figure 2a). While cohesive failure follows by delamination of the composite is observed for UHM CFRP-reinforced specimens whatever the metallic materials (see Figure 2b).

The results indicated in Table 2 for S235 carbon steel specimens show an increase of fatigue life by a factor ranging from 1.29 to 2.4. The maximum increase of lifetime is obtained for double side repair specimens. UHM_NT_S_A1 and UHM_NT_S_A2 fatigue life increase ratio for S235 steel plates were not indicated in Table 2. For this specimen’s reinforcement configuration, an applied stress range of 90 MPa shows a too slow propagation of the crack (no failure of the specimens after 3 million cycles). For this reason, the applied stress range was increased to 130 MPa, which does not allow a comparison in terms of fatigue cycle number with the others specimens.

In practice, it is often difficult to make a double side repairing due to the complex geometry of the cracked elements and more particularly for old riveted structures, which have angle iron elements and a lot of rivets. For single side repaired S235 carbon steel specimens, the maximum increase of lifetime is obtained for UHM CFRP reinforcement. This is why only this CFRP reinforcement was adopted for cracked wrought iron plates (see Table 3).
The non-repeatability of the tests for wrought iron specimens is clearly visible in Table 3. Nevertheless, for all CFRP-reinforced specimens the fatigue life increase ratio is significant with an increase lifetime ratio ranging from 2.12 to 3.85.

**Crack propagation curve**

As mentioned above, the evolution of the crack front shape during crack propagation for S235 carbon steel plates is determined using beach marking technique. The microscope observation of the crack surfaces is represented in Figure 3 for different reinforcement configuration.

![Crack propagation curves](image)

It is interesting to note that, for single-side UHM plate reinforcement, a corner crack appears at the other edge of the hole before complete failure of the specimens. That is not the case for single-side NM plate reinforcement. For double-side repair with NM and UHM plate, a corner crack also appears at the other edge of the hole for both cases. As expected, more striations are visible for CFRP-reinforced specimens depending on the reinforcement configuration. Two kinds of crack shapes, symmetric and un-symmetric about the mid-thickness axis, are observed. For un-repaired and double-side repaired specimens, the crack shape tends to be symmetric about the mid-thickness of the plate with the central point at the crack front (the maximum stress intensity factor is obtained for this central point in that case), see Figure 3a. While for un-symmetric specimens, the maximum stress intensity factor is obtained for the un-repaired surface intersection (see Figure 3b and 3c).

![Crack gauge images](image)

Figure 4c shows the crack surface of the wrought iron specimens. The brittle slag/inclusions and the non-homogeneity of the materials are clearly visible. The “beach” marking technique cannot be used for this material, so the crack propagation was followed by use of crack gauge (see Figure 4a and 4b). The crack length against cycle number is drawn in Figure 5 and Figure 6 for S235 carbon steel specimens and wrought iron specimens, respectively.
For all CFRP-reinforced S235 carbon steel plates, the reinforced specimens show a significant decrease of the crack propagation rate. Reinforced as early as possible and using UHM CFRP reinforcement allow a bigger increase fatigue lifetime. In all cases, the effect of CFRP laminate is maximal when the crack propagates under the composite laminate until a certain length after which the propagation of the fatigue crack becomes unstable. As for S235 carbon steel specimens, the CFRP-reinforced specimens show a significant decrease of the crack propagation rate even if fatigue test results show a wide dispersion. This is due to the non-homogeneity of the materials and because of the many inclusions.

In literature studies, the most investigated reinforcement configuration for cracked steel plates with centre notch (hole or crack) concerned the bonding of CFRP materials on all the cracked surfaces. In that case, the best fatigue strengthening effect is achieved. Liu et al. (2009), Wu et al. (2012) and Täljsten et al. (2009) have studied different reinforcement configuration with CFRP materials which do not cover the cracked surface (see Figure 7). In these studies, CFRP sheets and laminates are bonded on each side on the center crack and for different distance to it.

Liu et al. (2009) studied 5 layers MBrace CF350 sheets (Young’s Modulus of fibers is 552 GPa and equivalent modulus of the composite is 128 GPa) of 30mm-wide bonded on each side of the 5mm-diameter center hole and for single and double repair configuration. As expected, the single side repair configuration is less effective in
extending the fatigue life comparing with double side repair configuration. The fatigue life increase ratio was of 1.4 for single side repair and of 5 for double side repair specimens. Wu et al. (2012) show the clear influence of CFRP bonding locations on the fatigue behaviour studying two types of UHM CFRP laminates (E=477 GPa) locations on each side of the centre hole in steel plates and for double side repair configuration. Specimens with the longest distance of CFRP plates away from the crack tip yield the lowest strengthening efficiency with a fatigue life increase ratio of 3.26 compared with 5,82 for the other configuration. Täljsten et al. (2009) used two types of CFRP laminates for his study (E=155 GPa and E=260 GPa) pre-stressed and no pre-stressed with bigger wide of 50 mm. All the specimens tested were double side repair and the obtained results show an increase fatigue life ratio >>34 for specimen with CFRP laminate (E=260 GPa) pre-stressed to 12kN and >8 for specimen with CFRP laminate (E=155 GPa) pre-stressed to 15kN. The same specimens no pre-stressed show an increase fatigue life of 3.7 and 2.8 respectively.

In our case, the cracked specimens are un-symmetric (one crack emanating from the centre hole and reinforced only on the side of the crack) which leads to lower increase of the fatigue life for reinforced specimens. Nevertheless, as for the literature studies, the double side repair configuration and the use of UHM CFRP laminates are more effective in extending the fatigue life of cracked metallic plates.

### ASSESSMENT OF STRESS INTENSITY FACTOR FOR REPAIRED STEEL PLATE

The Stress Intensity Factor (SIF) is a key factor of the LEFM (linear elastic fracture mechanics). It is used to predict the crack propagation rate and thus assess the fatigue life of a cracked element. The SIF at the crack tip can be simply expressed in terms of the applied stress range, Δσ, the crack length, a, and a geometry correction factor, $F(a)$ (Albrecht and Yamada 1977):

$$\Delta K = F(a)\Delta\sigma\sqrt{a}$$  \hspace{1cm} (1)

Classical solutions of SIF values are available in literature for simple geometries of cracked elements (Tada et al. 2000, JSSC 1995, Albrecht and Yamada 1977). For the centre cracked steel plate with one crack emanating from the edge of the hole, Bowie et al. (1956) model with Newman modification (1976) (taking into account the finite width of the plate) can be adopted (Eq. 2).

$$F(a) = \varphi_1 \cdot f_1$$  \hspace{1cm} (2a)

$$\varphi_1 = 0.707 - 0.18X + 6.55X^2 - 10.54X^3 + 6.85X^4$$ \hspace{1cm} (Bowie solution)  \hspace{1cm} (2b)

$$X = \left(1 + \frac{a}{R}\right)^{-1}$$

$$f_1 = \left[\sec\left(\frac{\pi(2R + a)}{2(W - a)}\right)\right] \cdot \sec\left(\frac{\pi R}{W}\right)$$ \hspace{1cm} (Newman modification)  \hspace{1cm} (2c)

CFRP reinforcement will act in two ways on the SIF values. First of all, the CFRP laminate help to share the load applied to the cracked plate by transferring through the adhesive layer. As the crack propagates, more fatigue load can be taken by the CFRP laminates reducing the effective stress in the cracked steel plate. Secondly, the bonded CFRP laminates modified the geometry of the cracked element and then the geometry correction factor.

From the crack propagation curves obtained experimentally (cf Figure 5 and Figure 6), the experimental SIF can be calculated directly using the Paris law (Eq. 3) (Paris et Erdogan 1963). The "secant method" given in ASTM E647 (2001) was used for the determination of the crack growth rate da/dN (Eq. 4).

$$\left(\Delta K_{exp}\right)_u = \left[\frac{1}{C} \left(\frac{da}{dN}\right)_u\right]^{1/\nu}$$  \hspace{1cm} (3)

$$\left(\frac{da}{dN}\right)_u = \frac{a_{i+1} - a_i}{N_{i+1} - N_i}$$  \hspace{1cm} (4)

(da/dN)_u is the average crack growth rate over the crack length increment $a_{i+1} - a_i$ measured at the mid-thickness of the plates whatever the reinforcement configuration. The calculated values is for a crack length $\bar{a} = \frac{1}{2}(a_{i+1} - a_i)$. $C$ and $m$ are material constants determined experimentally from un-repaired reference specimens. Their values are 1.45.10^{-13} and 2.97 respectively for S235 carbon steel plates and 1.93.10^{-20} and 5.34 respectively for wrought iron plates (da/dN in mm/cycle and ΔK in MPa√m). Barsom (1974) suggests for mild steels: $C = 2.2.10^{-13}$ and $m = 3$. Another suggestion for old steels was given in ECCS (2005) and by Sedlacek et al. (1992): $C = 4.10^{-13}$ and $m = 3$ (values refer to upper range). Kühn (2013) has led a statistical analysis derived from an amount of 205 tests and has determined maximum and minimum values of Paris parameter for wrought iron materials: $C_{\text{min}} = 4.9.10^{-17}$ (R=0.1), $C_{\text{min}} = 5.7.10^{-28}$ (R=0.5) and $m_{\text{max}} = 9.3$ (R=0.5), $m_{\text{max}} = 3.8$ (R=0.5). Thus, the obtained results for both S235 carbon steel plates and wrought iron plates seem to be consistent with the compared literature studies. For
wrought iron it is recommended to apply the parameters referring to old steels. These parameters seem to be conservative but that allows compensating the high scatter of material behaviour. The SIF analysis is only done for S235 carbon steel specimens, which show a good repeatability and thus allow comparison between each reinforcement configuration. By plotting the stress intensity factor as a function of the crack length, the effectiveness of the reinforcement process can be assessed. SIF values will depend on the crack propagation stage, as ever mentioned by Wu et al. (2013b) who identified three stages of Mode I SIF with crack propagation when the CFRP is bonded away from the cracked area.

Figure 8 shows the SIF as a function of the crack length for repaired and un-repaired S235 carbon steel specimens.

![Figure 8 SIF against crack length for S235 specimens](image)

The SIF increases with the crack growth but it is different for the repaired specimens. Figure 8a shows the SIF for single side repair case with an initial crack length of 6 mm. It is clearly visible that UHM CFRP reinforcement leads to a more stable propagation of the crack (SIF values are stable for a longer crack length) and a higher SIF reduction. This last point was also noted by Wu et al. (2013a), who showed that the SIF of CCT steel plate depends on the relative stiffness, concluding that a higher stiffness resulting in greater reduction in SIF. Then, by comparing single side and double side repair cases (Figure 8a and b), we can see that, for UHM and NM pre-stressed CFRP single side reinforcement, the decrease of the SIF values happens before the crack has reached the edge of the CFRP plate. That is not the case for double side repair (see Figure 8b) for which the effective SIF decrease appears when the crack propagates under the CFRP laminate. The single side repair geometry configuration can explain this phenomenon as well as the fact that measures of crack length increment is done at mid-thickness of the specimens (un-symmetric crack shape, see Figure 3). For single side repair configuration, Figure 8c shows that, at the same crack length, SIF values are smaller for specimens with the smallest initial crack length. This phenomenon is more visible for UHM CFRP reinforced specimens.

CONCLUSIONS

In this paper, NM CFRP laminates and UHM CFR laminates were used to extend the fatigue life of cracked metallic plates with centre hole and one crack emanating from the hole. The pre-stressing technique of NM CFRP laminates was also investigated and double side and single side repair were done.

In order to assess the effectiveness of the CFRP reinforcement for strengthening old metallic structures, two types of metallic materials were used for the plates: mild steel and wrought iron. From the experimental results, it is evident that the fatigue behaviour of the cracked metallic plates is greatly improved by CFRP bonding. The results show an increase of fatigue life by a factor ranging from 1.25 to 2.4 for 235 carbon steel plates with different reinforcement configuration. The UHM CFRP reinforcement gave the best lifetime increase and was thus chosen for reinforcing wrought iron plates. Particular chemical and metallurgical characteristics of wrought iron lead to a
wide scatter of results for crack growth rate with the same repaired and un-repaired configuration. The “beach marking” technique cannot be used with this kind of materials (lot of inclusions) and the fatigue crack growth was thus being followed using crack gauge.

SIF evolution for each reinforced S235 carbon steel specimens was investigated in order to assess the efficiency of the reinforcement configuration. As expected, UHM CFRP reinforcement shows best results. For all cases, the repair efficiency is bigger when the initial crack length is smaller, as shown by Wang et al. (2013) and Yu et al. (2013). The next step of this study is to determine an empirical and numerical reduction factor for the SIF taking into account the particular geometry of the plates and of the reinforcement configuration. This type of study was ever done by Wu et al. (2013a) and (2013b) for centre-crack tensile steel plate (two symmetric cracks at hole edge) reinforced by CFRP bonded. In these studies, the authors showed the effects of CFRP bond location on the Mode I SIF and proposed a new correction factor as a function of crack length and bond location using both experimental and finite element models. Thus, it will be interesting in further work to adapt the methodology of these two studies to the case of a plate with only one crack at the edge of the hole and reinforced with only one CFRP laminate bonded in front of the crack tip. The final goal remains to determine a reduction factor for SIF for riveted assemblies reinforced by CFRP bonded.

ACKNOWLEDGMENTS

The authors express their strong knowledge to the French Railway Company (SNCF) for the support of this work and to Fyfe, Sika and Fressyinet for the providing of CFRP reinforcements.

ABSTRACT

The objective in this study is to develop a repair and strengthening method of existing steel members by Vacuum assisted Resin Transfer Molding (VaRTM) technology. First, coupon specimens of hybrid FRP plates were fabricated using VaRTM and were tested in order to investigate fundamental material properties. Next, in order to study repair effect and bonding strength, steel plates bonded the hybrid FRP plates using VaRTM were tested under bending load. The results show the quality of material properties of hybrid FRP plates are high and equivalent to a pultruded material. Although the bonding strength varied widely, the bonding strength was high in general. Therefore, the significant repair effect by the VaRTM technology was confirmed.

INTRODUCTION

FRPs have been recognized as a innovative structural material for an efficient rehabilitation and maintenance of infrastructures, because they are lightweight and advantageous for long-term durability. CFRPs, which are composed of carbon fibers, have been feasible for strengthening and repair of existing steel structures in practical use, so that they are high modulus, high strength, and easy to use in situ (Zhao 2013). Since CFRP strips are solid plates, a FRP bonding system is not advantageous to a discontinuous surface like a gap between members, connections and welded joints. Carbon fiber sheets are avetable to a discontinuous surface, however many layers of carbon fiber sheets are required because of a thin sheet and they increase construction period and construction cost. Therefore, the FRP bonding system for the construction of various situations is required.

Vacuum assisted Resin Transfer Molding (VaRTM) technology, which is available to fabrication of structural elements of aircrafts and blades of wind turbine, the objective of this study is the development of construction method for molding and bonding FRP to existing steel structures. This technology has been applied to strengthening of concrete structure (Uddin et al. 2013), not yet to steel structures. Figure 1 shows the schematic view of VaRTM technology.

Figure 1 Schematic view of VaRTM technology
First, in order to investigate fundamental material properties fabricated using VaRTM, coupon specimens of hybrid FRP (HFRP) plates which were composed of carbon fiber (CF) and glass fiber (GF), were tested. Next, in order to study the effect of strengthening and bonding strength, the steel plates bonded the hybrid FRP plates using VaRTM were tested under bending load.

**MATERIAL PROPERTIES OF HFRP PLATES FABRICATED BY VaRTM**

**Design of Test Specimens and Experimental Program**

*MATERIAL configuration and matrix resin*

The HFRP plates which were composed of CF and GF, were selected as reinforcement materials for steel structures. Table 1 shows the laminate configuration. The design equivalent elastic modulus was set to 60GPa, and the ratio of carbon fiber was approximately 40%. The thickness of HFRP plates were set to 5.0, 7.0, 9.3 mm with the arrangement of the number of GF and CF ply. The low-viscosity matrix resin (Toray ACE AUP40) which is widely used to CF sheets bonding system for concrete structures, was selected in consideration to the workability in situ. Figure 2 shows the fabrication of the HFRP plate by VaRTM technology. The HFRP plates were fabricated in size of 700x700 mm at room temperature.

*Test procedure*

Tensile test was based on ACI 440 (ACI 2004,) and conducted using the universal testing machine of 1,000 kN loading capacity. The loading speed was set to 2.0 mm/min. Figure 3 shows the configuration of tensile test specimens. The both ends were reinforced by steel tubes and expanded resin.

![Figure 3 Tensile test specimen](image)

Compressive test was based on JIS K 7018 (equivalent to ISO/DIS 14126) and conducted using the universal testing machine of 100 kN loading capacity. The loading speed was set to 0.5 mm/min. Figure 4 shows the
configuration of compressive test specimens. The both ends were reinforced by bonded CFRP plates of 2 mm thickness.

Test result and discussion

Tables 2 and 3 show the properties of tensile and compressive tests, respectively. Table 2 shows tensile strength and tensile elastic modulus were approximately 1400 N/mm², 60 kN/mm² respectively, and were lower with increasing the thickness. It was found that the tensile elastic modulus was slightly higher than design equivalent elastic modulus as shown in Table 1. Although the coefficient of variation was larger with increasing the thickness, the value of C.V. was 8.5% in tensile strength and the value was 6.4% in tensile strength, respectively and these values were enough low. The values of poisson's ratio were the same value in spite of the thickness and were approximately 0.30.

Table 3 shows the values of compressive strength were larger with increasing the thickness and the value of compressive elastic modulus was slightly small in the case of 9.3 mm thickness, however the values were the same or more than the design value. It was found that the scatter in compressive properties was small so that the values of C.V. were smaller than that of tensile test. In addition, the values of poisson's ratio were the same value in spite of the thickness and were approximately 0.33.

It was found that the C.V. of strength and elastic modulus is the range between 2 and 8.5%. Therefore, the quality of HFRP plates fabricated by VaRTM technology was as equivalent to pultrusion profiles. Tables 2 and 3 also show the average values of thickness of specimen and the volume fraction of fiber $V_f$. These tables indicate that the measured thickness are thicker than the design thickness and $V_f$ is smaller with decreasing the thickness. It was confirmed that the values of $V_f$ are approximately 50% in spite of the thickness in this study.

Figures 5 and 6 show the failure modes in tensile and compressive test. In most specimens, the tensile failure occurred in the middle of specimen. The maximum tensile forces were larger with increasing the thickness, so that the pull out failure in steel grips occurred before tensile failure. Therefore, the valid data in the case of 9.3 mm thickness was four specimens. In compressive test, the failure occurred between the grips, and in many specimens, the failure occurred near the grips.
EVALUATION OF BONDED JOINTS BETWEEN STEEL PLATE AND HFRP PLATE

Fabrication of Test Specimens and Experimental Program

HFRP plates, which were the same fiber configuration as shown in Table 1, were fabricated and bonded on the steel plates by VaTRM technology. Figures 7 and 8 shows the fabrication of specimen by VaRTM technology and the configuration of test specimen. The cantilever flexure test was selected as a simple loading system and the bonding strength between steel plates and HFRP plates were evaluated in this system (Shimizu et al. 2014). Table 4 shows the material property of steel plate. The surfaces of steel plates (L850×B150×t12 mm) were treated by disk grainder and cleaned by acetone. Four spesimens were prepared in each case varying the thickness.

Figure 9 shows the end of HFRP plate (7 mm thick) bonded by VaRTM. The end faces of HFRP plate were different shapes. The end shapes of 5 mm and 7 mm thick were smooth tapered shapes and that of 9.3 mm thick were almost vertical or rough shapes.

Moreover, in order to compare bonding strength by VaRTM, the four test specimens (No. 9.3e) were prepared as follows: the HFRP plate (L300×B100×t9.3mm) by VaRTM were bonded on the steel plates by the epoxy resin adhesive (Konishi E258RW). The method of surface treatment were sand blast in steel plates and sand paper in HFRP plates. The end face of HFRP plate was finished vertically as shown Figure 10.

![Figure 9 End of HFRP plate bonded by VaRTM](image3)

![Figure 10 End of HFRP plate bonded by epoxy resin](image4)

The cantilever flexure test was conducted using electro-hydraulic servo fatigue testing machine (load capacity: 100 kN). The concentrated load was applied by displacement control (0.05 mm/sec) until a clear change of strain in the end of the HFRP plate. Figure 11 shows the setup of the cantilever flexure test. Strain gages were installed on the upper and lower sides in the end and center of the HFRP plate in order to investigate the failure and the effect of strengthening. The location of strain gages (upper side: U1-U4, lower side: L1-L4) were also shown in Figure 8.
Effect of Strengthening by Externally Bonded HFRP Plates

Table 5 shows the thickness, the lowering rate of the strain in the center of steel plate (L4) and the debonding failure load. The theoretical values of the lowering rate were calculated using the average elastic modulus of HFRP plates in tensile and compressive tests and the young's modulus of the steel plate as shown in Tables 2 to 4, and were based on the equivalent bending rigidity as a perfect composite section and the bending stress of cantilever beam at the location of strain gage No. L4. The thickness in calculation were used the measured values. The thickness of HFRP plates bonded by VaRTM were slightly thicker than the thickness of coupon specimens as shown in Figures 2 and 3.

Table 5 shows that the experimental values of the reducing rate of steel strain are good agreement with the theoretical values and in. Moreover, the case of 9.3 mm thick results that the experimental value is slightly larger than the theoretical value, and shows a tendency to decrease the reducing rate. The case of specimen by epoxy resin adhesive also shows the same tendency and the equivalent effect of strengthening.

Debonding Failure Load

Figure 12 shows the relationship between the load and the longitudinal strain (U1 to U4) in case of 7-1. The steel strain of U1 is located at the part without strengthening. The strain of HFRP plate of U2, U3, U4 are located at 5, 15 and 150 mm from the end of HFRP plate in the fixed side. This figure shows all the strain straight increases with increasing load and in case of the strain of U2 to U4, the strain near the end of the HFRP plate is lower. In generally, the stain near the end of the HFRP plate was larger by bending moment based on the perfect composite section. Because the stress is not sufficiently transmitted due to the shear deformation of the HFRP plate.

On the other hand, it was found that the strain of U2 and U3 decreased drastically at the load of 1.72 kN. The minimum load, where the maximum strain occurred at the end of the HFRP plate, is specified as the debonding failure load, because it is considered that the strain decreases if the failure occurs at the end of the HFRP plate. Although, in the case of 7-1, the debonding failure load of U2 and U3 are the same value, the debonding failure load is evaluated using the strain of U2 in all the specimens, since the initiation of failure occurs at the end of the HFRP plate. In the case, where the failure load was not evaluated using the strain of U2, it was evaluated using the strain of U3.

Figure 13 shows the relationships between the applied load and the longitudinal strain in the case of 9.3 mm thick and Table 5 also shows the average value of the debonding failure load and the coefficient of variation in all the specimens. This figure indicates that the strain in the case of the epoxy resin adhesive is lower than that in the case of the VaRTM. This reason can be explained with the influence of the shear deformation depending on the thickness of adhesive layer.
Table 5 shows that the debonding failure load in VaRTM is the maximum value in 7 mm thick and the minimum value in 5 mm thick, and the debonding failure occurred under the bending yield load at the fixed end of the cantilever beam. In addition, the debonding failure load in the epoxy resin adhesive is lowest in all the specimens. This can be explained by the following reasons; in the fabrication process of VaRTM, the end face becomes the tapered shape and the stress concentration is reduced at the end of the HFRP plate. The coefficients of variation in debonding failure load are approximately 30% in VaRTM, and 20% in the epoxy resin adhesive. The debonding failure load varied widely in VaRTM. Because the end faces of the HFRP plates were not controlled in VaRTM process and were different shapes as mentioned above. It is possible to arrange an optional shape and easy to taper the end of HFRP plate by the VaRTM technology.

CONCLUSIONS

The results of tensile and compressive tests indicated that the coefficients of variation are small, so that the HFRP members fabricated by VaRTM technology have high quality. In addition, they have the high fiber volume of fraction and the effect of reinforcement. Moreover, the results of evaluation of bonded joints between the steel plate and the HFRP plate by the cantilever flexure test indicated the debonding failure load is generally high, although they varied widely. In our future work, this technology will be promoted for practical use. In ongoing project, the VaRTM technology has been developed for repair of steel plate girder ends with vertical stiffeners damaged by corrosion.

ABSTRACT

Fatigue failure is one of several failures in steel structures. In recent years, the application of bonding of carbon fiber reinforced polymer, CFRP, to the fatigue damaged member has been investigated for the retrofitting of existing steel structures. To investigate the extended fatigue life of the single edge cracked steel plate strengthened with CFRP, fatigue tests, FE analysis and theoretical prediction of fatigue crack propagation were carried out in this study. The experimental results showed that reinforcement with CFRP was effective to reduce crack growth ratio and the analytical investigation with FE analysis showed the stress intensity factor (SIF) could be effectively reduced by bonding of CFRP. Furthermore, a SIF of an edge crack covered with CFRP plates was estimated by the theoretical equation based on the linear fracture mechanics and crack propagation analysis was conducted by using the SIF. As the results of the crack propagation analysis, the estimated fatigue life of an edge crack repaired by bonding CFRP plates tended to be smaller than the fatigue life given by the tests.

CFRP plate, edge crack, axial loading, stress intensity factor, crack propagation analysis.

INTRODUCTION

At the weld joints of steel structures, initiation of fatigue cracks has been widely reported. Bonding of carbon fiber reinforced polymer, CFRP, has been developed to recover the corroded steel member or repair of fatigue cracks in steel structures (e.g. National Research Council, 2007; Chacon et al., 2004; Phares et al, 2003; and, Roach et al, 2008).

The previous researchers have investigated the extended fatigue life of crack repaired by CFRP bonding by the experiments and FE analysis. Sean et al. (2003) revealed that bonding of CFRP is effective to prevent crack initiation by experiments with notched steel plate and FE analysis focusing on stress concentration factor. Ye Huawen et al. (2010) investigated fatigue performance on tension steel plates strengthened with prestressed CFRP laminates by simple fracture mechanics model based on measured stress. Wang, H. T. et al. (2013) revealed the effect of FRP configurations on the extended fatigue life by FE analysis focusing on SIFs. Colombi, P. (2015) investigated the fatigue crack growth in CFRP-strengthened steel plates with edge crack by experiment, and the crack propagation analysis based on the FE results of crack opening displacement were conducted to confirm the reduction of a SIF. However, in these researches, the reduction of SIFs with CFRP-strengthened crack were evaluated by experimental results or FE analysis.

On the other hand, some researchers have tried to give the SIFs with CFRP-strengthened crack in the simple equation based on the linear fracture mechanics and composites mechanics (Liu et al, 2009 and Matsumoto et al, 2013). However, these researches were focused on CFRP-strengthened center-crack, therefore, the equation based on the linear fracture mechanics and composites mechanics to evaluate the SIF of CFRP-strengthened edge-crack have not been proposed.

This research conducted the fatigue tests on CFRP-strengthened edge-crack to investigate the fatigue life extension by bonding of CFRP. Additionally, the simple equation based on the linear fracture mechanics and composites mechanics to evaluate the SIF of CFRP-strengthened edge-crack was proposed.
FATIGUE TESTS

Specimen Geometry and Loading

The dimensions of the specimen used a steel plate of JIS-SM490Y are shown in Figure 1. In the specimen, an edge crack of length 10mm is installed at the center of the steel plate. CFRP plates were applied to the both sides of the steel plate, as shown in Figure 1. Longitudinal elastic modulus of CFRP plates is 170kN/mm², elastic modulus of adhesive is 1358N/mm². During the fatigue tests, the stress range was controlled as 80 or 100N/mm² with the stress ratio of zero.

Fatigue test results

Figure 2 shows the relationship between the crack length and the number of cycles. The Specimens N and N+C are the control specimen without CFRP plate and the specimen with CFRP plates, respectively. In these figures, the results of crack propagation analysis mentioned in the latter chapter are also shown as the soiled black and red lines. Comparison of theoretical analysis results and test results is discussed in the latter Chapter. As seen in Fig.2, the existing fatigue lives, which fatigue crack propagated to 25mm, in the Specimen N+C are 50 times longer than those in the Specimens N. Furthermore, CFRP plates worked without debonding during the fatigue tests.

FINITE ELEMENT ANALYSIS

FE model

By using FE model, loading of the Specimens N and N+C shown in Fig.1 is simulated. Table 1 shows the material properties of steel, CFRP plates and adhesive. Material properties of CFRP plates were calculated based on the theory of composite material. Transverse elastic modulus of CFRP plates shown in Table 1 is smaller than that assuming CFRP plates as isotropic material \( G = E/(2(1+v)) \), since transverse elastic modulus of the matrix resin composing CFRP plates is small. The previous equation of SIF for a crack covered with CFRP plates does not consider the shear deformation of CFRP plates itself (Matsumoto et al, 2013). Therefore, for the comparison, FE analysis assuming CFRP plates as isotropic material, of which Elastic modulus is 170kN/mm² and Poisson’s ratio is 0.34, was conducted additionally. In FE analysis, uniform axial loads of 1N/mm² are subjected to the both edges of the model.
FE results of the SIF

Figure 3 shows the FE results of the SIFs. In this figure, the theoretical results of the SIFs as described in the next Chapter are also shown as the dot-line, solid and dashed lines. As can be seen in Fig.3, the SIF is significantly reduced by bonding CFRP plates in both case of anisotropic and isotropic materials. The FE results of isotropic material is smaller than those of anisotropic material. This is because the stress distribution of anisotropic CFRP plates, which consider the shear deformation of the matrix resin composing CFRP plates, at the right on the crack is smaller than that of the isotropic CFRP plates.

![Figure 3 FE results of SIFs](image)

### STRESS INTENSITY FACTOR OF A CRACK REPAIRED BY CFRP PLATE

#### Equation of a SIF of a crack repaired by CFRP plate

Figure 4 shows the superposition principle of the SIF of a crack repaired by CFRP plates. Assuming the steel plate subjected to tensile stress of $\sigma_0$ (State 0 in Fig.4), the nominal stress, $\sigma_n$, is reduced by bonded CFRP plate, since the CFRP bonded section can be regarded as the composite section (State 1 in Fig.4). On the other hand, since the CFRP plates carry the additional stress at the crack, which cannot be distributed by the crack, the crack opening displacement covered with CFRP plate is reduced compared with unreinforced state. It can be assumed that this additional stress distributed to the CFRP plate on the crack, $\sigma_n$, is applied to the crack surface to close the crack (State 1 in Fig.4). State 1 in Fig.4 can divide into States 2 and 3 based on the superposition principle. Thereby, the SIF of a crack repaired by bonded CFRP plates, $K_I^{(0)}$, can be calculated by using the SIF of State 2 in Fig.4, $K_I^{(2)}$, and the SIF of State 3 in Fig.4, $K_I^{(3)}$.

$$K_I^{(0)} \equiv K_I^{(1)} = K_I^{(2)} - K_I^{(3)} \quad (1)$$

By using Eq.(1), the SIF of a center cracked plate covered with CFRP plates, $K_I^{(0)}$, is given in the following equation, which takes into account the crack opening caused by the thickness of adhesive $h$ (Matsumoto et al, 2013).

$$K_I^{(0)} \equiv \sigma_n F_w \left(1 - F_g \frac{h}{a} \right) \quad (2)$$

where $a$ is the edge crack length, $F_w$ is the correction factor for a central crack in a plate of finite width and $F_g$ is the geometry correction factor caused by CFRP bonding.

Generally, in case of an edge crack, $F_g = 1.12$, which is the free surface correction factor, is multiplied by Eq.(2), since the crack opening displacement of an edge crack exposed to the free surface becomes larger than that with a central crack. On the other hand, in case of an edge cracked plate all of which is covered with CFRP plates, it can be assumed that the effect of the free surface does not need to be considered in the calculation of the SIF, since the crack opening displacement is suppressed by bonded CFRP plates. Therefore, the SIF of an edge crack covered with CFRP plates is calculated by Eq.(2).

### Table 1 Material properties

<td>1.36</td>
<td>0.4</td>
<td></td>
</tr>
</tbody>
</table>

$E$: Elastic modulus (kN/mm$^2$), $v$: Poisson’s ratio, $G$: Transverse elastic modulus (kN/mm$^2$)
As mentioned in FE results of the SIFs, shear deformation of CFRP plates have modest effect on the SIF. Especially, in the poor fiber volume content of CFRP, the shear deformation becomes high. In the previous study, the conversion thickness of adhesive $h'$, which considered the shear deformation of CFRP plates caused by the matrix resin, was proposed by the following equation (Shirai et al, 2015).

$$h' = h + \frac{t_c}{3} \left( G_{czx}(1-V_c) + G_{e}V_c \right)$$  \hspace{1cm} (3)

where $h$ is the actual thickness of adhesive, $t_c$ is the thickness of CFRP plates, $G_e$ is the transverse elastic modulus of adhesive, $G_{czx}$ is the transverse elastic modulus of CFRP plates and $V_c$ is the fiber volume content.

Since $G_eV_c$ in Eq.(3) is negligibly small, $h'$ is able to assume by the following equation.

$$h' = h + \frac{t_c}{3} (1-V_c)$$  \hspace{1cm} (4)

In this paper, the conversion thickness $h'$ is used in Eq.(2) as a thickness of adhesive layer to calculate the SIF of an edge crack covered with CFRP plate. In this specimen, conversion thickness $h'$ is calculated as 0.37mm.

**Theoretical results of the SIF**

In Fig.3, the theoretical results of the SIFs are shown as dot-line, soiled and dashed lines. The theoretical results with adhesive thickness of $h = 0.25\text{mm}$ is good agreement with the FE results with isotropic CFRP plates, and the theoretical results with adhesive thickness of $h' = 0.37\text{mm}$, which included the shear deformation of CFRP plate, is also good agreement with the FE results with anisotropic CFRP plates.

**CRACK PROPAGATION ANALYSIS**

To clarify the fatigue life extension repaired by CFRP bonding, crack propagation analysis is conducted by using the following equation.

$$\frac{da}{dN} = C \left( \frac{\Delta K}{\Delta \sigma} \right)^m$$  \hspace{1cm} (5)

where $N$ is the number of cycles, $\Delta K_{th}$ is the threshold stress intensity factor of steel. In this paper, $\Delta K_{th}$ is assumed as 0. Material constants $C$ and $m$ are calculated by the relationship between $\frac{da}{dN}$ and $\Delta K$ given by the Specimen N ($C=5.781\times 10^{-17}$, $m=4.323$). Figure 5 shows the relationship between the SIF range divided by the stress range $\Delta K/\Delta \sigma$ and crack length $a$. The test results of $\Delta K/\Delta \sigma$ are calculated in the following equation.

$$\frac{\Delta K}{\Delta \sigma} = \left( \frac{\frac{da}{dN}}{C} \right)^{\frac{1}{m}}$$  \hspace{1cm} (6)

As can be seen in Fig. 5, the test results of $\Delta K/\Delta \sigma$ in the Specimen N+CFRP is smaller than the FE results of $\Delta K/\Delta \sigma$. One of the reasons is assumed that the adhesive thickness varies through the specimen and a part of adhesive thickness is thinner than the measured value. The results of the crack propagation analysis by using Eq.(5) was also compared with test results in Fig.2. In the Specimen N+CFRP, the analytical results of crack propagation velocity is higher than that of the test results, as seen from Fig.2. This is because the test results of $\Delta K/\Delta \sigma$ in the Specimen N+CFRP is smaller than the FE results of $\Delta K/\Delta \sigma$, as shown in Fig.5.
CONCLUSION

This paper presented the simple equation of Stress Intensity Factor of an edge cracked plate repaired by bonding CFRP plates, based on the linear fracture mechanics. By the proposed equation, it could successfully consider the effect of the shear deformation of CFRP plates on Stress Intensity Factor, and the estimated results of Stress Intensity Factor was good agreement with the FE results. However, the estimated fatigue life of an edge crack repaired by bonding CFRP plates tended to be smaller than the fatigue life given by the tests.

ABSTRACT

In the context of the strengthening for existing structure, the scientific community has recently focused its attention on fibre-reinforced cementitious matrix (FRCM) composites. Such materials are made from fabric meshes embedded in a cementitious matrix instead of an epoxy resin, such as FRP material. Unlike fiber-reinforced polymers (FRPs), characterized by an elastic tensile behaviour, the FRCMs exhibit an anelastic tensile behaviour with cracks formation. The FRCM plastic behaviour in tension made the tensile characterization more complex with respect to FRP composite and more parameters need to be evaluated.

For their widespread use, it is necessary to draft guidelines on their mechanical characterization, useful to designers, offering different types of tensile and shear-bond testing procedures. This paper will present an overview of research advancements on the mechanical behaviour of FRCM composites, summarizing the various types of experimental testing setup, identifying the critical issues and peculiarities. Moreover, a database, collecting the experimental results on tensile tests, will be presented and discussed focusing on the influence of single components properties on the global mechanical parameters of FRCM composite.

KEYWORDS

FRCM, tensile testing procedure, crack propagation.

INTRODUCTION

The advantages of FRCM material for retrofitting masonry structural elements are provided by the use of inorganic matrices with respect to epoxy resin, showing high fire resistance, permeability, applicability on wet surfaces, reversibility, easiness and reduced costs of installation.

The FRCM (Fabric-reinforced cementitious matrix) composite materials are composed by an inorganic matrix characterized by mortar or concrete in which a bidirectional large mesh textile reinforcement is embedded. The textile can be coated in order to ensure protection and to improve the adhesion between the matrix and the textile. The forefather of the FRCM is the ferrocement, a composite material made with a high quality mortar in which grid of steel bars of small diameters are inserted. More recent are the TRC (Textile Reinforced Concrete) and the TRM (Textile Reinforced Mortar) composites, which are used as strengthening material for masonry or concrete structure. The FRCM includes both the families.

The increasing adoption of FRCM materials as reinforcement of existing structures, leads to the need, for manufacturers and designers, to define some material characterization procedures and design rules. The scientific community is working in this direction, through various research projects, giving indications about the experimental evaluation of the mechanical behaviour of FRCMs. The qualification procedures of FRCM composites should reproduce the real behaviour of the material considering its different applications, especially when used as reinforcement of existing structures (flexural strengthening of reinforced concrete beams, reinforcement of arches and vaults, confining material of concrete columns, strengthening of masonry walls), evaluating both the constitutive tensile behaviour of the FRCM, and also the adhesion between it and the support material (masonry or concrete) and between mortar and fibres. In the present work the first issue is investigated.

The first experimental tests addressed to the mechanical characterization of FRCM specimens, that considered the overall material, and not the component materials (textile and matrix) individually, date back to the nineties (Dugas \textit{et al.} 1998). From those years many studies have been conducted by researchers at RWTH Aachen University School, Germany, (Jesse 2004, Molter \textit{et al.} 2004, Hegger \textit{et al.} 2006, Hartig \textit{et al.} 2009) who carried out and suggested different types of direct tensile tests, assessing advantages and disadvantages. Afterwards, more recently, a satisfying work was carried out by RILEM TC 232 and TC250.

Pointing towards the knowledge of the FRCM tensile constitutive law, the aim of this work is to gather, to compare and to discuss the results, available in literature, of experimental campaigns based on tensile tests on FRCM specimens. The comparisons are based on more than 350 data. Subdividing the experimental data in homogeneous
families based on test set-up typology and fibre grid, the average stress and strain values of the FRCMs tensile constitutive law are computed.

**TENSILE BEHAVIOUR: TESTING PROCEDURES**

The most common test typology used to characterize the tensile behaviour of FRCMs is the direct tensile test. The difficulty to define a tensile characterization procedure, able to determine the tensile constitutive behaviour of FRCMs, lies in the strong influence that various parameters, such as the material type, the specimen geometry, the specimen preparation, the test set-up, as well as the type of measuring instruments, have on the experimental results. Generally, the direct tensile tests, used for the mechanical characterization of different materials, consist in submitting a specimen (with rectangular or dogbone shape) under uniaxial tensile loading that increases monotonically. The specimen is clamped at the extremity ends by a stiff clamping jaws, that transmit and spread the tensile load to the specimen. It was noticed that for FRCM specimens the clamping typology strongly influences the tensile strength, the stresses distribution, the cracking evolution and the failure modes of the specimen (Hartig *et al.* 2011, De Santis *et al.* 2014, Carozzi *et al.* 2015, Arboleda *et al.* 2015). This is the main characteristic that differentiates the various types of tensile testing proposed by several authors.

![Figure 1](image.png) Direct tensile test type on FRCM specimen: rigid clamping (Type A), soft clamping (Type B) (Arboleda *et al.* 2015). In table the range values of the geometrical parameters are reported. \( L \) is the length, \( b \) the width, \( t \) the thickness of the specimen.

<table>
<thead>
<tr>
<th></th>

<td>6-12</td>
</tr>
<tr>
<td>Type B</td>
<td>200-600</td>
<td>30-180</td>
<td>7-12</td>
</tr>
</tbody>
</table>

As it emerges from the collection of experimental data, there are two basic types of direct tensile tests. One type is known as "Set-up A" (or clevis grip or rigid load application), and the other as "Set-up B" (or clamping grip or soft clamping) (Hartig *et al.* 2010, Arboleda *et al.* 2015). The two types are distinguished by the mode of the tensile load transmission from the testing machine to the specimen through the gripping plates (Figure 1). The set-up A allows to distribute the tensile load on the specimen through adhesive forces and shear stresses. This test set-up consists in applying two bolted rigid plates, subjected to tensile loading, glued with epoxy resin on the sample extremities, avoiding the slipping between the steel plates and the specimens, from which the connotation of "rigid" load application system. This clamping system can be designed to allow rotations to ensure a uniaxial tensile stress state and prevent parasitic bending moments. The set-up B permits the stress transmission between the specimen and gripping plates through Coulomb friction, applying a pressure orthogonal to the plate faces. In this case, the slipping between the plates and the specimens may occur. This clamping type, is, in fact, knew as "soft" clamping. The advantage of the set-up A methods, according to the technical acceptance criteria AC434, lies in the better stress distribution in the specimen, which avoids the mortar cracking in the area close to the clamping zone. It well reproduces the stress state when the FRCM is used as strengthening material and the textile is not constrained at the extremities, because of the typical specimen failure mode due to the slippage of the grid. The set-up B method is advantageous for the easy execution. The typical failure mode of the FRCM specimen is ascribable to the tensile failure of the grid because of the clamping pressure that avoids the sliding of the textile. This method can be more acceptable when the tensile constitutive behaviour of the FRCM want to be known.

In order to evaluate the stress-strain curve is necessary to define the measuring length on the sample and the type of measuring instruments for the strains evaluation. The most common measuring setup consist in applying on the coupon LVDTs, extensometers or utilize the photogrammetry measurement, that is a refined method to evaluate the crack propagation in the specimen during the test. Comparisons between the curves resulting from different
measurement systems have proven that the obtained strains are very similar (Contamine et al. 2011, Hegger et al. 2006). As suggested in Colombo et al. 2013 and Contamine et al. 2011, it can be useful to apply two LVDTs on both the specimen sides, in order to evaluate potential flexural effects due to the loading eccentricity or to evaluate possible defects of asymmetry in the specimen. According to De Santis et al. 2014 the measurement system applied on the entire free length of the specimen are effective if there are not sliding in the gripping zone, and however the measurement instrument base has to be large with respect to the crack spacing.

The typical uniaxial tensile behavior of FRCM is characterized by a trilinear curve composed of three branches, each of which identifies a different stage of cracking. In Figure 2 a generic curve is shown, in which the stresses $\sigma$ are calculated as the ratio between the load $F$ and the area of the dry textile cross section $A_f$, in order to account the tension stiffening phenomenon, while the strains are estimated on a representative length of the sample through measuring instruments. The first stage of the curve reproduces the tensile behaviour of the not cracked specimen, with a stiffness $E_t$. The second stage describes the behaviour of the specimen during the cracking propagation in which the cracks develop gradually and the mortar is still able to contribute to the composite stiffness: the tension stiffening phenomenon occurs. The third branch is influenced by the grid tensile strength and not by the already cracked mortar, and it is characterized by the slope $E_f$ parallel to $E_t$.

![Figure 2 Tensile stress-strain law representative of the FRCM behaviour.](image)

**COLLECTED DATABASE ON FRCM TENSILE TEST**

In the present work the data regarding the mechanical and geometrical characteristic of FRCM specimens made with different materials, the test set-up and the results of more than 20 experimental campaigns (441 tensile tests), available in literature, were collected. In Table 1 the range values of the mechanical parameters for each FRCM family represented by the grid nature, and the relative data numerosity are listed. The large range of values for cementitious matrix strength and for grid properties used in the experimental tests make the understanding of tensile FRCM behaviour particularly complex.

The experimental results were analysed by comparing the tensile trilinear behaviour (Figure 3) characterized by the three stages, such as the cracking point ($\sigma_{cr}$, $\varepsilon_{cr}$ in Figure 2), the transition point ($\sigma_{tr}$, $\varepsilon_{tr}$ in Figure 2) and failure point ($\sigma_{fu}$, $\varepsilon_{fu}$ in Figure 2). Due to the different grids, the tested specimens are grouped according to the bidirectional textile reinforcement composed by AR-Glass, Aramid, Carbon, Basalt, PBO yarns or steel unidirectional fibres. In the following graphs the colours of the reported data represent the different materials of Table 1.

</tbody>
</table>
The stress that characterizes the cracking stage $\sigma_c$, is compared with the mortar tensile strength (Figures 4a, b). The stress is computed with respect to the specimen area, through the ratio between the experimental cracking load $F_c$ and the specimen area $A_\sigma$. The different sizes of the point reported in the charts state the data numerosity for the average evaluation: bigger point size represents the mean value of results obtained by more tests. In Set-up B the first crack occurs for a stress lower with respect to the mortar strength. For the scatter of experimental data a direct relation between stress and mortar strength seems not is showed, instead for Set-up A the experimental data practically stay on the bisectrix, that means, as expected, the cracking stress depends directly on mortar tensile strength.

In Figures 4 (c, d) the slope of the third branch of the FRCM tensile stress-strain law in average $E_3$, computed as reported in Figure 2, is represented versus the elastic Young’s modulus of the textile material $E_t$. It emerges that, effectively, for the data obtained with the set-up B (Figure 4d) the slope $E_3$ of ultimate stage of the curve, in which the specimen is significantly cracked and the mortar is not able anymore to contribute at the composite stiffness, is ruled by the grid tensile behaviour with stiffness $E_t$. Instead in Figure 4(c), the third branch stiffness is lower than that of the grid, this is probably due to the eventual textile slippage into the mortar for the case of the FRCM tested with the set-up A.

CONCLUSIONS

A collected database on FRCM tensile tests with 441 data was presented. Attention was posed on grouping the data in homogeneous families based on grid nature and on the adopted experimental set-up with the final goal to evaluate which experimental procedure correctly describes the actual tensile behaviour of FRCM for design purpose. A first analysis of parameters describing the tensile behaviour was performed and the dependency of FRCM mechanical properties on the single components properties was highlighted. In the future work more data.
will be collected with focus on the cracking propagation stage depending on cementitious matrix and on grid nature, with also the aim of establishing the tension-stiffening model of FRCM materials by accounting the effects of various parameters, such as the test setups, the types and the mechanical properties of reinforcing fibers as well as the grid sizes.

ABSTRACT

Fiber reinforced cementitious matrix (FRCM) composites represent an alternative to fiber reinforced polymer (FRP) composites for strengthening existing civil structures. FRCM is comprised of fibers, usually in the form of a textile with an open-mesh configuration, embedded in an inorganic mortar matrix. It shares the advantages of FRP systems and overcomes some of its drawbacks, which makes it suitable for a wide range of applications. Although research on this topic is still scarce, it has been shown that debonding represents a key factor in its performance. In order to gain more insight in this issue, a series of classical push-pull single-lap direct shear tests were carried out on basalt, carbon, and glass FRCM-concrete joints. The results allow for comparing the performance of the joints with carbon, basalt, and glass fibers in terms of applied load – global slip response and failure mode. The influence of matrix age was also investigated. The curing time of the mortar matrix was found to influence the load carrying capacity of carbon FRCM – concrete joints.

KEYWORDS

FRCM, basalt, carbon, glass, concrete, debonding.

INTRODUCTION

Fiber reinforced polymer (FRP) composites have been proven to be effective in repairing or strengthening structures. The most common types of fibers used in FRP composites are carbon, glass, or more recently basalt. Although FRPs have shown good results in terms of bonding and application, they present some drawbacks. These include: regulations on how to handle the epoxy bonding agents due to the toxicity of the components, low permeability and diffusion tightness, and poor compatibility with a concrete substrate (Blanksvärd et al. 2009).

Fiber reinforced cementitious matrix (FRCM) composites are intended as an alternative to FRP composites for strengthening existing masonry and concrete structures. FRCM is comprised of fibers, usually in the form of a textile with an open-mesh configuration, embedded in an inorganic mortar matrix. It shares the advantages of FRP systems and overcomes the above-mentioned drawbacks.

Research on the use of FRCM composite in strengthening applications is still in its infancy, and comprehensive studies of the stress transfer mechanism and bond properties of FRCM composites are not yet available. Only a few studies have been carried out to compare the behavior of FRCM – concrete joints (D’Antino et al. 2015), and a systematic study on the influence of fiber type is not yet available. Moreover the bond between the base concrete and the matrix is not completely understood, especially since the bond between the base concrete and the mortar can be influenced by drying shrinkage (Orosz et al. 2010).

It is important to note that strengthening of a structure usually requires it to be temporarily taken out of service, so short curing times are desirable, which is an advantage of using FRP composites. Therefore, for the case of FRCM composites, it is of interest to understand the influence of matrix curing time on composite strength development.
EXPERIMENTAL PROGRAM

The composites were comprised of a bidirectional balanced fiber net made of basalt, carbon, or glass and a cementitious mortar matrix. Mechanical properties of the fabrics are provided in Table 1 in terms of ultimate tensile strength $f_t$, ultimate tensile strain $\varepsilon_f$, and modulus of elasticity $E_f$ as given by the manufacturer. Fiber net geometrical properties are also presented in Table 1. The cross sectional area of the bundles $A_b^*$ was provided by the manufacturer. The fiber nets are characterized by fiber bundle spacing $b$, width $b^*$, and thickness, $t^*$. Values of $b^*$ in Table 1 were measured, and values of $t^*$ were calculated as $A_b^*/b^*$.

Note 1. Value reported by the manufacturer

The matrix was a ready-mixed cementitious non-shrink, fiber reinforced compound mortar, and it was used in each composite. The matrix used in this study was not specifically designed for improved bonding with respect to any of the fiber nets studied. It is a commercially-available repair mortar for both concrete and masonry applications. The compressive strength $f_{cm}$ and flexural strength $f_{cf}$ of the mortar were determined at various ages according to the standards (EN 12390-3 2009) and (EN 12390-5 2009), respectively. The prisms sizes for the flexural tests were 40x40x160 mm. The two halves of each prism were placed between 40x40 mm loading plates of a press to determine the compressive strength of the mortar. The average value of $f_{cm}$ was 16.4 MPa, 25.0 MPa, 32.8 MPa, at 3, 7, and 28 days, respectively, and the average value of $f_{cf}$ was 3.63 MPa, 4.55 MPa, and 6.83 MPa, at 3, 7, and, 28 days, respectively. The average compressive strength of the concrete prisms was 59.3 MPa determined from six 150 mm cubes tested according to (EN 12390-3 2009) at 28 days.

The composite strips were bonded to the surface of unreinforced concrete prisms. The concrete prisms were 125x125x500 mm. The fiber strips were 500 mm long with three longitudinal fiber bundles. The width $b$ of the composite strip was chosen as a function of the spacing $b$ and width $b^*$ of the bundles in the fiber net, so that three bundles of the net would be fully embedded in the matrix. The composite width was 75 mm for basalt and glass FRRCM specimens and 60 mm for carbon FRRCM specimens. The bonded length used in this study was $l = 330$ mm and was chosen based on previous studies of PBO FRRCM-concrete joints (D’Ambri $et al.$ 2012, D’Antino $et al.$ 2014). The concrete surface was cleaned and prepared with light sandblasting prior to applying the composite. Wood forms were first attached to the concrete prism to allow for good control of the bonded area (Figure 1a), then a mortar layer of 4 mm thickness was cast onto the concrete surface. The fiber net was subsequently placed on the surface of the fresh mortar. A second set of forms was attached on top of the fiber net to secure it in place and to cast the external layer of mortar with a thickness of 4 mm (Figure 1b). The specimens were then cured under normal ambient conditions until the day of testing.

![Figure 1 a) Specimen preparation before applying the composite, b) test specimen after application of the composite, c) experimental setup](image-url)
A single-lap (direct) shear test setup was adopted in this study. A push-pull configuration was used in which the composite fibers were pulled while the concrete prism was restrained (Figure 1c). A similar test setup has been used in (Sneed et al. 2014), among other studies, to test other FRCM composite-concrete joints. Two aluminum plates were glued to the end of the fiber net using a thermosetting resin (Figure 1c). The aluminum plates were then introduced between two steel plates that were bolted together to clamp the fiber net. The steel clamp was attached to a pinned joint through which the load was applied to the bare fiber strips. The concrete prism was restrained using a 50 mm thick steel plate anchored with four 18 mm diameter rods to the fixed end of the testing machine. The loading was applied in displacement (machine stroke) control at a rate of 0.05 mm/min using a closed loop servo-hydraulic universal testing machine.

Global (loaded end) slip \( g \) was measured using two linear variable transducers (LVDTs) that were attached to the concrete surface close to the composite side edges and oriented parallel to the bonded length. The rod of the LVDTs reacted against an aluminum L-profile that was glued to the bare fiber net outside of the bonded area. The term \( g \) is defined as the displacement between the fibers just outside of the composite at the loaded end and the adjacent surface of the concrete prism (Carloni et al. 2014), and is computed as the average of the two LVDT measurements.

Twenty-seven specimens were tested in this study, and the test variables were fiber type (carbon, glass, or basalt) and matrix age (3, 7, or 28 days). Test specimens are listed in Table 2. Each series is identified by acronyms indicating the textile type and age in days of the composite at test date. The identification of a particular specimen within a series is indicated by the digit at the end of the group name (example: B_03_2 indicates basalt fibers, age at test date of 3 days, second specimen of the series). Results of basalt FRCM specimens tested at 3 days were disregarded and are not included due to problems with the data acquisition system. Specimens with glass fibers were tested only at 7 and 28 days.

D – delamination of composite from concrete substrate
DC – delamination within the composite (between the two matrix layers)
FP – fiber pull-out (debonding of fibers from the embedding matrix)
RESULTS AND DISCUSSION

Summary of results

Table 2 reports the peak load $P_{\text{max}}$, global slip at peak load $g_{\text{Pmax}}$, the equivalent stress in the fiber bundles at peak load $\sigma_{\text{Pmax}}$ computed as $P_{\text{max}}/n\Lambda_b^*$ where $n$ is the number of longitudinal fiber bundles ($n=3$), the equivalent maximum strain in the fibers $\varepsilon_{\text{Pmax}}$ computed as $\sigma_{\text{Pmax}}/E_f$, the load at first crack formation in the composite $P_{\text{cr}}$, and the corresponding global slip $g_{\text{Pcr}}$, and observed failure mode.

In Table 2 the symbol “-” indicates that no data were recorded for the particular parameter. The presence of “-” across the entire row indicates that the composite strip detached from the concrete prism prematurely, usually during clamping of the aluminum plates in the steel clamp, especially for basalt and glass specimens since the fabric stiffness of the two fiber nets is much higher compared to that of the carbon net. For a successfully tested specimen, the presence of “-” in $P_{\text{cr}}$ and $g_{\text{Pcr}}$ indicates that no cracks were noticed on the surface of the composite before the peak load was reached. Some specimens showed an unreasonably low peak load compared to other specimens within the same group. The authors believe that this could be caused by the nonuniform distribution of the applied load among the longitudinal fiber bundles. It was also observed that specimens with a lower peak load showed a high rotation of the L-profile. In (Carloni et al. 2014) a criterion is used to determine whether the results of a specimen can be considered reliable or not based on the rotation of the rigid plate used to measure $g$. In this study specimens that showed “large” rotations of the L-profile were marked as “Fail” in Table 2 and were disregarded from further analysis. Large rotations were determined by comparing the measured load-displacement responses of the individual LVDTs. It should be noted that in the case of the present study this check was only qualitative since detailed bond-slip relationships for the tested composites are not currently available. Usually, large rotations were also characterized by lower peak loads.

(a) Carbon FRCM
(b) Basalt FRCM
(c) Glass FRCM

Figure 2 Applied load $P$ - global slip $g$ response of FRCM-concrete joints
Applied load $P$ - global slip $g$ response

Figure 2 shows the applied load $P$ – global slip $g$ of specimens in the carbon, basalt, and glass FRCM series, respectively. Only results of specimens with “Pass” in Table 2 are plotted. In each graph of Figure 2, plots with same line type correspond to specimens of the same series and tested at the same age. All specimens with carbon fibers (Figure 2a) failed by debonding of the fiber bundles from the embedding matrix. This represents a typical behavior observed for FRCM-concrete joints where the FRCM composite consists of uncoated, high modulus fibers such as carbon or PBO (D’Antino et al. 2014, Sneed et al. 2014). After an initial almost linear branch, the response becomes nonlinear as the microcracking occurs at the fiber-matrix interface. The applied load increases until the effective bond length is fully established and the bond mechanism reaches the free end of the bonded length (Carloni et al. 2014). After the peak load, the fiber bundles were observed to pull out of the matrix, and the load gradually decreases until it reaches constant plateau. The constant load after the bundles are completely debonded is associated with friction (interlocking) (D’Antino et al. 2014).

The load response of the basalt FRCM-concrete joints (Figure 2b) was characterized by an initial linear response, followed by a sudden decrease in load associated with an increase in global slip. These jumps were associated with the formation of cracks parallel to the composite width, and the delamination of the composite from the loaded end up to the location of the crack. Subsequently, the load increased and additional cracks were observed up to the peak load when the specimens failed by complete delamination of the composite from the concrete substrate. No damage was observed on the concrete surface, indicating that failure occurred at the matrix – substrate interface.

The limited number of specimens with glass fiber nets (Figure 2c) that were considered to “pass” the criterion showed a behavior similar to that of the carbon fiber specimens. The specimens show an initial linear behavior followed by a nonlinear branch as a result of fiber-matrix interface damage. The applied load increases up to the peak load where either fiber pull-out or complete composite delamination from the substrate was observed to occur. No damage was observed on the concrete surface after the composite detached.

Influence of fiber type

In this section a comparison of specimens tested at 28 days is carried out between the three series. Figure 3 shows the equivalent stress $\sigma$ - global slip $g$ relationship for all specimens that “passed” the criterion in Table 2. Plots with the same line type in Figure 3 correspond to specimens of the same series. The highest maximum stress was observed in specimens with basalt fibers (average of 837 MPa) at a corresponding slip of approximately 3 mm. The stress determined for specimens with carbon fibers (average of 635 MPa) was lower than that of the basalt but higher than that of the glass fibers (average of 523 MPa). The maximum stress in the carbon fibers was reached at a slip of approximately 1 mm. Delamination of the composite from the substrate was the dominant failure mode observed for basalt, whereas fiber pull-out was observed for carbon and glass. This suggests that the bond strength of the fiber-matrix interface for the basalt FRCM composite is higher than for carbon and glass FRCM composites. Since failure occurs at the weakest interface, for basalt it is the composite-substrate interface, therefore delamination occurred. It should be noted that the results are only valid for the materials used in this study.

Figure 3 Stress $\sigma$ - global slip $g$ response of carbon, basalt, and glass FRCM-concrete joints at 28 days
Influence of matrix age

Influence of curing time on the bond behavior on FRCM – concrete joints was studied for carbon, basalt, and glass FRCM composites. For the sake of brevity as well as limited available information, the discussion of the influence of matrix age is limited to specimens with carbon nets presented in Figure 2a. A clear difference in terms of peak load can be observed between tests carried out at 3, 7, and 28 days. The average maximum load at 3 days was 0.92 kN (51% of the 28 day average maximum load), at 7 days was 1.29 kN (72% of the 28 day average maximum load), and at 28 days was 1.79 kN. On the other hand, the residual capacity did not appear to be significantly influenced by matrix age, which may be explained by the fact that the residual capacity is associated with mechanical interlocking and not bond (D’Antino et al. 2014). A similar increase in maximum load was also observed for basalt and glass FRCM, however, more tests need to be carried out for a better understanding.

CONCLUSIONS

In this paper, experimental results of 27 single-lap direct shear test of carbon, basalt, and glass FRCM composites bonded to a concrete substrate are presented, of which 16 were found to show reliable results. The load responses and failure modes differed between the tested composites. Carbon and glass FRCM specimens failed by fiber debonding from the embedding matrix, while basalt FRCM specimens failed by delamination from the concrete substrate. Basalt and glass FRCM specimens showed cracks on the matrix surface during testing. The load at which the first crack occurred was generally much lower than the maximum load. In contrast carbon FRCM specimens did not show any cracks on the matrix surface.

Based on limited test results, despite having a lower capacity compared to basalt, carbon FRCM could be more suitable for strengthening application because of the increased rigidity and lack of matrix cracking. More tests should be carried out in order the better identify parameters that influence the load response of FRCM composites using commercially available fiber nets and textiles.

Results from this study show that matrix age influences the strength of carbon FRCM composites, especially the bond strength of the fiber-matrix interface.

ACKNOWLEDGMENTS

The first and second authors would like to acknowledge the technical and economical support from the European Network for Durable Reinforcement and Rehabilitation Solutions (endure), a Marie Skłodowska Curie Initial Training Network. G&P Intech of Altavilla Vicentina (Italy) is gratefully acknowledged for providing the FRCM composite materials.

REFERENCES

ABSTRACT
Shear failure of reinforced concrete (RC) beams is an undesirable mode of failure due to its sudden and brittle nature and thus needs to be carefully evaluated when planning a strengthening intervention. The use of fiber reinforced polymer (FRP) composites has shown to be capable of providing an adequate increase in shear strength. However, in recent years, there is interest in developing new techniques in which the positive attributes of FRP are utilized but some of its drawbacks are overcome. Among these techniques, fiber reinforced cementitious matrix (FRCM) composites, in which the organic resins are replaced by inorganic mortars, have shown promising results. In this paper, a bibliographical review of the available literature on FRCM shear strengthening of RC beams is carried out. Two available design models are evaluated using a database compiled by the authors. The review shows that FRCM is able to provide an increase in strength and performance comparable to RC beams strengthened with FRP. However, the models are not able to accurately predict the behavior of FRCM strengthened beams.

KEYWORDS
FRCM, FRP, reinforced concrete, shear, strengthening.

INTRODUCTION
Fiber reinforced polymer (FRP) composites have proved their efficiency for upgrading existing structures for bending, shear, and confinement, allowing a time/cost efficient intervention. However, some limitations, mainly related to the use of organic resins, have been pointed out (Al-Salloum et al., 2012). Fiber reinforced cementitious matrix (FRCM), a composite material that employs an inorganic cement-based matrix instead of an organic matrix, allows for overcoming some of the drawbacks presented by FRP composites. While research carried out on the topic is still scarce, the effectiveness of this technique for flexural and shear strengthening and confinement of axially/eccentrically loaded RC elements has been confirmed (ACI 549.4R, 2013; Triantafillou and Papanicolaou, 2006; Ombres, 2015).

This paper summarizes the major findings on the topic of shear strengthening of RC beams with FRCM composites. In the first part, a detailed bibliographical review of the available literature on the shear strengthening of RC beams using FRCM composites is carried out. In the second part, two published design models proposed to predict the contribution of the FRCM composite to the shear strength of RC beams, including the ACI 549.4R (2013) expressions, are assessed using a database of experimental results compiled by the authors.

EXPERIMENTAL DATABASE
A total of 14 articles related to shear strengthening of RC beams using FRCM composites were found in the technical literature. Table 1 summarizes the references including the author(s), year, beam cross-sectional shape, number of strengthened beams tested, type of failure observed, strengthening configuration, and presence of anchors for each article. Eighty-three strengthened beams are included in the database.

Evaluation of the Database

In this paper, the shear strength provided by the FRCM system \( V_{FRCM} \) is calculated by subtracting the shear strength of the corresponding control beam \( V_{CON} \) for each test. The ranges of the main geometrical and mechanical properties of the strengthened specimens and the FRCM composites are reported in Table 2 (a/d=shear span to effective depth ratio; \( f'_{c} \)=mean cylinder compressive strength of concrete; \( \rho_{long} \)=longitudinal steel reinforcement ratio, \( A_b/b_d \); \( \rho_w \)=internal transverse steel reinforcement ratio, \( A_w/b_w \); \( \rho_f \)=fiber reinforcement ratio, \( 2n t_f/b_w s_f \); \( \rho_{cm} \)=FRCM reinforcement ratio, \( 2(n+1)t_m/b_w s_f \); \( \varepsilon_{fu} \)=bare fiber ultimate strain; and \( f'_{c,cm} \)=cementitious compressive matrix strength; where \( A_b \)=longitudinal steel reinforcement area; \( A_w \)=internal transverse steel reinforcement area; \( s \)=internal transverse steel reinforcement spacing; \( t_f \)=nominal thickness of fiber sheets; \( n \)=number of layers of fibers \( w_f \)=width of FRCM strips; \( s_f \)=spacing of FRCM strips; and \( t_m \)=nominal thickness of a matrix layer):

463
Figure 1 (left) presents the variation of $V_{FRCM}/V_{CON}$ as a function of the average shear strength (stress) $v_{CON}$ of the control beam computed according to Eq. 1:

$$v_{CON} = \frac{V_{CON}}{b_{w}d}$$ (1)

In Figure 1 (left), it is observed that the increase in shear strength attributed to the FRCM composite varies from 3% to 195% with an average value of 54%. It also can be seen that the effectiveness of the system appears to decrease for larger values of $v_{CON}$.

Regarding failure mode, Triantafillou and Papanicolaou (2006) and Bruckner et al. (2006) witnessed fiber rupture and beam cracking clearly visible on the surface of the FRCM jacket for fully wrapped elements. Although detachment, which is described as debonding of the FRCM jacket from the substrate in this paper, is reported in some the references (Contamine et al., 2013; Ombres, 2015; and Jung et al., 2015), other failure modes such as diagonal tension, slippage of the fibers through the mortar, and partial fiber rupture, referred to herein as no-detachment failure mode, have also been described in the available literature (Al-Salloum et al., 2012; Escrig et al., 2015; Baggio et al., 2014; Azam and Soudki, 2014; and Tetta et al., 2015).

The possible interaction between the internal and external shear reinforcement for FRCM systems has been reported by Blanksvard et al. (2009) and Ombres (2015), who witnessed a significant reduction in the strain values measured in the stirrups of the strengthened beams when compared with the control beam. In Figure 1 (right), it can be seen that the effectiveness of the strengthening system reduces when the ratio of the axial stiffness of the stirrup to the fibers $\rho_{w}E_{s}/\rho_{f}E_{f}$ (where $E_{s}=\text{elastic modulus of stirrups}$, and $E_{f}=\text{elastic modulus of the bare fibers}$) increases.

The use of FRCM anchorages has shown mixed results. Baggio et al. (2014) evaluated the efficiency of FRP spike anchors for rectangular beams strengthened in shear with U-wrapped FRCM composites and reported that the beam with anchors showed an increase of only 3% over the strengthened beam without anchors. L-shaped steel sections were used by Bruckner et al. (2008) to anchor the FRCM system for U-wrapped T-beams. The increase in shear capacity varied from 19% for elements without anchors to a maximum of 29% when anchors were present, depending on the number of fiber layers. Tzoura and Triantafillou (2015) used a 3 mm thick curved steel section fixed to the slab with threaded rods to anchor FRCM U-wrapped T-beams. The increase in strength range from approximately 18% for elements without anchors to a maximum of 187% when anchors were present, depending on the density of the textile.

ASSESSMENT OF AVAILABLE MODELS

This section assesses two models proposed in the literature to estimate $V_{FRCM}$; the models by Triantafillou and Papanicolaou (2006) and ACI 549.4R (2013) are referred to herein as Model 1 and Model 2, respectively. Both models are based on the well-known truss analogy and differ mainly in the expression used to evaluate the stress (strain) in the FRCM system along the shear crack. Model 1 is based on the properties of the bare fibers, and its evaluation is carried out using a database (DB1) from the tests in Table 1 that excludes elements that included anchors and/or that failed in flexure. Model 2 is based on the mechanical properties of the FRCM system as a composite, which were reported only by four of the references (Ombres 2015; Contamine et al. 2015; Escrig et al. 2015; Jung et al. 2015). A subset of DB1 that includes tests from these four references, referred to as DB2, was used to evaluate the performance of Model 2. For each model, values of test-to-predicted ratios of $V_{FRCM}$, termed $V_{test}/V_{pred}$, are computed, where $V_{test}$ is the value of $V_{FRCM}$ determined from the experimental test by subtracting...
the shear strength of the corresponding control beam, and \( V_{\text{pred}} \) is the value of \( V_{\text{FRCM}} \) determined by the model. Average (AVG) and coefficient of variation with respect to the mean value (COV) values of \( V_{\text{test}}/V_{\text{pred}} \) are also reported for each model.

**Model 1: Triantafillou and Papanicolaou (2006)**

Model 1 was first presented for fully wrapped rectangular beams and then extended for U-wrapped elements (Tzoura and Triantafillou, 2015). The predicted additional shear strength provided by the FRCM system is computed by Eq. 2:

\[
V_{\text{FRCM}} = \rho_f \sigma_{\text{eff}} b_w d_f; \sigma_{\text{eff}} = 0.5E_f \varepsilon_{fu}
\]  

where \( d_f \) is the effective depth of the jacket. The effective stress in the FRCM system (\( \sigma_{\text{eff}} \)) is computed based on the average strain reached across the shear crack, taken as 50% of the ultimate strain of the bare fibers, \( \varepsilon_{fu} \). In Figure 2, values of \( V_{\text{test}}/V_{\text{pred}} \) are plotted versus \( V_{\text{test}} \).

For elements that failed by detachment of the strengthening system, Figure 2 (center) shows that Model 1 tends to overestimate the contribution of the FRCM composites, which is corroborated by an AVG=0.51. For the remaining elements, Figure 2 (right) shows that \( V_{\text{test}}/V_{\text{pred}} \) ratios seem to be directly proportional to \( V_{\text{test}} \). In order to calculate the effective average strain in the fibers (\( \varepsilon_{\text{eff}} \)), Eq. 2 is rearranged in the form of Eq. 3:

\[
\varepsilon_{\text{eff}} = \frac{V_{\text{test}}}{E_f b_w d_f}
\]

Figure 3, in which the values of \( \varepsilon_{\text{eff}}/\varepsilon_{fu} \) are plotted in terms of the \( \rho_f E_f/\Gamma_{c}^{2/3} \), shows that the ratio \( \varepsilon_{\text{eff}}/\varepsilon_{fu} \) tends to decrease with increasing \( \rho_f E_f/\Gamma_{c}^{2/3} \), with lower values of \( \rho_f E_f/\Gamma_{c}^{2/3} \) for elements that did not show detachment. Assuming a constant concrete strength of the substrate, this finding indicates that a less stiff strengthening solution, i.e. lower values of \( \rho_f E_f \), might avoid the onset of detachment.

**Model 2: ACI 549.4R (2013)**

\( V_{\text{FRCM}} \) of RC beams strengthened by continuous U-wrapped or continuous fully wrapped FRCM composite is computed according to Eq. 4:

\[
V_{\text{FRCM}} = n A_f \sigma_{\text{eff}} d_f; \sigma_{\text{eff}} = E_{\text{FRCM}} \varepsilon_{\text{eff}} = \varepsilon_{\text{FRCM,u}} \leq 0.004
\]  

In Eq. 4, \( A_f \) is the area of mesh reinforcement per unit width effective in shear, and \( n \) is the number of fiber layers. Figure 4 shows values of \( V_{\text{test}}/V_{\text{pred}} \) versus \( V_{\text{test}} \). For elements that failed by detachment of the strengthening system,
Figure 4 (center) shows that although most of the tests (9 out 13) fall below the $V_{\text{test}}/V_{\text{pred}}=1.0$ line, the value of AVG equal is 1.03. On the other hand, for elements that did not show detachment, Figure 4 (right) shows that values of $V_{\text{test}}/V_{\text{pred}}$ are considerably larger than 1.0. Thus the accuracy of Model 2 is highly affected by the failure mode considered.

![Graphs showing $V_{\text{test}}$ versus $V_{\text{pred}}$ for Model 2 with different failure modes](image)

In Figure 5 values of predicted (model) and calculated (Eq. 5) strain ratios $\epsilon_{\text{eff}}/\epsilon_{fu}$ are plotted against $\rho_{E_{\text{FRCM}}}f_{c}^{2/3}$. It can be seen that values of calculated $\epsilon_{\text{eff}}/\epsilon_{fu}$ for the model are always lower than 25%. The agreement between the calculated and predicted strain ratios appears to be clearer for elements that failed due to detachment. It is also interesting to note that beams that failed by detachment have values of $\rho_{E_{\text{FRCM}}}f_{c}^{2/3}$ larger than 0.003. This implies that less stiff solutions, either in terms of $E_{f}$ or $E_{\text{FRCM}}$, should be used in order to avoid detachment of the system from the substrate.

**Comparison of the performance for Models 1 and 2**

Table 3 summarizes the AVG and COV values determined for the 2 models studied. The best AVG value is observed from the results of Model 2 when elements with detachment are considered (1.03), but the largest AVG is also found for the same model (3.70) for elements that did not show detachment. Model 1 tends to highly overestimate the contribution of the FRCM system for elements that did not show detachment but presents a more consistent behavior in terms of COV for both failure modes.

\]
CONCLUSIONS

The experimental evidence gathered in this article proves that the FRCM system is able to provide an increase in the shear strength of RC beams from 3% to 195% with an average of 54%. A possible interaction between the internal transverse steel reinforcement and the FRCM system has been observed. This effect appears to be more pronounced for higher values of $\rho_s E_s / \rho_f E_f$. For fully wrapped elements, the failure mode has been associated with fracture of the fibers. For side bonded and U-wrapped beams, detachment of the FRCM jackets has been reported. However, failure without detachment has also been witnessed together with diagonal cracking, slippage of the vertical fibers through the mortar, and/or partial fiber rupture. According to the available experimental results, strengthening solutions with lower values of $\rho_s E_s / f'c^{2/3}$ or $\rho_f E_f / f'c^{2/3}$ might avoid the onset of detachment. Although Model 1 overestimates the additional shear strength provided by the FRCM composite, it presents a more consistent behavior regarding values of COV when compared to Model 2.

ABSTRACT

One of the most commonly used technique for retrofitting and/or strengthening of reinforced concrete members is external bonding of fibre reinforced polymer (FRP) materials. Use of epoxies and resins to bind or impregnate the fibres has been seen as drawbacks in the FRP strengthening technique especially in the regions where high temperatures persist. Textile reinforced mortars (TRM), which uses cement-based inorganic mortars in place of organic binders, have emerged as a possible replacement of FRP to overcome the aforementioned drawbacks. This study focuses on studying the behaviour of shear-deficient RC beams strengthened with TRM and to compare the ultimate failure loads and modes of failure with control and RC beams detailed as per ACI 318-08. Overall eight beams, two control, two shear-deficient, and four strengthened, were tested under four-point bending with varying shear spans. Control beams were detailed in flexure and shear as per ACI 318-08, while shear deficient and strengthened beams have same flexural reinforcement as in control beams with no shear reinforcement. Two of the four strengthened beams were strengthened in shear with TRM by providing U-shaped TRM wraps in the shear span. Evenly distributed strips were provided in the shear span for one set of two beams while full wraps were provided in shear span in the remaining beams. Results indicate that use of TRM resulted in better performance of shear deficient RC beams and has a potential to be used in strengthening of RC beams.

KEYWORDS

Strengthening, shear-deficient, RC beams, textile reinforced mortar.

INTRODUCTION

Researchers in recent decades have focused their research on the use of fibre composites in reinforced concrete (RC) structures that needs strengthening and/or retrofitting due to deterioration resulting from number of causes. Fibre Reinforced Polymers (FRPs) have been frequently used in this regard both for research purposes and in strength restoration and/or upgrading of existing structures due to various reasons like upgrade of design codes, deterioration in structures or their members due to unforeseen loads, under design, change of usage modes etc. Despite of successful use of FRP in terms of strength upgradation (Teng et al. 2002), there are a few drawbacks in using FRP which have been identified by researchers including costly application, reduced fire resistance, potentially harmful solvents for workers involved in the installation of FRPs, poor applicability of FRP on moist surface and at colder temperatures (Aldea et al. 2007, Olivito et al. 2013). For this reason, researchers have looked into using cementitious binding materials which may replace the epoxies used with FRPs (Garcia et al. 2010) and help overcome the above mentioned problems. Preliminary researches related to fibre meshes embedded in cementitious mortar dates back to 1980’s (Gardiner et al. 1983). The interaction between fibre and matrix is replaced by grids of fibre, which are held together by knitting the fibre roving in at least two directions, which are commonly placed orthogonally. The spacing between the roving can be varied while manufacturing to obtain the desired mechanical properties of the textile grids and the distribution of the cementitious mortar through the openings. The cementitious material should possess high workability along with adequate shear and tensile strength to restrain early de-bonding. The combination of these fibre grids and cementitious matrix is commonly termed as Textile Reinforced Mortar (TRM) (Triantafillou et al. 2006), although various authors have referred to it with different names (Ombres 2011). The research being conducted in the area signifies that TRM can play a pivotal role for strengthening of structural members in terms of flexure, shear and confinement (Brückner et al. 2006, Triantafillou et. al 2013, Loreto et. al 2015).
This study focuses on studying the behaviour of shear-deficient RC beams, with varying shear spans, strengthened with TRM and to compare the ultimate load carrying capacities and modes of failure with control and RC beams detailed as per ACI 318-08.

**EXPERIMENTAL PROGRAM**

A total of eight beams were used in the study. All the beams were of 1.828 m length with a cross section of 152 mm × 203 mm. The longitudinal reinforcement was taken as 0.5 $\rho_{\text{max}}$ as per ACI 318-08 code. The study was conducted for the shear span-to-depth (a/d) ratios of 2.46 and 3.38. The control beams for both a/d ratios did not have any transverse reinforcement in form of shear stirrups. Two beams, one each for the a/d ratios, were cast having the same flexural reinforcement as control beams along with shear reinforcement as per ACI 318-08 code. Results of these beams were compared to the beams which had the same longitudinal reinforcement and no shear reinforcement. Remaining four beams were strengthened in shear for both the a/d ratios with U-shaped TRM wraps using two different schemes, one being fully wrapped in the shear span while the other one having 76 mm wide TRM strips at 125 mm centre to centre spacing. Reinforcement and strengthening details of the beams are shown in Figures 1-3. Nomenclature of the beams used in this research is given in Table 1.

Figure 1 R/F details for ACI beams with a/d ratio 2.46 and 3.38

Figure 2 R/F details for TS with a/d ratio 2.46 and 3.38
Concrete used for the beams was of 20.68 MPa (3 ksi) while yield strength of steel was found to be 414 MPa (60 ksi). For application of TRM, high strength mortar was used, with a 28 days strength of 27.6 MPa (4 ksi), and strips of 76 mm width were provided in U-shape. Centre to centre distance between them was 127 mm. The beams were tested in four point bending at a loading rate of 0.5 kN/min. Deflections and crack progression was noted up to the failure of the beams.

RESULTS AND DISCUSSIONS

Load Carrying Capacities and Failure Modes

Table 2 shows the failure modes and load carrying capacities of the control and strengthened RC beams. The control beams CB-1 and CB-2 failed in shear as expected. CB-1 failed before the start of major flexural cracking, while beam CB-2 failed at the yielding load with the development of shear cracks in the shear span along with major flexural cracking in the constant moment zone. Beams ACI-1 and ACI-2 failed in flexure as expected. The beam ACI-1 showed 18% increment in load carrying capacity as compared to CB-1 while beam ACI-2 carried almost the same load as CB-2 showing a marginal increase of 1%. Excessive flexural cracking was observed in the flexural region at failure in beams ACI-1 and ACI-2 showing the effectiveness of shear reinforcement provided in the beams.

Beams strengthened with TRM strips, TS-1 and TS-2, failed in flexure, with TS-1 beam showing 35% increase in load carrying capacity and TS-2 showing 9% increase in failure load in comparison with the respective control beams. Both the beams carried a higher load than the respective RC beams ACI-1 and ACI-2, 15% and 8% respectively. Failure in beams fully wrapped with TRM, TF-1 and TF-2, varied from post yield mortar failure to flexure. Beam TF-1 failed by failure of mortar immediately after yielding of reinforcement at 12% increased failure load as compared to CB-1. Beam failed almost at the same load as CB-2 and ACI-2 showing no increase in load carrying capacity. Excessive flexural cracking was observed in the flexural region at failure in beams TS-1, TS-2 and TF-2 while no major flexural cracking was observed in beam TF-1 due to the premature failure of mortar which can be attributed to improper bonding of TRM with concrete.

Load-deflection Curves

Load-deflection curves of control and strengthened beams with a/d ratio of 2.46 are shown in Figure 4. Load-deflection curve of control beam shows a sudden failure of beam with no clear yield point due to the development
of major shear crack in the shear span. Beam ACI-1, detailed with shear reinforcement steel according to ACI, showed a desirable flexural behaviour with very clear yield point and excessive flexural cracking as discussed in the preceding section. The beam TS-1, which was strengthened with TRM strips showed deformations comparable to that of ACI-1 but carried a higher load than ACI-1 as discussed earlier. At the ultimate load there is a sudden drop in the curve which can be attributed to the failure of mortar but before that excessive flexural cracking had occurred. Beam TF-1, fully wrapped with TRM in shear span, showed a distinct yield point but a sudden drop in load carrying capacity can be observed which is indicative of the post yielding shear failure due to premature failure of mortar used for external bonding of TRM. Yield load of beams ACI-1, TS-1 and TF-1 is almost similar indicating the effectiveness of internal and external shear reinforcement.

Figure 4 Load-Deflection Curves for a/d ratio 2.46

Figure 5 shows the load-deflection curves for control and strengthened beams with a/d ratio of 3.38. The control beam CB-2 showed a similar pattern as was observed in CB-1 i.e., sudden drop in load carting capacity due to major shear crack in shear span. Load-deflection curves of beams ACI-2, TS-2 and TF-2 are almost similar and represent typical flexure behaviour, showing a very distinct yield point and a ductile post yield response accompanied by excessive flexural cracking in pure flexural zone. A sudden drop is noticed in the case of TS-2 but that is after large deflections and excessive cracking making the failure ductile.

Figure 5 Load-Deflection Curves for a/d ratio 3.38

CONCLUSIONS

Following are the conclusions drawn from the study:

Use of TRM is effective in strengthening of shear deficient RC beams in shear as it contributes to shear capacity of the beams along with increasing the ductility and transforming the failure mode from brittle to shear as can be seen in the case of TS-1, TS-2 and TF-2.
For a/d ratio of 2.46, use of TRM resulted in maximum increase of 35% and 15% in load carrying capacity as compared to beams CB-1 and ACI-1.

For a/d ratio of 3.38, use of TRM resulted in maximum increase of 9% and 8% in load carrying capacity as compared to beams CB-2 and ACI-2.

TRM can be as effective in increasing shear capacity as internal shear reinforcement and has a potential to be used in strengthening of existing shear deficient RC beams.

ABSTRACT

Lots of underground reinforced concrete (RC) structures, which were designed and constructed by former design standards, were collapsed or damaged due to uneven settlement in the Great East Japan Earthquake in 2011. It was pointed that the reinforced amount of the structures designed by the former standard was insufficient. A new reinforced method by using Carbon Fiber Reinforced Plastics (CFRP) grid with Polymer Cement Mortar (PCM) shotcrete for RC beams has been proposed. The objective of this study is to reveal the bonding behaviour of CFRP grid and evaluate the effect of shearing capacity of RC beams by using CFRP grid with PCM shotcrete method. It is carried out by two series of tests, such as bonding tests of CFRP grid and loading test of RC beams.

KEYWORDS

CFRP grid, PCM shotcrete method, RC member, bonding behaviour, strengthening effect.
grid as parameters in 5 types of specimens (Table 1), including 3 specimens for each type. The schematic of specimens (ex. FP50VH/FP50VL) and the installed position of strain gauges are shown in Figure 1. The results of bonding tests are summarized in Table 2 with mean values among the three specimens in each type shown. It can be seen that for all specimens, CFRP grids, which are not embedded in PCM (Base metal), were broken in the end. Relationship between grid points and the strain of CFRP grid at 12kN, 2/3 of ultimate load of the grid, is shown in Figure 2.

Figure 2 Distribution of strain of CFRP grid (P=12kN)

As a result, it can be seen that the strain of CFRP grid decreases as the number of grid point increases. It can be concluded that the tensile force acting on the CFRP grid is transmitted to the CFRP grid and concrete through
PCM. Compared with FP50VH and FP50VL (type of PCM as a parameter), the strain of No.5 grid point in FP50VH decreases to zero at the end, but that of FP50VL remains at about 2000×10⁻⁶. It is concluded that transmission ability of high strength PCM is better than that of low elasticity ones. The calculation method of the distribution ratio for each grid point is shown in Eq. 1 and Eq. 2.

\[ S = \sum_{i=1}^{4} \frac{A_i}{A_{400}} \times 100 \]  
\[ A_i = \frac{1}{2} \times (D_{i-1} + D_i) \times h_i \]  

where \( S \) is distribution ratio (%), \( h_i \) is interval of CFRP grid (mm), and \( D_i \) is strain of measurement point.

The results at 12kN, 2/3 of ultimate load of the grid, are shown in Figure 3. As the result, the distribution ratios of No.1 grid point in FP50VH (44%) and FP75VH (43%) are almost the same, while the distribution ration in FP100VH (56%) is higher than those of FP50VH and FP75VH. For specimens with vertical grid, it can be concluded that the distribution ratio of grid point becomes larger as the interval of horizontal grid increases. In addition, the total of distribution ratio is 70-80%, when the number of grid points is 2. And the total of distribution ratio of grid is over 90%, when the number of grid points is 3 or more. As a result, bonding behavior is sufficient.

**SHEAR STRENGTHENING EFFECT ON RC BEAM**

In this study, it is intended for sluice which is an important structure (Figure 4) placed across a river embankment to be used to drain waste water from protected inland and pump water from river. In the present method, the evaluation of shear strengthening on RC beams reinforced by FRP is based on the concept of effective strain of FRP rod (JSCE, 1996) or shear reinforced efficiency of FRP sheet (JSCE, 2000). However, evaluation of shear strengthening on RC beam reinforced by CFRP grid has not been established. In order to evaluate shear strengthening on RC beams by using CFRP grid with PCM shotcrete, loading tests of RC beams were carried out.

![Figure 4 Sluice](image)

Figure 5 shows production process of the specimens. Firstly, existing concrete is produced in I form. Span length of specimen is 4750mm and dimension of cross section is 750mm×500mm (height × width). After surface treatment by blasting, CFRP grid is attached to the surface of existing concrete by using rivet anchors as temporary fix. Then, primer is sprayed in order to prevent dehydration before PCM shotcrete.

Table 3 shows material properties for CFRP grid. Table 4 shows the types of specimens. There are 4 types of specimens including P-1 reinforced by CR4 CFRP grid, P-2 reinforced by CR8 CFRP grid, P-3 reinforced by CR4 CFRP grid whose interval of horizontal reinforcement (50mm) is 1/3 to other specimens (150mm), and P-4
reinforced by CR4&6 CFRP grid whose horizontal grid is CR6 and vertical grid is CR4. For all specimens, shear rebar at the SD295 D10 setting with a 250mm interval and main rebar at the SD345 D35 were used, where SD295 and SD345 are specified by JIS.

Figure 6 shows the shape of specimens and the situation of CFRP grid. In order to investigate the shear strengthening effect on RC beams reinforced by CFRP grid, strain gauges were placed at several locations of CFRP grid in both vertical and horizontal direction.

[1]: Horizontal grid is CR6, vertical grid is CR4.

Figure 7 shows the relationship between load and displacement. All specimens were shear fractured in the end. Compared with P-1, which is reinforced by CR4, maximum load of P-2 reinforced by CR8 is improved by about
7%. And compared with P-1 and P-3, since the interval of horizontal grid of P-3 is 1/3 to that of P-1, maximum load of P-3 is improved by about 8%, and stiffness of curve is higher after about 600kN. At about 200kN, flexural cracks occurred on the surface of specimens. However, since the peeling of CFRP grid occurred early during loading test in P-4, the maximum load of P-4 is lower than that of P-1.

Figure 8 shows the relationship between load and strain of CFRP grid. It was seen that the obliquely shear cracks were confirmed in the surface of specimen at about 400kN during the loading test. The strain of vertical and horizontal grids both increase at the same time. It is found that both vertical and horizontal grids contribute to shear resistance. In Figure 8(a) (c), the strain of vertical grids abruptly become small, it is concluded that peeling occurs between CFRP grid and existing concrete before maximum load.

![Figure 7 Load-deflection curve of loading tests of RC beams](image)

![Figure 8 Load-Strain of shear rebar and CFRP grid](image)
Figure 9 shows crack distribution of RC beam at maximum load. During loading test of RC beam, the small width flexural cracks occur on the surface of specimen first. Then the shear cracks occur on the line connecting the load position and fulcrum. The length and width of cracks increase accordingly as the load increases. Finally, part of the upper edge of concrete is crushed. Furthermore, fracture situations of CFRP grid after loading test are confirmed by peeling the PCM, and the result is shown in Figure 9. It can be seen that parts of CFRP grid, which is above the shear cracks, are delaminated.

**EVALUATION OF SHEAR CAPACITY**

Shear Capacity is calculated by Eq. 3. $V_{con}$, $V_{pcm}$, $V_{se}$ and $V_{g}$ are share of shear capacity of concrete, PCM, shear rebar and CFRP grid. The calculation method of share of shear capacity of CFRP grid is shown in Eq. 4. The comparison of shear capacity is shown in Table 5. Calculated Value A is calculated by Eq. 4 where $\varepsilon_u$ is maximum tensile strain of CFRP grid (14000×10^{-6}). $\varepsilon_u$ of Calculated Value B is calculated by Eq. 5 which applied the concept of effective strain of CFRP rod (JSCE, 1996).

[2]: Number in () shows Experimental Value / Calculated Value.
where $\varepsilon_s$ is Strain of CFRP grid, $E_w$ is Young’s Modulus of CFRP grid (N/mm²), $A_w$ is total area of cross section of CFRP grid in interval $S_t$ (mm²), $S_t$ is arrangement interval of CFRP grid (mm), $z = d/1.15$, and $\gamma_b = 1.15$.

$$
\varepsilon_s = \left(\frac{\rho_{str} E_{st}}{\rho_{web} E_w} \times 10^{-4}\right)
$$

where $f'_{cd}=(h/0.3)^{0.1}$, $p_{str}=A_r/(b_w d)$, $p_{web}=A_d/(b_s S_t)$, $f'_{cd}$ is design compressive strength of concrete (N/mm²), $d$ is effective height (m), $b_w$ is width of cross section of specimen (mm), $A_r$ is area of cross section of main rebar (mm²), and $E_{st}$ is Young’s Modulus of tensile rebar (N/mm²).

As a result, the ratio of Calculated Value A and its Experimental Value is higher than 1.00 in P-1 and P-4. However, in P-2 and P-3, the ratio of Calculated Value A and its Experimental Value is below 1.00. It can be seen that Calculated Value A is unable to evaluate the shear capacity. The ratio of Calculated Value B and Experimental Value is considerably higher than 1.00 in all specimens. It can be seen that Calculated Value B, which applies the concept of effective strain of CFRP rod, is excessive evaluation. In consideration of these observations, the improved design formula of shear capacity based on the concept of effective strain of CFRP grid should be proposed in order to make a better evaluation of shear capacity on RC beams by using CFRP grid.

Figure 10 shows the strain of CFRP grid in both vertical (as shown by □) and horizontal (as shown by ○) direction. In addition, results of a previous study (R. Guo et al. 2015) are also shown in Figure 10. A new calculation method of effective strain of CFRP grid (Eq. 6 shows) is proposed by regression analysis of the peeling strain of vertical grid, when peeling occurs between CFRP grid and existing concrete. Furthermore, it is found that horizontal grid also contributes to shear resistance. Therefore, Figure 11 shows the comparison between the strain of vertical and horizontal grid. It can be observed that relationship between the strain of horizontal grid and peeling strain of grid, when peeling occurs between CFRP grid and existing concrete. Furthermore, it is found that horizontal grid of effective strain of CFRP grid (Eq. 6 shows) is.

$$

where $\rho_{hor}$ is area of cross section of horizontal CFRP grid per unit length (mm²/mm)
CONCLUSIONS

The main findings of this investigation can be summarized as follows:

1. In bonding test, the strain of grid points reduces in turn, and tensile force to CFRP grid is transmitted by each grid point. The total of distribution ratio of grid is over 90% when the number of grid points is 3 or more. Bonding behaviour is sufficient.

2. From experiment data of the loading test of RC beams, it is concluded that part of CFRP grid peels off before maximum load. It is found that both vertical and horizontal grids contribute to shear resistance.

3. Calculation methods of effective strain of CFRP grid are proposed. The evaluation method by considering both vertical and horizontal grid is the most reasonable approach.

ABSTRACT

A new strengthening composite and bonding system, namely Fibre Reinforced Polymer (FRP) grid-Ultra High Toughness Cementitious Composite (UHTCC), for Reinforced Concrete (RC) beams is explored in this paper. In this system, UHTCC is applied as the reinforcing material and the bonding agent between the FRP grid and the concrete substrate. Four RC beams externally strengthened with a composite layer of FRP-UHTCC applied to the side faces in the bending-shear regions for a four-point bending test setup and one similar test for a reference RC beam without strengthening were tested to investigate their structural performance. The reinforcement ratio of the FRP grid and the construction method of the UHTCC were the two test parameters. The experimental results highlighted two failure modes: 1) the typical shear-compression failure of concrete at the critical sections in the reference beam, and 2) the partial debonding failure of FRP-UHTCC along the interface with the concrete in all strengthened beams. The shear force capacity of the strengthened RC beams were greatly improved with the increase of the FRP grid reinforcement ratio from 0.03% to 0.2%. The maximum increase of this shear force capacity for all the strengthened beams compared to the reference beam was 59%. The construction speed can be somewhat accelerated by spraying the UHTCC layer. However, the interfacial bonding performance between the FRP-UHTCC system and the concrete is expected to be reduced in this case.

INTRODUCTION

Due to different design requirements for resiliency and sustainability, increase of external loads due to extreme events such as earthquakes or deterioration of structural elements due to environmental effects, strengthening and rehabilitating the existing reinforce concrete (RC) structures is becoming an urgent need in the past few decades. Fibre Reinforced Polymer (FRP) as a novel material for strengthening RC structures has been widely accepted because of well-known advantages, such as light weightiness, high strength, good corrosion resistance, and higher durability (Zheng et al. 2016; Wang et al. 2014, 2015; Yao and Teng 2007). However, the bonding behaviour at the interface of FRP-to-concrete substrate may be seriously affected by some environmental factors, such as water moisture, ultraviolet (UV) light, high temperature, and fire, especially when using the epoxy resin as an interfacial adhesive (Hashemi and Al-Mahaidi 2012; Gamage et al. 2006). Therefore, some scholars attempted to replace the epoxy resin with inorganic or cementitious materials to develop new fibre composite reinforcing systems for strengthening RC structures, such as dry fibre sheets bonded with cementitious materials (Babaeidarabad et al. 2014; Xu et al. 2007), fibre-reinforced inorganic polymer (FRIP) composites (Dai et al. 2014; Ding et al. 2014) and textile reinforced mortars (TRM) (Koutas et al. 2014; Triantafillou and Papanicolaou 2006). These methods utilized the several advantages of cementitious materials. Particularly, the engineered cement-based adhesive possesses a much better material compatibility with the concrete substrate compared to the epoxy-based one.

Although using cementitious or inorganic materials to strengthen RC structures may improve their load carrying capacities and meet the functional requirements of structures under the normal service condition, some deficiencies of those materials still exist, including incompatibility of deformation between the FRP reinforcement and the
cement-based matrix, need for larger amounts of FRP reinforcement increasing cost, poor penetration ability of FRP sheet/plate, and low tensile strength and durability (Dehghani et al. 2015; Kim et al. 2014; Wu and Sun 2005). For the purpose of overcoming such drawbacks and for optimizing the strengthening method, attempts are made in the presented test program to develop a relatively new strengthening system, i.e. FRP grid in conjunction with Ultra High Toughness Cementitious Composite (UHTCC). In this FRP-UHTCC system, the UHTCC layer has two functions: 1) strengthening the RC structures, and 2) bonding the FRP grid and the concrete substrate (Zheng et al. 2015, 2016; Wang et al 2015, 2016; Chen et al. 2010). This new strengthening system is expected to provide a dual effect to the original RC structures due to the high strength of the FRP grid and the strain-hardening behaviour of the UHTCC. Meanwhile, the UHTCC as a bonding agent is expected to suppress the width of cracks and prevent the crack-induced debonding failure due to the multiple cracking behaviour of the UHTCC.

TEST PROGRAM

Design of specimens

A total of five RC beams with rectangular cross sections were tested in this study. Beam B0 was the reference without any strengthening and the other four RC beams (B1-1, B2-3, B3-5, and B4-3) were strengthened for shear with a 30 mm thick composite reinforcement layer (CRL) consisting of Basalt FRP (BFRP) grid and UHTCC. All test specimens had identical dimensions of 1800 mm in length (span length of 1700 mm), 300 mm in width and 200 mm in depth. Two ribbed steel bars (HRB335 grade) with diameter of 12 mm and four ribbed steel bars (HRB335 grade) with diameter of 20 mm were longitudinally placed at the top and bottom sides of the RC beams as compression and tension steel reinforcement, respectively, to avoid flexural failure prior to shear failure. The thickness of the concrete cover was 30 mm for both the top and bottom steel reinforcement. The transverse shear reinforcement in the form of closed steel stirrups were plain round bars (HPB235 grade) with diameter of 6 mm and spacing of 200 mm centre to centre. The common details of the cross section and steel reinforcement for the test beams are shown in Figure 4.

The investigated variables in this test program were the reinforcement ratio of the BFRP grid and the construction method of the UHTCC layer. Three thickness of BFRP grid were used to externally strengthen the UHTCC overlay: 1 mm thickness for beam B1-1, 3 mm thickness for beams B2-3 and B4-3, and 5 mm thickness for beam B3-5. In addition, two different construction methods of the UHTCC layer were applied to investigate their effect on the shear force capacity of the strengthened beams: casting for beams B1-1, B2-3, and B3-5, and spraying for beam B4-3. The material and construction properties of all test beams are summarized in Table 3.

All beams were cured for 28-days under the laboratory conditions and polished with a grinding wheel to remove the laitance and sundry on the side surfaces of the test specimens. Subsequently, sixteen steel bolts with diameter of 6 mm were symmetrically embedded into the concrete on the side surfaces of the RC beams where four of them installed at each of the two end sections and the two loading point sections. Afterwards, the BFRP grids were fixed

Figure 4 Common details of cross section and steel reinforcement for the test beams
on the surfaces of the test specimens through those steel bolts. As for the construction method of casting the UHTCC, a 30 mm thickness of the UHTCC layers were cast along the longitudinal directions of the beams after they were placed in wooden formworks. For the construction method of spraying the UHTCC, the CRL was formed by multiple spraying of the UHTCC mixture to the side surfaces of test specimens using an approximate thickness of 10 mm each time through a machine sprayer. It is noted that the strengthening using the FRP-UHTCC system was only applied in the bending-shear regions only, i.e. excluding the zero shear regions between the load application points of the beams, refer to Figure 4.

Test Materials

The designed strength grade of concrete for the RC beams was C30. Ordinary Portland cement (P.O 42.5 grade), fine river sand and crushed stone aggregate with maximum aggregate sizes of 5 mm and 20 mm, respectively, and water were mixed together to produce the concrete. During the casting process of the concrete, three cubic samples with dimensions of 150 mm×150 mm×150 mm were cast to determine the concrete compressive strength. The 28-day average compressive strength of concrete was 29 MPa, as shown in Table 3.

For the UHTCC, ordinary Portland cement (P.O 42.5 grade), fine silica sand, fly ash, silica fume, chopped PolyVinyl Alcohol (PVA) fibre and admixtures were mixed together to form this layer. During the casting process of the CRL, four cubic samples with dimensions of 70.7 mm×70.7 mm×70.7 mm were cast to determine the UHTCC compressive strength. The 28-day average compressive strength of UHTCC was 27 MPa for beams B1-1, B2-3 and B3-5, and 25 MPa for beam B4-3, as shown in Table 3.

Three types of steel reinforcement were used in the test program: HPB235 grade plain round bars with diameter of 6 mm for the stirrups, HRB335 grade ribbed bars with diameters of 12 mm and 20 mm for the compression (top) and tension (bottom) reinforcement of the RC beams. For these 6 mm, 12 mm, and 20 mm diameter bars, the yield strength values were 547 MPa, 580 MPa, and 605 MPa, respectively, and the ultimate strength values were 598 MPa, 641 MPa, and 683 MPa, respectively.

The BFRP grid was manufactured by Jiangsu Green Materials Vally New Material T&D Co., Ltd, China. In this grid, the transverse and horizontal fibre reinforcement was made of continuous basalt-based untwisted yarn and infiltrated into the saturated resin to form the two-way grid after the moulding resin dried. The dimensions of the BFRP grid were 625 mm×300 mm and the rigid fibre reinforcements in the BFRP grid were arranged at 50 mm centre to centre along the transverse and longitudinal directions, as shown in Figure 5. Three different thickness values (1 mm, 3 mm, and 5 mm) of the BFRP grid were used to reinforce the RC beams. The average elastic moduli of the 1 mm, 3 mm, and 5 mm thick BFRP grid were 52 GPa, 53 GPa, and 57 GPa, respectively, and the corresponding ultimate tensile strength were 357 MPa, 386 MPa, and 416 MPa, respectively.

![Figure 5 Dimensions of the used BFRP grid](image)

Test setup

All test beams were subjected to a two-point symmetric load separated by 500 mm centre to centre through a rigid distribution girder. The speed of vertical load was 0.5 kN/min before the cracking of concrete at the tensile surface of test beams, and 1.0 kN/min was set up for the subsequent loading until failure. The variation of the vertical load was collected by a loading sensor connected to a 500-kN hydraulic jack. Five LVDTs were symmetrically placed at the sections of two supports, two loading points and mid-span to measure the changes of the vertical deformations. Three strain gauges (labelled SG1, SG2 and SG3) were bonded to the surface of the stirrup at different elevations within the bending-shear regions to monitor the strain variations. The test setup and locations of the measuring points are shown in Figure 6.
TEST RESULTS

Failure modes

The typical shear-compression failure of concrete was observed for the reference beam B0 due to the eventual concrete crushing at the bending-shear region, as shown in Figure 7a. For the strengthened beams B1-1, B2-3, B3-5, and B4-3, the partial debonding of the CRL along the interface of the CRL-to-concrete was exhibited under the locations of loading points before the shear-compression failure, as shown in Figure 7b. Moreover, several fine cracks were uniformly distributed in the UHTCC layer due to the multiple cracking properties of UHTCC, as shown in Figure 7b. To further investigate the bonding performance of the CRL-to-concrete interface, one of the FRP-UHTCC layers was removed from one side surface of the failed beam, as shown in Figure 7c and 4d. The inside surface of the FRP-UHTCC was almost fully bonded with the crushed concrete, which indicated that the FRP-UHTCC played an important role in improving the shear performance of the RC beams due to the good interfacial bonding performance of the FRP-UHTCC to the concrete substrate.
**Load-deflection response**

The load-deflection responses of all test beams at the loading point and mid-span sections are shown in Figure 8. For all strengthened beams B1-1, B2-3, B3-5, and B4-3, there was a remarkable increase in the shear force capacity when the CRL was bonded to the side surfaces of the test beams, as shown in Figure 8 and Table 4. The increase of the shear force capacity for all these strengthened beams ranged between 27% and 59% compared to the reference beam B0.

![Figure 8 Load-deflection relationships of all test beams](image)

For the reference beam B0, when the applied vertical load reached 36 kN (approximately 12% of the ultimate load), a few of the flexural cracks appeared at the tension (bottom) side of the beam. With increasing of the external load, the flexural cracks gradually propagated to the top part of the test beam and continually propagated towards the locations of the loading points. When the vertical load reached 226 kN (approximately 76% of the ultimate load), the first critical diagonal crack formed followed by yielding of the stirrups within the bending-shear regions. When the vertical load approached 296 kN, the relative sliding movement of the concrete at the bending-shear regions occurred along the propagation direction of the critical diagonal crack and the shear-compression failure mode of beam B0 took place, as shown in Figure 7a.

Beam B1-1 was strengthened with 1 mm thickness of BFRP grid and UHTCC. When the load approached 65 kN (approximately 17% of the ultimate load), a few of flexural cracks were formed at the tension side of the beam in the pure bending (zero shear) region. With the load further increasing, new flexural cracks continually formed at the bending-shear regions and the previous concrete cracks gradually propagated to the top surface of the test beam. When the vertical load increased up to 206 kN (approximately 55% of the ultimate load), a few of the diagonal cracks appeared at the surface of the FRP-UHTCC layer and continually propagated to the position of the loading point. When the load approached 221 kN (approximately 59% of the ultimate load), an interfacial crack formed along the interface of the CRL-to-concrete. When the vertical load of 376 kN was applied, the partial debonding failure of the CRL occurred at the interface between the FRP-UHTCC layer and the concrete substrate. Simultaneously, the relative sliding movement of the concrete at the bending-shear regions took place, as shown in Figure 7b.

Notes: SC stands for Shear-Compression failure, PD stands for Partial-Debonding failure.

For the other three strengthened beams B2-3, B3-5, and B4-3, similar observations to those of beam B1-1 took place during the testing process. By comparing with beam B1-1, the shear force capacity of beams B2-3 and B3-5 increased by 73 kN and 95 kN, respectively, due to the increase of the BFRP grid reinforcement ratio. It should be noted that the shear force capacity of beam B4-3 was lower than that of beam B2-3 due to the construction
method of spraying the UHTCC. This suggests that indeed the construction speed maybe accelerated by using spraying UHTCC, but the interfacial bonding performance between the CRL and the concrete substrate will most likely be reduced. As a result, the interfacial bonding property deserves more research attention when using the spraying construction technique for the UHTCC as a strengthening layer.

**Stress-strain response of stirrups**

The strain distributions of stirrups using gauges SG1, SG2, and SG3 in the reference beam (B0) and the strengthened beams B1-1, B2-3, B3-5, and B4-3 within the bending-shear regions are shown in Figure 9a, 6b, and 6c, respectively. It can be observed that the strains of the stirrups in the strengthened beams were significantly decreased compared to those of the reference beam B0, due to the strengthening effect of the FRP-UHTCC. Moreover, the FRP-UHTCC strengthening system greatly improved the shear force capacity of the RC beams by sharing the tensile stresses with the internal stirrups in the bending-shear regions.

Compared to the reference beam, several finer cracks were uniformly distributed in the UHTCC layer, and the width of these cracks were greatly decreased due to the multiple cracking performance of UHTCC. It should be noted from Figure 9 that the FRP-UHTCC layer can effectively share the tensile actions of concrete and stirrups due to its good interfacial bonding performance. As a result, the toughness of UHTCC deserves more research attention when using the UHTCC as a strengthening layer.

**CONCLUSIONS**

Four strengthened beams and one reference beam were experimentally investigated to determine the shear behaviour of these RC beams when strengthened with a composite layer of FRP-UHTCC. Based on the experimental observations, the following conclusions can be drawn:
The final failure modes of the four strengthened beams were partial debonding of the CRL along the interface between the FRP-UHTCC and the concrete substrate due to the propagation of diagonal cracks of the RC beams. As expected, the typical shear-compression failure of concrete was observed in the reference beam.

The shear force capacity of the tested RC beams were greatly improved after strengthening with the composite FRP-UHTCC compared to the reference beam. In addition, the shear force capacity of these strengthened beam increased by 27% to 59% compared to the reference beam depending on the reinforcement ratio of the FRP grid, which varied from 0.03% to 0.2%.

The construction speed can be accelerated by using the spraying construction technique of the UHTCC layer. However, the interfacial bonding performance between the FRP-UHTCC and the concrete substrate is expected to be reduced with this technique compared to the usual casting construction technique.

ABSTRACT

Considering the cured surface and reinforcement layers of FRP textile and construction technology of ECC, the static axial compressive experimental program on FRP textile reinforced ECC confined circular reinforced concrete (RC) column was carried out in this paper. Based on the test results, the numerical analysis model was also established using the finite element software. The test results show that all strengthened RC column failed by the rupture of FRP textile and the ultimate compressive strength and deformation capacity of confined RC column was enhanced with the reinforced layer of FRP textile increased. After surface treatment, the bonding behavior of FRP textile and ECC interface and compatibility of those two materials were significantly improved. Besides, the composite strengthened layer combined with either smeared or sprayed ECC strengthening and BFRP textile can provide effective lateral confining stress to the strengthened RC columns and delay the buckling of longitudinal reinforcement. The analytical results show that the finite element model can simulate the mechanical process of the strengthened RC columns effectively.

INTRODUCTION

Maintaining and upgrading the safety of concrete structures is a massive challenge throughout the world. The development of bonded fiber-reinforced polymer (FRP) system represents a major breakthrough in the strengthening of concrete structures over the past two decades. However, this technology suffers from a major weakness for the outdoor buildings, especially bridge engineering. For example, the degradation of bonding performance at the FRP-to-concrete interface could be occurred under the combined actions of moisture (e.g. Wang et al. 2013; Dai et al. 2014; Zhang et al. 2015), high temperature and fire (Xu et al. 2014). This is an obvious fact that the organic polymer (e.g. the epoxy resin) is usually applied as an interfacial bonding adhesive and a saturate impregnate for FRP fiber sheet.

To solve this problem, attempts have been made to replace the epoxy resin by using the cement-based material to develop new inorganic polymer or modified cement mortar for strengthening reinforced concrete (RC) members, such as dry fiber sheet bonded with cementitious materials, fiber-reinforced inorganic polymer (FRIP) composites, FRP textile reinforced mortar and concrete (TRM/TRC) and FRP grid reinforced cement mortar (e.g. Xu et al. 2011; Xun et al. 2012; Ding et al. 2014;Zheng et al. 2016). Compared with epoxy resin, a few of distinct disadvantages are still exited in the inorganic materials, such as low extensibility and easy brittleness. In this paper, a new strengthening system, FRP textile reinforced engineered cementitious composite (ECC) system is proposed to strengthen RC columns. In this technique, the high ductility of ECC is sufficiently utilized to overcome the natural shortcomings of above mentioned inorganic materials. Therefore, better material compatibility between ECC and concrete substrate can be obtained and bad actions of ultraviolet (UV), elevated temperature and moisture will not be happening. Moreover, a double confined effect is expected to be able to act on the RC column so as to enhance its load capacity and improve the deformation of that element.

EXPERIMENTAL PROGRAMS

Specimen Description

A total of fifteen RC columns subjected to the concentric compression loading were manufactured in this test
program. Among them, three non-strengthened RC columns and twelve FRP textile reinforced ECC (FRE) confined RC columns were made to study their compressive mechanical performance. All tested specimens were divided into six groups (i.e. Group RC, Group FRE1, Group FRE1E, Group FRE2E, Group FRE3E, and Group FRSE1). Each group had three identical specimens as listed in Table 1. The non-strengthened Group RC was set to the control group. The rest three Groups FRE1E, FRE2E and FRE3E were reinforced with FRE composite jacket consist of basalt fiber reinforced polymer (BFRP) textile and a layer of ECC with a 30mm fixed thickness. Group FRE1 confined with one layer of BFRP textile. One layer, two layers and three layers of epoxy-sanded BFRP textiles were used for group FRE1E, FRE2E and FRE3E, respectively. To improve the bond between BFRP textile and ECC, the epoxy adhesive resin was brushed onto the two side surfaces of BFRP fiber bundle to act as a bond layer and then 0.3~0.6 mm fine aggregate were spread onto the epoxy resin immediately to form the coarse interface. Meanwhile, the sprayed ECC was used for Groups FRES1 to investigate the influence of construction technology on the confinement of the core concrete.

All RC columns had a circular cross section with dimensions of 600 mm in length and 200 mm in diameter. Six longitudinal deformed steel rebar with 12mm diameter were uniformly distributed along the circumference as the internal steel reinforcements. The stirrups were 6mm diameter round steel rebar spaced 150 mm. Extra stirrup reinforcements were provided at two ends of RC columns to avoid the local compression failure. Details of the experimental program are presented in Table 1 and Figure 1.

Before strengthening, the surfaces of RC columns were polished firstly. A layer of ECC with approximately 10mm thick was smeared on the side surface of RC column using a smooth metal trowel. Then the epoxy-sanded BFRP textile was wrapped along the circumference of RC columns and pressed slightly into the first ECC layer, as shown in Figure 2a. After that, the cover ECC layer was smeared to protect the internal BFRP epoxy-sanded textile and form a composite reinforced jacket, as shown in Figure 2b. It should be noted the process of manufacturing the composite reinforced jacket for specimens in Groups FRES1 is similar with that of other strengthened specimens except the sprayed ECC layer.

**Material Properties**

The design strength grade of concrete for the RC columns was C30 according to *CHINA DESIGN SPECIFICATION OF CONCRETE STRUCTURES*. Ordinary Portland cement, fine and coarse aggregate with a maximum size of 20mm and water were mixed together to manufacture the concrete. The water cement ratio was 0.6. During the stage of casting test columns, three cube samples with dimensions of 150mm×150mm×150mm were reserved to obtain the compressive strength of concrete. The average value of 28-day compressive strength for the concrete was 37.4MPa.
Unidirectional tensile tests were conducted to investigate the mechanical properties for BFRP textile and ECC. For BFRP textile, each fiber bundle of it was 5.42mm wide, and the clear spacing between the adjacent fiber bundles was 25mm. The nominal thickness of each layer for BFRP textile was 0.67mm. The materials used in the production of ECC mixture were Ordinary Portland cement, fly ash, silica sand with a maximum particle size of 0.6mm, polycarboxylate-based high range water reducing admixture (HRWRA), and polyvinyl alcohol (PVA) fiber. To speed up the condensation of sprayed ECC, the accelerator was added into sprayed ECC. The mixed details are given in Table 2. The PVA fibers mixed in the ECC were produced by Kuraray Co., Ltd of Japan and its detailed material properties are presented in Table 3. To characterize the direct tensile behavior of ECC mixture, three dog-bone specimens (as seen in Figure 3) were used for direct tensile tests (Kuang et al. 2015; Yu et al. 2015), which were conducted under the displacement control at a loading rate of 0.25mm/min. Details of coupons for material properties were presented in Table 4.

### Test Setup

For detecting the axial and longitudinal strains of FRE composite jacket, four strain gauges with a gauge length of 60mm were installed on the two opposite surfaces at the mid-height section of FRE-confined RC column. The axial deformations of all test cylinders, with or without FRE confinement, were also measured using two linear variable displacement transducers (LVDTs) installed 180° apart on the top of RC column. Besides, for the internal longitudinal steel reinforcement, 5mm-length strain gauge was attached on its surface to observe the development of axial strain. Same strain gauge was applied on the steel stirrup to obtain the hoop strain. As for BFRP textile, strain gauges were bonded on the axial and hoop fiber bundles to measure two directional strains.

Uniaxial compression tests of all RC columns were performed using a 5,000-kN capacity servo-controlled MTS machine. Each cylinder was first loaded to around one-third of its unconfined capacity to check the alignment. The axial load was then increased at a load rate of approximately 2.4kN/s until the specimens failed. During the test, all strain gauges and LVDTs data were recorded using a data acquisition system capable of reading one set of data per second.

### RESULTS AND DISCUSSION

#### Failure Mode

Typical failures of the test specimens are shown in Figure 4. The control specimen failed with concrete crushing after the longitudinal reinforcing steel rebar yielded. A plurality of vertical cracks was distributed on surface of the column body. Relatively, all reinforced specimens failed with the circumferential tensile rupture of cured fiber bundles at the vertical main fracture of FRE jacket. Meanwhile, failure was usually accompanied by many micro cracks rather than deboning over a large portion of the cylinder height. This indicated that the characters of ECC, e.g. multiple cracking, high ductility and good bond behavior with substrate concrete, were obtained during the test progress.
It was a remarkable fact that the composite jacket with sanded textile ruptured as an integral in group FRE1E–FRE3E (Figures 4c–4e). Comparatively, the test result showed that an obvious interface slipping phenomenon occurred between ECC and textile in group FRE1 (Figure 4b).

Figure 4 Failure Modes of Specimens

Load-Displacement Responses

The load-displacement responses of all specimens are shown in Figure 5. In the rising stage, the curve slope of confined columns was similar to those of control specimens (Group RC), which indicated that FRE composite jacket had limited resistant effect to core concrete when load was small. The growth of loading rate caused vertical cracks in ECC and then resulted in the stiffness of column reduced gradually. After longitudinal steel rebar yielded, axial stiffness decreased more significantly. The increase of hoop deformation caused rapidly expanding cracks. Therefore, the confined columns damaged with BFRP textile rupture finally.

Figure 5 Load-Displacement Curves

Compare to the control specimens, the average cracking load (near 950kN) of Groups FRE1E–FRE3E improved by 73%. Besides, the average ultimate load of Group FRE1E, FRE2E and FRE3E increased by 44.6%, 49% and 56.4%, respectively. This indicated that the ultimate compressive strength of confined columns could be enhanced, to an extent, by improving the textile layers. It was worth mentioning that the average ultimate compressive strength of Group FRSE1 increased by 62.6%, which indicated that FRE composite jacket constructed by sprayed ECC, could provide effective confinement to core concrete. Table 5 shows the details of cracking and ultimate loads for all test specimens.

Stress-Strain Responses

The axial compressive stress-strain curves of FRE1E, FRE2E, FRE3E and RC were presented in Figure 6. Here, axial reinforcement strain was used to present the axial deformation of specimens in this paper. As the figure shows, the curve can be divided by two parts. Similar to those of conventional FRP-confined concrete with a sufficient level of FRP confinement (Teng et al. 2007), the stress-strain curves of FRE-confined concrete from the present tests also exhibited a monotonically ascending bilinear shape with rapid softening in a transition zone around the stress level of unconfined concrete strength. Both the compressive strength and the ultimate axial strain were significantly enhanced. However, be worth mentioning, the curve slope of part two was gentler than that of conventional FRP-confined.

</table>

The typical hoop strain responses of ECC and BFRP textile are shown in Figure 7. As presented, both of them were very little when the axial compressive stress lowered than 15MPa. The strain increased rapidly as the axial compressive stress reached to 35MPa. Obviously, the circumferential strain of sanded textile and ECC were basically the same throughout the test progress. Therefore, there was no interface slip occurred between them. On the contrary, the hoop strain of ECC was obvious much larger than that of textile in FRE1-1. This was consistent with the failure mode.

FINITE ELEMENT MODELING

Finite element modeling (FEM) of wrapped as well as control specimens were carried out in order to analyze the experimental results. ABAQUS, a general-purpose nonlinear finite element program, was employed for the numerical simulation. The concrete damaged plasticity model was used to simulate concrete (CODE FOR DESIGN OF CONCRETE STRUCTURES). Based on the axial tension test, plastic model was used to assign material properties to ECC and steel. As shown in Figure 8, σ<sub>cr</sub>, ε<sub>cr</sub>, σ<sub>cu</sub>, ε<sub>cu</sub> are cracking stress/strain and limiting stress/strain of ECC. Besides, BFRP textile simulated with linear elastic material, and the compressive behavior of longitudinal textile was not considered in this simulation. Static general analysis method was used to calculate the model and there was no interface slipping occurred between ECC and textile. Details of numerical model are shown in Figure 9.

Figure 8 ECC tension response
Figure 9 Numerical Model
Figure 10 Comparison of Failure Mode
Figure 11 Comparison of experimental and simulated results

As shown in Figure 10, the PEEQ (equivalent plastic strain) result of simulated specimen was similar to that of experimental cylinder for selected specimen FRE1E. The destruction area of FRE composite jacket was focus on the center of column, and the angle between cracking direction and specimen axis was about 45°. The result showed that the simulated specimens also damaged with BFRP textile rupturing, which was matched with the experimental result.

The compared results of test and simulation were shown in Figure 11 and Table 5. As seen in Table 5, the average ratios of cracking load and ultimate load between simulation and experimental result were 0.955 and 1.032 respectively. And the standard deviations were only 0.068 and 0.048 respectively. This verified the feasibility of the finite element modeling.

CONCLUSION

After surface treatment of textile, the bonding behavior of BFRP textile-ECC interface was significantly improved. Either smeared or sprayed ECC reinforced with BFRP textile could provide effective lateral confining stress to the core RC columns and delay the buckling of longitudinal reinforcement.

The effectiveness of the proposed new confined method was validated through a series of experimental programs. The test results indicated the loading capacity and axial deformation of the strengthened RC column were improved obviously.

The analytical results show that the finite element model can simulate the mechanical process of strengthened RC columns effectively.

ABSTRACT
This work aims at studying on reinforced concrete (RC) beams shear-strengthened by Carbon Fibre-Reinforced Polymer (CFRP) grid and sprayed mortar. Clearly understanding the behaviour between stirrup and CFRP grid is necessary for evaluating the effective of the strengthening work. Two RC beams were fabricated; the control beam was not strengthened while the other was shear-strengthened by CFRP grid and sprayed mortar. The four-points bending tests were conducted until both of beams were failure. The main data of the experimental program was presented and analysed to show the interaction between stirrup and CFRP grid. The experimental results indicated that the shear strength of RC beam was significantly increased by the CFRP grid and sprayed mortar. Bonding between concrete and sprayed mortar is one of the most important factors that influence the effective reinforcement. Cracks occurring in RC beam after the plastic period considerably affect the behaviour between stirrup and CFRP grid.

KEYWORDS
RC beams, shear-strengthening, CFRP grid, sprayed mortar, stirrup.

INTRODUCTION
In recent decades, the reparation of existing structures such as building, bridges, etc., have been amongst the most importance challenges of civil engineering. The primary reason for strengthening of structure includes upgrading of its resistance to withstand underestimated loads, restoration of lost load carrying capacity due to corrosion or other types of degradation. Carbon fibre reinforced polymer (CFRP) composites are widely used for strengthening concrete structures because of their advantages over conventional strengthening methods. And strengthening with externally bonded CFRP fabric has shown to be applicable to many kinds of structures. In recently years, many concrete structures have been strengthened by CFRP grid and in many specific cases it shows the advantage when comparing to CFRP sheets or plates.

Many previous experimental researches have been carried out over the past decade to study on the performance of concrete beams strengthened in shear with externally bonded FRP composites. I.A. Bukhari [1] has reviewed existing design guidelines for strengthening continuous beams in shear with CFRP sheets and proposes a modification to Concrete Society Technical Report. On the other hand, Wen Yong Chen [2] studied the shear behaviour of RC beam with FRP grid and supposed that RC beams strengthened with FRP grid have good shear behaviour both increasing shear capacity and controlling of the crack width. In research of Rui Guo [3] examined the effect of shearing capacity of RC beams with haunch by PCM shotcrete method with CFRP grid and adhesive properties of the reinforced interface between PCM and existing concrete was investigated and analysed. All these articles have not focused on the behavior between stirrup and CFRP grid. The main purpose of this research was to examine the effective of CFRP grid in improving the shear strength by analyzing strain of stirrup in non-strengthened RC beam and the strain of CFRP grid in the shear strengthened RC beam. This research also illustrates the behaviour between stirrup and CFRP grid in simply-supported singly-reinforced concrete beams. In fact, shear resistance capacity of RC beam gradually reduced by the time of exploiting and corrosion is one of the most important reasons causing loss of concrete-strength and reduction of sectional area of reinforced bars. In order to solve this problem, this experimental program studies on two RC beams that have same dimensions, concrete, main reinforcement bars but different in diameter of stirrup bars. The shortages of shear resistance capacity would be added by CFRP grid and sprayed mortar.
EXPERIMENTAL PROGRAM

Material

The test experiment consisted of casting and testing two beams. Two RC beams were fabricated using the ready mix concrete with the compressive strength of 34.1 N/mm$^2$ (Table 2) and the aggregate G1, G2 (with the range of finenesses of 1±1@ and 3±1%, respectively). In the mix proportion of concrete, high early strength Portland cement was used and water-cement was 0.556 with the addition of admixtures (Table 1).

Sprayed mortar was polymer-modified cement with the proportion of premixed mortar, shot polymer and water was 25kg, 1.21kg and 4.1kg, respectively. In order to increase the adhesion of the interface, an epoxy primer was applied to the surface of concrete before spraying mortar.

D32 was the tension reinforcing bar and D6, D10 were the stirrups and reinforcing bar in the compressive zone. CFRP-CR8 with grid spacing of 100x100mm was used to enhance shear strength. The mechanical properties of these materials are given in the Table 3.

Test specimens

The control beam had not been any strengthened while the remain had been shear strengthened with CFRP grid and sprayed mortar. Both of beams have the original size was 200x500x2750mm. The control beam, name RC beam 1 (RC1), is normal RC beam used D32 bar as the tension reinforcements, the compression reinforcements and the stirrups was D10, the stirrup spacing was 200mm. The remain, RC beam 2 (RC2), was strengthened by CFRP grid and sprayed mortar. CFRP grid was placed along the beam web and the sprayed mortar to create a 20mm additional layer on both sides of RC beam 2. With the assumption that the shear strength in this beam was lost due to corrosion, the section area of the stirrups reduced. In RC beam 2, D6 bar was used as stirrup which is smaller type in the RC1 (D10). Electrical resistance strain gauges were embedded to reinforced bars, stirrups, concrete and CFRP to monitor the variation of stress and strain in two beams (Figure 6 and Figure 7).
Casting RC beams

Firstly, the substrate concrete beams were cast in wooden molds and the curing by moisture-retaining material. Eight days after making the substrate beams RC2, their web’s surface was sand blasted. Four days later, CFRP grid was place on the both sides of beam using steel bold anchors.

In the next day, an epoxy primer was applied and the repair mortar was sprayed after epoxy layer had dried. Finally, a curing compound was sprayed on the mortar surface. The tests were carried out at the age of 27th and 29th day of the substrate beams. Figure 3 and Figure 4 shows the specimen’s fabrication procedure.

Test procedure

The four-points bending test was conducted with 2 beams (Figure 5). During test, when appearing the first flexural crack and the first diagonal crack, the specimens were unloaded to mark the cracks and take photographs. After that continually increase the load until 2 beams were failed. During the test, the failure processes were monitored by strain gauges embedded to concrete, reinforce bars and CFRP grid.

RESULTS AND DISCUSSIONS

Effectiveness of CFRP grid and sprayed mortar

The loading results of each test specimen are listed in Table 4. Design values were calculated according to the Standard Specifications for Concrete Structures-Design [6]. The flexural crack appeared when the flexural cracking strength of material exceeds. After that, if the stress reached the shear strength of concrete, shear cracks would occur. The design shear capacity of RC beam 1 is the sum of concrete and reinforcement while it of RC beam 2 is the sum of all components as concrete, reinforcement and CFRP grid.

</tbody>
</table>
According to Table 4, the maximum load of RC2 (757kN) is higher 9.7% than it of RC1 (690kN). Noted that, cross sectional area of stirrup bar had been reduced from D10 to D6, equivalent to 66% of sectional area reducing. It shows that, CFRP grid had positive effect in shear strengthening. The composition of concrete, rebar, mortar and CFRP grid worked well together.

An unreasonable value of maximum load design of the two beams. Test load of RC1 was much more than design load due to the safety ratio in Standard Specifications [6]. Applying the formula for calculating shear strength of steel bar to CFRP grid was not appropriately, some coefficients in the formula was not reasonable with FRP.

Figure 6 and Figure 7 show locations of strain gauges embedded on rebar, concrete, and CFRP grid in RC beam 1 and RC beam 2. The cracks occurred during the test also were described in the Figure 6 and Figure 7, the ultimate cracks (the red curves) were largest crack at ultimate failure state of each beam.

In order to understand more clearly about the effectiveness of CRFP grid, comparing the different in strain between stirrup in RC1 and RC2 is shown in Figure 8.

The initial purpose of strengthening by CFRP grid is to take over the losing shear strength caused by reducing cross sectional area of stirrup bars. Based on Figure 8 and Table 5 the effectiveness of strengthening was better than expected.

In general, strains on stirrup S1, S2, S3, S4 (location of each stirrup showed in Figure 6, Figure 7) in RC1 were significantly longer than in RC2. The ultimate strain on S2, S3 in RC2 is over 0.015 while in RC1 is over 0.025 (Figure 8).

When the load was under 400kN, the ratio of strain in RC2 to strain in RC1 at a same stirrup is around 0.5 (Table 5). At the period of load from 400kN to 550kN, values of stirrups S2, S3, S4 in RC2 are even higher than in RC1. This is because 2 reasons: The first, strain values of S2, S3 in RC2 were from 1248x10^{-6} and 1822x10^{-6}. With values of Young’s Modulus of Steel is 2x10^5 N/mm2 (Table 3) and Yield strength of Stirrup is 417 N/mm^2 (Table 2), stirrup would become plastic at the value 2,085x10^{-6}. In this period, stress in Stirrup no longer increase. The second, in the RC beam 2, stirrup steel was D6 bars, smaller than 66% in cross sectional area than in RC beam 1. In addition, many cracks developed around the position of S2, S3, and S4 (Figure 7) caused stress concentration.

When the load is over 400kN, S4 in RC2 higher than in RC1 (Figure 7), the ultimate crack cross over the position of stirrup S4 (RC2). There was stress concentration phenomenon here.

**Behaviour between CFRP grid and stirrup in RC beam 2**

![Stirrup S4 and CFRP grid G35](image1)

![Stirrup S3 and CFRP grid G30](image2)

Figure 18 Load versus strain curves on stirrups and CFRP grid in RC beam 2

501
Bonding between concrete and sprayed mortar is one of the most important factors influence the effectiveness of reinforcement. The behaviour between stirrup and CFRP grid at the same positions in RC beam 2 reflects the bonding between concrete and sprayed mortar. Strain gauges on CFRP grid G4, G14, G30, G35 and Strain gauges on stirrup bars: S1, S2, S3, S4 were at respectively same positions in the RC beam 2. Locations of these strain gauges are shown in Figure 16. Those data of the bending test are listed in Table 10. Figure 18 illustrates the load versus strain curves of stirrups and CFRP grid in RC beam 2.

Regarding to the strain curves when the load is from 300kN to 550kN, according to the collected data in Table 10 and graph in Figure 18 it is supposed that: When the load is over 350kN, Strain values of stirrup were higher than CFRP (except stirrup S1), comparison ratio of S3/G30 and S4/G35 is higher than S2/G14. At the load of more than 700kN, different in strain between stirrup S4 and CFRP grid G35 became larger. Especially, at the ultimate stage, strain of S4 was 5 times higher than G35 (4.9 times at load of 750kN). Strain gauges at the same position differed strongly. This tendency proved that, these materials (CFRP grid and stirrup) had no longer worked together and bonding between concrete and mortar was able to be damaged. These because of following reasons: Firstly, when the strains of stirrups S2, S3, S4 was over 2,085x10^-6 (this value has been calculated in previous section), stirrups became plastic state, deformation of stirrups increase rapidly after this point. Secondly, when increasing the load from 320kN to 425kN, the cracks occurred and developed deeper and wider, compression area of cross section reduced, and most of them located on the same position with S2, S3, S4 (Figure 16). Once the crack crossed the locations of stirrups and CFRP grid, adhesion of mortar to concrete surface was also damaged. About some unexpected values: when the load was low (under 200kN), strain value of G30 (too small or under 0) on CFRP grid would not be accurate. Stirrup S1, at the load over 400, strain value of S1 smaller than CFRP because, stirrup S1 worked in elastic state in whole stage of test, and there was almost no crack occurred on this location.

CONCLUSIONS

The experimental program was conducted to study on shear strengthening RC beams by CFRP grid and sprayed mortar. Base on the data and the analysis, effect of strengthening and interaction between CFRP grid and stirrup has been more clearly understand. Two following conclusions have been drawn:

The first, the test show that using CFRP grid and sprayed mortar can enhance a significant effective in shear strengthening to RC beams. The shortage of shear resistance capacity in RC beam 2 due to stirrup bars had a reduction of cross sectional area can be added by CFRP grid. With the assumption that cross sectional area of stirrup substantial reduced (66% in the test), RC beam was reinforced by CFRP grid and sprayed mortar, and shear bearing capacity of RC beam increased more than expected (9.7% much more than the control beam).

The second, the behaviour between CFRP grid and stirrups reflects the bonding between concrete and sprayed mortar. It is one of the most important factors that influence the effective reinforcement. According to results from the experiment, when increasing the load, variations of stirrup strain and CFRP grid strain at a same position in strengthened RC beam normally have similar tendencies. Cracks occurring after the plastic period of RC beam considerably affect the interaction between stirrup and CFRP grid, strain values of stirrup and CFRP grid had

502
unexpectedly changed in this period. In general, it is shown that the composition of concrete, steel rebar, mortar and CFRP grid have worked properly.

From these above comments about the experiment work, it is supposed that shear-strengthening RC beams by CFRP grid and sprayed mortar provides valuable reinforcement.

ABSTRACT

Despite the clear advantages of confinement of concrete structural elements with fibre-reinforced polymers (FRPs) for strength and deformability enhancement, concerns as to their performance at elevated temperature, or in fire, remain. The results of a series of elevated temperature experiments on FRP and textile reinforced mortar (TRM) strengthening systems for confinement of circular concrete columns are presented. The behaviour and effectiveness of the respective confining systems is studied up to temperatures of 400°C. A total of 24 concrete cylinders were wrapped in the hoop direction with different amounts of FRP or TRM, heated to steady-state temperatures between 20 and 400°C, and loaded to failure in concentric axial compression under a steady-state thermal regime. The results indicate that the effectiveness of the FRP confining system bonded with epoxy decreased considerably, but did not vanish, with increasing temperatures, in particular within the region of the glass transition temperature of the epoxy resin/adhesive. Conversely, the TRM confining system, bonded with inorganic mortar rather than epoxy, demonstrated superior performance at 400°C as compared against tests performed at ambient temperature. Additional research is needed to better understand the reasons for this.

FRP, textile reinforced mortar, TRM, strengthening, high temperature, fire, confinement.

INTRODUCTION

A popular application of FRP is strengthening concrete columns by confinement with FRP in the hoop direction (Bisby et al. 2011). However, the performance of FRP systems at elevated temperatures is potentially problematic since much of their strength, stiffness, and bond properties are lost at temperatures that are rapidly exceeded in building fires (Chowdhury et al. 2011). Carbon fibres used in FRP systems are capable of resisting temperatures of more than 800°C; however, epoxies used to bond the fibres and adhere FRP systems to concrete lose a considerable proportion of their mechanical properties at temperatures as low as 60°C-82°C (ACI 2008). These reductions in mechanical properties can be expected in the region of the epoxy’s glass transition temperature ($T_g$) as it changes from hard and brittle to soft and plastic. Testing has been carried out previously to investigate the performance of FRP confining systems for concrete columns during standard fire exposures (e.g. Chowdhury et al. 2007) and during both transient and steady-state heating to elevated temperatures (Rickard et al. 2013). This testing has shown that considerable (approximately 50%) loss of effectiveness of the FRP strengthening system occurs at temperatures as low as 15°C below the $T_g$ of the epoxy adhesive, which is thought to be due to reductions in the tensile strength of the FRP wraps at these temperatures. To alleviate the reduced effectiveness of FRP systems at high temperatures, a novel textile-reinforced mortar (TRM) has been proposed for strengthening of reinforced concrete (RC) columns (Bournas et al. 2007). In an effort to develop strengthening systems with enhanced performance at elevated temperatures, this paper presents initial research aimed at investigating the performance and effectiveness of both FRP and TRM confining materials of concrete at elevated temperatures, such as would be experienced during a fire, when the confining system is active under sustained load; this was done by testing concrete cylinders with different amounts of FRP or TRM confinement at various temperatures. The main objective was to develop an initial understanding of the confining mechanisms at elevated temperature and to suggest defensible limiting temperatures for FRP and TRM strengthening systems in fire.
EXPERIMENTAL PROGRAM

Thirty tests were performed on normal strength concrete cylinders that were loaded at both ambient and elevated temperatures. All tests were performed under a steady state thermal regime. Since this is the first ever study of its kind; a goal of the study was to identify aspects for further investigation. Details of the experimental program are given in Table 1. All tests were on 100mm diameter, 200mm tall concrete cylinders; this was chosen as it allowed test specimens to fit within a bespoke environmental chamber fitted within a 600kN materials testing frame; it is noteworthy that a size effect may be relevant to the performance of both FRP and TRM wrapped cylinders, and additional research is needed on this topic. Parameters varied within the testing program included:

Type and amount of confinement: Six cylinders were tested without confinement to determine the unconfined concrete properties and to determine the reductions in concrete properties caused by heating to the maximum exposure temperature used (400°C). Twelve cylinders were wrapped with FRP (six with a single layer and six with three continuous layers). The fibres used were carbon textile reinforcement with an open weave and a weight of 220g/m². The fibres’ manufacturer datasheets (Bentonex RC225-TH12) gave a tensile strength and modulus of elasticity of the carbon fibres was 4800MPa and 225GPa, respectively, with a nominal thickness of 0.062mm (Bentonex 2016) (trade names given only for factual accuracy). The fibres were saturated and bonded using Sikadur 330 epoxy adhesive system (Sika 2016). The TRM system also used Bentonex RC225-TH12 carbon fibre textile reinforcement. This was bonded with a cementitious mortar based on an inorganic dry binder consisting of cement and polymers at a ratio of 8:1 by weight, ISOMAT (2016). The water-binder ratio in the mortar was 0.23:1 by weight, resulting in plastic consistency and good workability. The hoop overlap length was chosen as 100 mm.

Thermal Exposure: Temperatures were chosen in the range of the glass transition temperature \(T_g\), as determined from dynamic mechanical analysis and the decomposition temperature \(T_d\), as determined from thermogravimetric analysis) of the epoxy adhesive/saturant. The epoxy resin used in the current study has a \(T_g\) of 58°C based on tan delta peak from DMA testing. Samples were heated without any applied load at a heating rate of 10°C/min until the target temperature was reached, and all samples were then held at the target testing temperature for 60 minutes before testing (to assure a uniform sample temperature).

* \(T_g\) – epoxy glass transition temperature; ** \(T_d\) – epoxy decomposition temperature
All samples were tested in an Instron 600LX testing frame with an integrated environmental chamber at a loading rate of 1mm/min (crosshead displacement) until failure. Axial and hoop strains were measured using image correlation analysis via digital images captured every 5 seconds during testing with post-testing analysis performed in GeoPIV software (White et al. 2003). Full details of the image analysis technique are avoided here but have been presented for similar testing by Rickard et al. (2013). Temperatures were monitored during testing by a single thermocouple for air temperature (placed next to the sample) and a single thermocouple mounted on the surface of the sample at mid-height. Testing occurred six months after casting the concrete.

**EXPERIMENTAL RESULTS**

Summary plots showing the results of all tests listed in Table 1 are given in Figure 1, and numerical summaries of the tests are given in Table 2.

* "Rupture" refers to FRP failure in hoop tension, “adhesive” refers to loss of confinement by debonding, “Mixed” refers to failure which displayed a combination of rupture/adhesive failure.

**Unconfined Concrete Cylinders**

Six unwrapped (plain) concrete cylinders were tested. Two were tested to define ambient strength, and the remaining four were tested at selected elevated temperatures (100 °C, 150 °C, 200 °C and 400 °C) in order to assess the effects of elevated temperature on the strength and stiffness of the unconfined concrete; such that any strength reductions observed for the FRP and TRM confined specimens could be attributed (or not) to reductions in the effectiveness of the confining mechanism. The average ambient unwrapped concrete strength was 16.1 MPa. The concrete strength was reduced slightly, by 15% and 12% at 100 °C and 150 °C, respectively, before recovering to a strength 5% above that at ambient at 200 °C. At 400 °C there was no obvious reduction in compressive strength. Whilst its difficult to draw definitive conclusions regarding the effects of elevated temperature exposure on the plain concrete cylinders due to the small number of specimens tested, it is noteworthy both that these test data contradict the widely accepted concrete strength reductions with temperature suggested in the Structural Eurocodes.
(CEN, 2004) – which indicates an expected compressive strength reduction of between 15 and 20% at 400°C, depending on the aggregate mineralogy – and that similar strength trends seem to underlie the responses of the FRP and TRM confined specimens (discussed below). The lack of reduction in compressive strength of the concrete at 400°C suggests that additional research is warranted in this area.

The lack of reduction in compressive strength of the concrete at 400°C suggests that additional research is warranted in this area.

Tests on FRP Confined Concrete

Figure 1 and Table 2 show a clear trend of reducing FRP confined concrete strength with increased steady state exposure temperature; although with such a small number of samples it is difficult to clearly distinguish if this is attributed to concrete thermal damage effects and/or loss of FRP confinement effects. Whilst the results for FRP confined cylinders are similar to those previously reported by Rickard et al. (2013), additional testing with a larger number of cylinders will be required to have greater statistical confidence in the results obtained.

It is clear that exposure temperatures above \( T_g \) cause considerable reductions in the strength of FRP confined concrete cylinders. It is also clear, however, as previously reported by Rickard et al. (2013), that the FRP wrap provided considerable additional strength at all temperatures tested, particularly for the case with three continuous layers of carbon fibre reinforcement. For the case of three layers of FRP, the confinement continued to enhance the failure strength at temperatures well above \( T_g \). For example, strength was enhanced by more than 200% at 400°C. The confinement provided by the single layer of FRP is much less; this is likely the result of frictional bond strength for the three layer wrapping, which is able to provide confinement even once the adhesive has lost the majority of its mechanical properties.

Tests on TRM Confined Concrete

For the TRM confined concrete cylinders, Figure 1 and Table 2 show that the TRM system was marginally less effective than the FRP system for a single layer at ambient conditions, and that it’s performance was similarly affected by exposure to a temperature of 100°C, losing 23% of its strength at this temperature. This is likely due to a combination of reductions in the strength of the concrete itself at this temperature (discussed previously) combined with reductions in the effectiveness of the confinement (for reasons which remain unknown). However, at temperatures above 100°C the TRM system recovered its strength more rapidly than either the plain or FRP confined specimens, and at 400°C the single layer TRM confined sample actually tested stronger than the sample tested at ambient.

Similar observations can be made regarding the performance of the three layer TRM confining system. In this case the strengthening provided by the TRM system was considerably less, by 33%, than the three layer FRP system, probably because of differences in the observed failure mode; tensile pull-out of the fibres from the cementitious matrix followed by partial fibre fracture in the case of the TRM, compared with tensile fibre fracture over the height of the cylinder in the case of the FRP. Figure of the TRM wrapped specimens was considerably less violent and absorbed more energy than for the FRP wrapped specimens, particularly at lower temperatures. This may present advantages, particularly in seismic strengthening applications. However, at elevated temperature the three layer TRM system displayed similar response as for the single layer TRM system, with mild reductions in strength.

![Figure 19](image-url)

Figure 19 Ultimate Compressive Strength and Percentage Strengthening versus Temperature
at 100, 150, and 200°C (likely for the reasons discussed in the previous paragraph), but a small increase (by 7%) in strength at 400°C as compared with the strength at ambient.

Increases in the effectiveness of the TRM system at elevated temperature are striking, particularly for the case of the three layer TRM system, and may be due to thermal prestressing of the carbon fibres during heating, as has previously been suggested by Rickard et al. (2013) for multiple layer FRP confining systems at elevated temperature. Since carbon fibres generally have a negative coefficient of thermal expansion, whereas the concrete core has a positive coefficient of thermal expansion, thermal dilation of the concrete core during heating will develop tensile stresses in the carbon fibre mesh, and provided that bond is maintained (either by adhesion or by winding friction) the wrap will self-press, which can be expected the enhance both the strength and stiffness of the TRM confined cylinders. This hypothesis warrants additional research, and may indicate that unprotected TRM systems are capable of providing effective (i.e. active) confinement of concrete at temperatures up to and exceeding 400°C (something that epoxy-based FRP systems are unable to do).

**Axial/Hoop Stress versus Strain Response**

Typical stress-strain curves obtained during steady state testing using the image correlation analysis are given in Figure 4. For clarity only the ambient temperature, specimens confined with three layers, 150°C, and 400°C tests are shown. It was difficult to obtain consistent strain information during these tests due to thermal effects on the image correlation technique; the results should therefore be taken as only indicative of the response. It is noteworthy that both the strength and stiffness of the confined concrete appear to be significantly reduced at 150°C, whereas these appear to be recovered at 400°C. Again, this behaviour warrants further investigation, both for confinement research but also for structural fire engineer research on concrete structures. Further image correlation analysis results will be presented at the conference.

![Figure 20 Stress-Strain Curves for Cylinders with Three Layers of Strengthening: (a) FRP wraps, and (b) TRM wraps](image)

**PRELIMINARY CONCLUSIONS**

The following preliminary conclusions can be drawn on the basis of the tests reported herein:

Considerable loss of effectiveness of the FRP wrap system occurred at temperatures as exceeding the $T_g$ of the epoxy adhesive used. This is thought to be due to reductions in the tensile, and more importantly bond, strength of the FRP wraps at these temperatures.

The ultimate load capacity of FRP wrapped cylinders continued to decrease with increasing temperatures; however the FRP wrap continued to provide some confinement at all exposure temperatures, both for a single layer and for a triple layer, even at 400°C which is well above $T_g$. This is possibly attributed to bond retention resulting from winding friction, which appears to be (as expected), much more effective for three continuous layers of FRP than for a single layer.
FRP rupture was the observed failure mode at temperatures below 100°C; above 100°C the failure mode was observed to transition to bond failure in the FRP overlapping zone.

Minor loss of effectiveness of the TRM wrap system occurred at temperatures between 100 and 200°C. This is thought to be due to reductions in the compressive strength of the concrete at these temperatures (as corroborated by compression tests on unconfined concrete at these temperatures). However, both single and triple layer TRM wrap systems demonstrated enhanced strength at 400°C.

It appears that differential thermal expansion between the carbon fibre reinforced wraps (contracting) and the concrete column (expanding) caused a slight prestress of the FRP and TRM systems during heating.

The number of FRP and TRM layers of wrapping (hence the effective overlap length used) had a significant impact on the confinement effectiveness at elevated temperature; however, additional testing is required to study the influence of wrapping with multiple continuous layers on the performance of FRP and TRM confined concrete at elevated temperature.

**RECOMMENDATIONS**

The following are recommendations for future work in this area:

Further tests on unconfined concrete at elevated temperature are required to better understand the effects of heating on reduction in unconfined concrete compressive strength.

Additional repeat tests, particularly on FRP and TRM confined concrete, are required to ensure statistical confidence in the results obtained and to corroborate the results and hypotheses presented herein.

Other available FRP and TRM wrap systems and materials need to be studied to allow generalization of the observations made during the current study.

Cylinders tested in this project were subjected to loads at elevated temperatures for relatively short periods of time. The potential effects of prolonged loading and heating, as might occur in warm service temperatures, require study since creep may cause failure at lower temperatures under long term loading.

Additional tests should be conducted on FRP and TRM confined RC columns at full-scale.

ABSTRACT

Fiber Reinforced Polymer (FRP) materials have been extensively studied and applied all over the world in the last two decades. Nowadays a new generation of inorganic composite materials is also widely studied for seismic strengthening of ancient masonry construction. The new technique is studied for those cases in which a localized epoxy-bonded reinforced show its limits due to the weak nature of the substrate. In these cases Fiber Reinforced Mortar (FRM) systems are used as external strengthening coating, in forms of fibrous grids immersed in a brittle matrix made by hydraulic or cementitious mortar. The results of an extensive experimental program are presented in this study, which involved twelve full scale masonry walls subjected to diagonal shear tests. Two different configuration of masonry walls were studied: six walls were built with a single layer of limestone masonry blocks and six walls were built with a double curtain of limestone blocks separated by a layer of inconsistent mortar and connected by six transverse bond-stones. Low-strength hydraulic mortar was used as binder between the blocks. These configuration were chosen to replicate typical walls found in real heritage masonry buildings. Two different strengthening FRM systems were applied on both sides of the specimens and studied. The first consisted of an industrially pre-cured rigid Glass FRP grid immersed in a lime-based mortar. The second system was an hybrid system made by a dry glass fiber net immersed in a lime-based mortar in which a polymer primer was added as bond promoter. The results of the mechanical tests highlighted in all cases a remarkable increase of shear strength due to the weak properties of the unstrengthened walls. Brittle failure due to diagonal sliding along the joint was observed in unstrengthened masonry. The presence of the FRM has resulted in a pseudo-ductile behaviour of the specimens in both cases, even if different failure modes were observed for the two FRM systems. Fiber rupture and a full composite action was observed for the polymer added FRM system, while extensive cracks and local spalling was observed by testing the fully inorganic system.

INTRODUCTION

Structural deficiencies of poor masonry buildings under horizontal forces are well known, and protection of the cultural heritage has become a priority when seismic hazard is considered. Due to the low mechanical properties of masonry constituents, and lack of proper design, horizontal forces may cause shear failures in loading bearing walls which lose their stiffness and strength under cyclic actions. Seismic events all over Europe and Asia, in the last decades, had consequences that have alerted scientists and engineers, due to the brittle failures of masonry buildings. When severe earthquakes forces invest a masonry system two scenarios may open: 1) the masonry is not connected and thus local disaggregation or local rigid overturning cause collapse; 2) masonry is well connected and internal forces are carried by shear walls. In this second case the seismic vulnerability is related to the shear strength of the masonry panels, which often incorporate poor materials such as soft stone and weak limestone mortars. A quantitative study on how the weak hydraulic masonry is able to carry shear forces was conducted by Augenti & Parisi (2011). When the mortar is poor, failure is due to sliding along the blocks; when the mortar is strong, shear cracks pass through the blocks. In the last decade innovative techniques were studied and applied in order to increase the in-plane shear strength of masonry walls. Fiber Reinforced Polymer (FRP) materials were investigated in forms of laminates (Valluzzi \textit{et al.} 2002). The effectiveness of FRP-strengthening was confirmed in recent studies also for historical limestone masonry (Marcari \textit{et al.} 2011) and bricks (Saghafi \textit{et al.} 2013). Recently new materials with inorganic matrix were developed and studied for the strengthening of ancient masonry (Carozzi \textit{et al.} 2014), in these cases the bonding agent is not a polymeric resin and its application is diffused and not localized. Inorganic matrixes, mostly cement based, were proposed in recent studies as strengthening systems.
with a continuous fibrous reinforcement (Babeidarabad 2014; Gattesco & Dudine 2010, Gattesco et al. 2015; Menna et al. 2015; Yardim et al. 2016). In this experimental study twelve full scale masonry walls were built and tested in diagonal shear until failure. Limestone masonry blocks were regularly packed by using a weak limestone mortar, to simulate historical construction found all over southern Europe. Two type of specimens were tested: single wall and double head-faced walls. The results show that the low shear properties of the tested masonry dramatically increased after the installation of the FRM reinforcements.

**EXPERIMENTAL PROGRAM**

Twelve walls specimens were built with two different construction schemes, to simulate the real findings in historical buildings. Six were built as single walls (“S2” labels), the remaining six specimens were built as double walls (“D2” labels). In this case the two masonry curtains were separated by a non structural thickness of 80 mm made by inconsistent mortar. They were connected by six transverse bond-stones as shown in Figure 1, in which the design geometry of the specimens is illustrated. The geometry of the specimens was studied in order to maintain a slenderness ratio of 12 between the height and the structural thickness. Therefore in doubled wall specimens the structural thickness is the same to that of single walls.

![Figure 1 Geometry of wall specimens (quotes in mm)](image)

The mortar that was used to build the specimens was a poor limestone-based mortar without cementitious binder, as same as it was done by the ancient master builders. Mortar specimens were poured and stored under the same laboratory conditions of the wall specimens. The mechanical properties of the mortar were measured in laboratory by testing 10 specimens for each type of test. A compressive strength of 1.68 MPa, an elastic modulus of 4478 MPa, a tensile strength of 0.13 MPa, and a mass density of 1592 kg/m$^3$ were found. The experimental program, specimen dimensions and type of FRM reinforcement are reported in Tables 1 and 2.

A mechanical characterization of the masonry was also carried out. Masonry specimens were tested under compression to measure the nominal strength of the material. Three single wall specimens (1000x1200x160 mm) and three double-face walls (800x650x150 mm) were subjected to compression load until crushing failure. The average strength of the single walls was 4.38 MPa, while for double-face the average strength was 6.01 MPa. Three double face-walls were also tested by applying the load at 90° respect to the masonry stacking, in direction parallel to the horizontal joints; in this case the average ultimate strength was 4.12 MPa.

Two different strengthening systems were used for the shear reinforcement that was applied on both sides of the specimens. The first system is represented by a rigid Glass FRP (GFRP) grid embedded in a coating which is made by an hydraulic lime mortar. This technique is an evolution of the traditional steel-reinforced coatings, but with advantages of reduced thickness and absence of galvanic corrosion. The GFRP grid was industrially formed by using AR-glass (alkali resistant) fibres and an epoxy/vinylester resin, and it has a 66x66 mm spacing. Four GFRP mechanical anchors were provided in forms of bent pultruded bars injected across the masonry thickness, as shown in the representative Figure 2. This system can be applied by using traditional construction techniques. The mechanical properties of the GFRP grid were provided by the manufacturer with reference to the composite section: tensile strength 1000 MPa, ultimate strain 3%, elastic modulus 27 GPa.

The second reinforcement system is represented by a dry AR glass mesh having a density of 220 g/m$^2$ immersed in a limestone-based matrix which is applied to the masonry by using a polymer-added primer that is able to generate crosslinking in presence of water. The primer has the double function of bond promoter between masonry and mortar, and between mortar and fibers. Four FRP connectors in forms of CFRP spike-bars were applied. The procedure does not require temperature or moisture control as done in presence of epoxy resins as mandatory.
advantage of this system is represented by the high bond retention (similar to FRP), very low thickness (less than 10 mm) and ease of installation. The strength and elastic modulus of the glass fibers are respectively 1500 MPa and 70 GPa as reported by the manufacturer. Two repetitions for each unstrengthened and strengthened schemes were tested by using a test set-up illustrated in Figure 2. The test set-up has a steel angle-toe welded to a stiffened H-shape profile, to avoid deformation of the loaded angle. A second similar device was applied at the opposite corner of the specimen. Finally, a third device was connected to the bottom device. Four steel bars were used as diagonal tendons, and the diagonal force was provided by a hydraulic jack (maximum axial load equal to 933 kN, stroke of 257 mm) interposed between the top devices. Four LVDTs were placed along the four diagonals of the specimens (both sides), and two additional horizontal LVDTs were placed on both sides at the centre, to detect potential out-of-plane displacements. The reference points on the diagonals were placed at a distance of 1050 mm. Diagonal compression load and signals from displacement transducers were contemporarily recorded by an electronic data logger.

![Shear reinforcement scheme with GFRP reinforced coating - Experimental diagonal shear set-up](image)

For all specimens three load-unload cycles were run at low values of the applied load to press the voids that are present inside the masonry system. This allowed to avoid strain readings that are not relevant with the real mechanical behaviour of the panel. In Tables 1 and 2 the experimental program is resumed.

RESULTS AND DISCUSSION

Experimental results highlighted the mechanical benefit that was provided by the presence of the FRM reinforcement systems, even if important differences may be remarked. Different failure modes were found since the strengthening system were very different. In Figure 3 they are illustrated, and in Tables 3 and 4 a synthesis of the experimental results is listed. It can be seen that the maximum shear load carried by the walls increased up to 8 times for single walls and up to 5 times for double walls. In both cases unreinforced specimens had a typical failure with sliding along the mortar joints. This occurrence testified the important role of the connection produced by the transverse blocks. After the crack opening along the compression strut the specimens did not show a significant residual capacity. This brittle failure mode is typical of masonry panels subjected under in-plane loads when the strength of the mortar joint is much lower than the strength of the blocks. Crushing phenomena in the blocks were not evident, while a macroscopic misalignment of the joints was visible at the end of the test. Specimens strengthened with rigid GFRP grid in limestone coating exhibited a progressive cracking opening, which started on the compressed diagonal and then spread along the entire panel.

In double-face walls at high loads failure was accompanied also by opening of the free corner, even if this was not the direct cause of the collapse. Local spalling of the coating was observed and even under severe damage the wall was able to maintain its load capacity. In the case of the second FRM system, in which a polymeric primer was used, debonding of the coating was not observed, and cracks were mostly horizontally directed. Failure was
anticipated by fibres slippage inside the matrix, and was due to fibre rupture accompanied by horizontal sliding of the wall. After fibre rupture, spalling of the inorganic skin was observed.

In Figure 4 (a&b) the load versus diagonal strain curves are reported for all the tested specimens; with reference to an average value obtained from both sides of the walls along the compressed diagonal. All the averaged curves that are shown in the paper are stopped in correspondence of a strain equal to 0.003 since in many cases, after this point the comparison may be affected by local effects.

Extensive damage of the specimens, or local crushing at the corners in fact produced a strong loss of stiffness leading to different softening branches. Even if in all cases the presence of the FRM produced a huge increase in strength it is important to distinguish the different behaviour of the curves after the reverse point, due to the different strengthening systems. In the case of GFRP reinforced coating the plateau seems horizontal, with a light decreasing trend, due to cracking. While in the case of polymer-added glass-FRM system an hardening trend is visible, due to the stress that arises in the glass fibres. Local sudden loss of load were due to loose of friction and local slipping, which was not the cause of the failure, since the ultimate strain of the fibres was exploited along the central region of the panels.

Figure 4 Load vs diagonal compression strain experimental diagrams

The most important result that was evident after the tests was the change of the masonry in terms of mechanical response. The unreinforced masonry, that showed brittle failure after the formation of the diagonal strut, turned into a new reinforced state, when FRM was installed. In fact after the failure of FRM specimens, the inspection of the masonry core revealed a monolithic masonry panel under the coating, and its stiffness was maintained by the presence of the fibres also for loads that were four five times the ultimate of unreinforced masonry. Another important aspect to be discussed is that even if differences in terms of failure mode and maximum loads were recorded with reference to the different FRM systems, in all cases the failure was not due neither to delamination of the reinforcement layers, nor to the debonding of the FRP anchors. This indicates that stress transfer mechanisms are different if compared to the case of FRP-strengthened walls, in which the ultimate capacity is entrusted to the local bond stresses between the masonry substrate and the FRP strips. The pure composite action, that is desirable in FRP-strengthened substrates, was not found in walls with GFRP reinforced coating and was present only at the
first loading stages in walls reinforced with the second glass-FRM system, afterward the stress transfer was due to friction between fibres and matrix until fiber rupture.

CONCLUSIONS

An experimental program was carried out in order to investigate the effectiveness of two different FRM systems in shear strengthening of masonry walls made with regular limestone blocks and weak hydraulic mortar. Two different construction techniques, widely found in the field were considered: single walls and double curtain walls, with transverse blocks used as connectors. Different fibrous strengthening systems were used, a rigid GFRP grid and a soft dry glass fiber net. The first was immersed in a 8 MPa hydraulic lime mortar, the latter was immersed in a limestone mortar added by a polymeric primer which is able to increase the cross linking in presence of water. After a complete mechanical characterization of the constituent materials, shear diagonal tests were performed on unreinforced and FRM-reinforced masonry. Totally twelve samples were tested until failure. Unreinforced masonry, as expected, exhibited a brittle failure at low load levels, due to the sliding along the mortar joints of the diagonal struts. Important remarks may be reported by considering the results obtained in all cases, which can be considered as a first milestone for future studies:

the presence of the FRM reinforcing systems strongly increased the load capacity of the plain masonry. Both in the cases of single or double walls, the peak load exceeded from 5 up to 8 times the capacity of the unreinforced masonry;

the effectiveness of the FRM reinforcement was higher in single walls respect to double curtain walls;

the presence of the FRM reinforcing systems changed the mechanical behaviour of the masonry in terms of failure modes and strain energy retention;

the presence of the FRM reinforcement avoided the complete disaggregation of the masonry panels, which in the real field is the main cause of losses in human lives;

the failure modes were not caused by delamination or debonding of the strengthening FRM systems, this recalls the attention about the importance of transverse connections made by four injected FRP bars per each specimen.

Thus the behaviour of FRM-strengthened masonry appears far from the failure modes found in FRP-strengthened masonry.

Extensive cracking was visible in FRM-strengthened masonry, especially when pure limestone mortar was used as matrix. In this case the diagonal strut region appeared to be enlarged due to the new stress field developed by the presence of the internal fibrous reinforcement. Friction and slippage between fiber and matrix anticipated fiber rupture and was observed in the polymer added glass FRM system. Due to the low number of experimental data, further results will be necessary in order validate or discuss the conclusions of the present study.

ABSTRACT

From the perspective that an aggressive environment may cause damage to cementitious materials, curing agents of fiber reinforced cementitious matrix (FRCM) composite allows chemical agents to attack the reinforcement fabrics. In such cases, the accelerated interfacial FRCM debonding mechanisms interfere which reduce its mechanical performance. This task was conducted to investigate the long-term durability performance of the FRCM composite. In this study, environmental aging conditions were the freeze-thaw cycles, high humidity cycles, high temperature cycles, immersion into salt solution, and immersion into alkaline solution. Different FRCM reinforcement ratio and two surface roughness of concrete were also included. Two test methods were used to evaluate the FRCM composite’s bond performance (pull-off test and bending test). The bending test results revealed that the FRCM composite bond performance was not influenced by the environmental exposure. While the test results for the pull-off strength were scattered, possibly due to the environmental degradation or a lack of proper quality control during the initial FRCM composite application or applying the load.

KEYWORDS

FRCM composite, bond, pull-off test, bending test, environmental conditioning.

INTRODUCTION

Using fiber reinforced cementitious matrix (FRCM) to repair deteriorated, damaged, or structurally unsafe concrete members, is an increasingly popular technique. The previous experimental works have been proving that FRCM composite application is economic, durable, convenient, and labor friendly (Babaeidarabad et al. 2014; Ombres 2011; Loreto et al. 2014). The long-term in-situ performance of the FRCM composite-concrete interfacial bonding is a primary concern due to the potential for age-related environmental degradation. A study on the bond strength-slip relations for the PBO-FRCM composite externally bonded to concrete blocks was reported by D’Ambrisi et al. (2012). Carloni et al. (2013) conducted an experimental study on the applicability of a fracture mechanic based approach to understand the stress transfer mechanism of FRCM composites externally bonded to a concrete substrate. Results were analyzed to determine the effective bond length, which can be used to establish the load-carrying capacity of the interface to design the strengthening system. Results also determined the interfacial behavior between fibers and matrix and highlight the role of the cementitious matrix in the stress transfer. D’Ambrisi et al. (2013) experimentally analyzed the bond between FRCM composite made out of a poly(paraphenylene benzobisoxazole) (PBO) net embedded in a cement based matrix and the concrete. The results allowed estimating the effective anchorage length and evidence that the debonding occurs at the fibers/matrix interface after a considerable fibers/matrix slip. The results also confirm the effectiveness of the FRCM materials as external reinforcements for concrete and the obtained experimental results can be used to calibrate a local bond-slip relation in the design of the external reinforcement. One other study related to D’Ambrisi et al. (2013) is an experimental and analytical investigation on bond between carbon-FRCM composite and masonry. Experimental results of double shear tests involving different bond lengths can be used to calibrate a local bond-slip relation that is essential in the modeling of the structural behavior of masonry elements strengthened with carbon-FRCM. D’Antino et al. (2014) conducted a single-lap shear test on specimens with FRCM composite strips bonded to concrete blocks. Test parameters included different FRCM composite attachment area and reinforcement ratio and the stress-transfer mechanism that characterized the FRCM composite was determined. Arboleda et al. (2014) studied the durability of FRCM composite in terms of different environmental exposure under bond pull-off testing. Two types of FRCM composites were investigated (carbon fabric and PBO fabric with cement based matrix).
results for tensile and bond strength retention percentages after environmental exposure revealed no significant degradation concerns. Sneed et al. (2015) demonstrated a comparison study between single-lap and double-lap shear test on the bond failure mechanism of PBO-FRCM composite. Ombres (2015) shaded the light on a comparison between experimental results and theoretical predictions of the bond-slip law for PBO-FRCM composite attached to concrete. The comparison results concluded that the nonlinear proposed model described analytically the bond-slip law is influenced by experimental results and the available experimental data are not sufficient for a reliable calibration of parameters that define the model. This experimental work was looked up other aspect of view to investigate the long-term durability performance of bonded FRCM composite to concrete substrate. The environmental aging conditions were the freeze-thaw cycles, high humidity cycles, high temperature cycles, immersion into salt solution, and immersion into alkaline solution that were based on the recommendations of AC434 (2013).

EXPERIMENTAL PROGRAM

Description of FRCM composite

The FRCM composite that considered in this study was consisted of poly(paraphenylene benzobisoxazole) (PBO) fabric and cement based matrix. The PBO fabric was made of spaced strands in two directions. The PBO fabric strand has a width of 5 mm (0.2-in.) in the longitudinal direction and a width of 3 mm (0.12-in.) in the transverse direction. The free spacing between the strands is approximately 5 mm (0.2-in.) and 22 mm (0.9-in.) in the longitudinal and transverse directions, respectively. The nominal thickness of the strands is 0.2 mm (0.008-in.) and 0.12 mm (0.0045-in.) in the longitudinal and transverse directions, respectively. As reported by the manufacturer, the PBO fabric’s ultimate tensile strength per unit width is 276 kN/m (18.9 kip/ft) in the longitudinal direction which is about 3.5 times its’ tensile strength in the transverse direction. The bonding agent is a cement based mortar that has less than 5 percent polymer. Figure 1 shows the PBO-fabric and the cementitious matrix.

![Figure 1 a) Polyparaphenylene Benzobisoxazole (PBO) mesh, b) Inorganic Matrix](image)

Specimen preparations

Two test methods were used to evaluate the FRCM composite’s bond performance (pull-off test and bending test). The test matrix was divided into two phases of specimen preparations. In the first phase, the specimens were prepared for pull-off test. In the second phase, the specimens were prepared for bending test.

Specimen preparation and conditioning for pull-off test

In this phase, concrete blocks with a 508 mm (20-in.) length, a 150 mm (6-in.) width, and 150 mm (6-in.) height were casted for attaching one layer of FRCM composite. The average compressive strength of the three tested cylinders was 41 MPa (6000 psi) at 28 days based on ASTM C39 (2014). All of concrete substrate surfaces were roughened in order to provide better bond performance with FRCM composite. The sandblasting method was used for concrete surface roughness to a level of 0.5 mm (0.02-in.). That penetration level simulated the surface profile CSP3 when the concrete specimens were lightly sandblasted (Technical guidelines No.03732 and No.03730, International Concrete Repair Institute (ICRI), 1997). For FRCM composite installation, the hand lay-out method was followed with respect to the guidelines of ACI 549 (2013). The installation method consisted of four steps. The first step was to wet the concrete surface. The second step was to apply the first layer of the cementitious mortar (X MORTAR 750) with a nominal typical thickness of 3 mm (0.1-in.). The third step was to place the PBO-fabric and press it gently into the cementitious mortar. The fourth step was to apply the second layer of the cementitious mortar to the same thickness, and level FRCM composite surface. All of the concrete specimens cured for 28 days under laboratory conditions before any exposure or testing. The environmental exposure and aging were the main parameters for this test. The exposure conditions and aging were based on the recommendations in the AC434 (2013). The specimen’s matrix for pull-off test included five exposure conditions, as represented in Table 1. In the first conditioning, specimens were mentioned under laboratory conditions that
served as control specimens. In the second conditioning, specimens were exposed to an environmental regime that included 50 cycles of freezing and thawing, 150 cycles of humidity, and 150 cycles of high temperature. In the third conditioning, specimens were placed inside a moisture chamber under 100% relative humidity. In the fourth conditioning, specimens were immersed into a salt solution that demonstrated the case of exposure to seawater (PH level of 7). In the fifth conditioning, specimens were immersed into an alkaline solution that demonstrated the case of ocean water (PH level of 13). The aging condition was the third study parameter. Some of the specimens were tested after one environmental regime cycle (72 days) and other specimens were tested after an aging time of 166 days based on the recommendation of AC434 (2013). The environmental regime was established according to Missouri state weather conditions. The data was collected from the National Weather Service and Worldwide Weather Station during a time frame from 1980 to 2013. The environmental regime is presented in Figure 2. In the test matrix, the defined specimen name is represented by two letters and one number. The first letter, P, represents the test type (pull-off). The second letter, L, E, H, S, or A, represents the exposure condition (laboratory, environmental, humidity, saltwater, or alkaline solution). Finally, the number, 1, represents the number of ply. The salt solution was prepared by mixing NaCl of 3% by the weight of required solution to immerse the specimens. While, the alkaline solution was prepared by adding NaOH of 0.4% by the weight of the required solution.

Figure 2 Environmental conditioning regime

Specimen preparation and conditioning for bending test

One test specimen consisting of two concrete blocks were spaced 12.5 mm (0.5-in.) by wood piece and a strip of the FRCM composite was attached to one face of the connected concrete blocks. The concrete blocks were casted to have a 254 mm (10-in.) length, a 150 mm (6-in.) width, and a 150 mm (6-in.) height. The average compressive strength of the three tested cylinders was 41 MPa (6000 psi) at 28 days based on the ASTM C39 (2014). Two different surface preparations were considered in order to examine the effect of concrete surface roughness on FRCM composite bond performance. The first roughness level of 0.5 mm (0.02-in.) simulated the surface profile CSP3 when the concrete specimens were lightly sandblasted. The second roughness level of 1 mm (0.04-in.)
simulated the surface profile CSP6 or CSP7 when the concrete specimens were medium-heavy sandblasted. These penetration levels were based on technical guidelines No.03732 and No.03730 specified by International Concrete Repair Institute (ICRI, 1997). The FRM composite strip had a 100 mm (4-in.) width and 432 mm (17-in.) length. The FRM composite installation procedure and curing were as preceded for the pull-off test specimens, except that the installation procedure was repeated successively for the specimens with four plies of FRM composite. The specimens’ matrix for bending test included two exposure conditions (laboratory condition and environmental regime cycles), as represented in Table 2. The environmental regime cycles are represented in Figure 2. In the test matrix, the defined specimen name is represented by three letters and one number. The first letter, B, represents the test type (bending). The second letter, L or E, represents the exposure condition (laboratory or environmental). The third letter, L or H, represents the surface roughness (light or heavy). Finally the number, 1 or 4, represents the number of plies.

**TEST METHODS**

**Pull-off test**

This test method was implemented in order to examine various environmental exposures on the bond performance of FRM composite. The pull-off test was performed based on the general procedure of the ASTM C1583 (2013). A minimum of five specimens for each FRM composite exposure were tested as recommended by ACI 549 (2013). After specimens were aged in exposure conditions, they were left in laboratory conditions for seven days to dry out, and then a 50 mm (2-in.) diameter bit was used to perform 12.5 mm (0.5-in.) depth cores. A vacuum cleaner was used to get rid of all the concrete dust then steel disks attached to FRM composite surfaces by epoxy adhesive. The specimens were left to cure the epoxy adhesive for at least three days before testing. The pull-off tester was used to pull the attached steel disks to the cored specimens. The incremental load was applied to produce an approximate stress rate of 35 kPa/second (5 psi/second). Figure 3a shows a representative specimen under pull-off testing. The pull-off test revealed the pull-off strength and the bond failure mode.

![Figure 3 a) Specimen under pull-off test, b) Specimen under bending test](image)

**Bending test**

This test method was selected to reveal the impact of surface roughness and environmental regime cycles on multilayers of FRM composite. The test setup was designed to simulate a reinforced concrete beam in bending with a preexisting crack at the mid-span (Pellegrino et al. 2008; Silva et al. 2008). All of the specimens were loaded at two points that spaced 150 mm (6-in.) apart and simply supported at each end thereby subjecting the FRM composite to bending stresses.
composite to a direct tension. Two linear variable differential transducers (LVDT) were used to measure the mid-span displacements. All of the specimens were subjected to a constant load rate of 0.25 mm/minute (0.01 in/minute). A representative specimen under a bending test is seen in Figure 3b. The bending test results revealed the FRCM composite’s tensile strength, mid-span displacements, and failure mechanism.

RESULTS AND DISCUSSIONS

Pull-off test results

The pull-off strength of five specimens based on the exposure condition is represented in Figure 4a. The pull-off strength was computed by dividing the peak load over the net cross-sectional area that specified by ACI 549 (2013). Bond failure was observed in all specimens at the interface between the PBO fabric and the cementitious matrix, as seen in Figure 4b. All of the specimens had pull-off strength greater than the 1.4 MPa (200-psi) defined as a minimum value by ACI 549 (2013). The test results had a large scatter for all types of exposure, which might be due to the manual control in applying the load. The specimens exposed to the salt solution and alkaline solution had lower pull-off strength in comparison with other exposure conditions at 72 days aging, while the aged specimens to 166 days had higher pull-off strength. That concluded the non-influential effect of using such composite in repairing or strengthening applications that exposed to salt or alkaline environment.

Bending test results

The bending test results were determined as the average tensile strength of three tested specimens, which is represented in Figure 5a. The tensile strength was calculated from Eq. (1):

$$\sigma = \frac{P}{nb}$$

(1)

where, \(\sigma\) is the tensile strength, MPa (Psi), \(P\) is ultimate load, \((N \text{ or } Lb)\), \(n\) is the number of PBO fabric plies, \(b\) is the width of FRCM composite strip, and \(t\) is the thickness of FRCM composite strip, which was equal to 5 mm (0.2-in.) for one ply and 10 mm (0.4-in.) for four plies. The tensile strength results revealed that the number of FRCM composite plies was the most influential factor on the failure mode type and tensile strength of the tested specimens. The performance of the specimens with a heavily roughened surface was insignificant in comparison to the specimens with lightly roughened surface. In addition, the environmental regime cycles showed insignificant effect on the tensile strength of the tested specimens. The strengthened concrete blocks with one ply of FRCM composite exhibited a slippage bond failure mode, as seen in Figure 5b, while the strengthened concrete blocks with four plies of FRCM composite failed due to the FRCM composite’s debonding from the concrete substrate, as seen in Figure 5c. The representative applied loads with specimens’ displacements at the min-span are seen in Figure 6a and 6b, respectively. The global slip is defined as a specimen’s displacement at the mid-span where a maximum slippage occurred in the PBO fabric after increasing the applied load. The applied load-global slip relationships were influenced by the number of FRCM composite’ plies used. For concrete blocks with one ply of FRCM composite, the load started to increase linearly up to the point where slippage in the PBO fabric started to enlarge. Then, the load was increased to ultimate values with observed loss in its stiffness. As the specimen reached its’ ultimate load capacity, the load capacity was incrementally dropped to the point where the global slip was continuously extended at a constant load. This phenomenon was observed in single lap shear test that was conducted in previous research (D’Antino, 2014). The shear stress due to the friction force between the PBO fabric and the bonding agent (cementitious mortar) revealed the continuous global slip (D’Antino, 2014). However, for concrete blocks with four plies of FRCM composite, the specimens exhibited a rapid linear drop in their load capacities when the FRCM composite debonded from the concrete substrate, as seen in Figure 6b. The bending test was able to predict the failure mode with respect to the FRCM composite’s reinforcement ratio, as it was
observed for testing full-scale reinforced concrete beams in flexure (Babaeidarabad et al. 2014; Ombres 2011; Loreto et al. 2014). The average tensile loads of bonded four plies of FRCM composite to concrete blocks were only 1.25 times that tensile strength of bonded one ply of FRCM composite to concrete blocks due to the premature failure of FRCM composite. The comparison between the two test methods revealed that the ultimate tensile strength of the tested specimens under bending were much greater than that produced due to the pull-off test. In the pull-off tests, a pulling-off load was applied perpendicularly to the PBO fabric alignment, while in the bending test a direct tensile load was applied parallel to the PBO fabric alignment. That concluded the observed higher strength of FRCM composite in bending test rather than pull-off test.

CONCLUSIONS

An experimental study on the bond performance between externally applied FRCM composite and the concrete block is presented. The differences of the pull-off test results for various exposure conditionings were discharged due to partially scattering of the experimental data. The exposure conditionings did not influence the failure modes of FRCM composite. Variations in the applied load and the global slip were determined in the bending test, and the translation of the ultimate loads during delamination was experimentally observed. Failure mode of FRCM composite was observed to be highly dependent on the number of FRCM composite’s plies. The heavily and lightly concrete surface preparations coincided with respect to their ultimate tensile strength. The impermeable property of the cementitious matrix concluded that the saltwater or alkaline solution had no effect on the bond performance of FRCM composite. Higher pull-off strengths were determined for the specimens aged to 166 days in comparison with 72 days as the specimens continuously cured.

ABSTRACT

The innovative composite material Textile-Reinforced Concrete (TRC) opens up new application areas in structural concrete engineering and has many advantages for the building industry. By using non-corrosive technical textiles made of alkali-resistant glass (AR-glass) or carbon, the concrete covers can be minimized resulting extremely slender concrete members. In addition, they provide ecological and economic benefits, which can be recognized in the realized application projects. This paper summarizes selected filigree structures, which only could be fulfilled with textile-reinforced concrete. In this connection the self-supporting and bearing structures will be presented.

KEYWORDS

Filigree constructions, facades, pedestrian bridge, AR-Glass, Carbon, Textile-Reinforcement.

INTRODUCTION

During the last 30 years reinforced concrete surfaces were plastered increasingly or clad with aluminium or wood. This is due to its corrosion-prone reinforcement, which can lead to undesirable surface damage by concrete spalling. Consequently a corrosion resistant material such as textile-reinforced concrete inspires the renaissance of concrete surfaces. The use of the new composite material allows the production of thin-walled components, which are characterized by low weight and great slenderness. TRC is particularly suitable for self-supporting building structures such as facade plates (Figure 1). The conventional 90 mm thick reinforced concrete plates can be replaced by only 20 to 30 mm thin textile-reinforced concrete plates (e.g. Kulas et al. 2011). Another application is the use of textile-reinforced concrete for supporting structures with chloride attack. Existing steel reinforced bridges require high concrete cover to be able to protect the steel from carbonation and chloride attack. By application of high-strength and corrosion-resistant fabrics, the bulky structure can be counteracted. This leads to a revival of the concrete construction for shells (Figure 1).

SELF-SUPPORTING COMPONENTS

Small-sized facade

Smaller facade panels of TRC with element sizes up to about 2 m² and a thickness of about 20 mm are often used for ventilated facades. The low weight, the associated cost savings for transport and attachment and not least the
architectural design options are reflected in numerous applications in recent years. The applicability is especially promoted by the first officially approved textile concrete slab betoShell®.

**Large-sized facade**

Small-sized facade panels require a large number of fasteners per square meter facade surface, which represents a significant cost share of the total construction. Besides, such facades show a high joint portion, which is not always desirable from architectural view. Therefore, in collaboration with industry partners Hering Bau and solidian, large formatted tiles were developed at the Institute of Structural Concrete and the Institute of Building Materials of the RWTH Aachen.

The large-format facade panel with a panel thickness of 50 mm, which is about 6.2 square meters and was completed in 2014, is an architecturally sophisticated panel for the new business building "SchieferErlebnis" in Dormettingen (Figure 2). The size and the light weight reduce assembly time and the costs.

Constructively it concerns ventilated facade systems. The facade elements are fastened on the supporting wall and a thermal insulation is interposed between the two layers. Therefore the total thickness can be significantly reduced compared to conventional wall structures. The material-saving design with simultaneous gain in space inside the building is a good example of energy-efficient construction with reduced CO₂ emissions.

The facade panels have maximum dimensions of 1.5 m x 4.1 m with a panel thickness of only 50 mm. An efficient carboxylic textile, which achieved tensile stresses of about 3000 N/mm² in the composite body, was sufficient to ensure the load-bearing capacity (e.g. Hegger et al. 2007). To the anchorage fasteners, known from reinforced concrete, were modified for the small panel thickness.

In experimental studies, the load-bearing capacity of the facade panels was proved. To meet the demands of the client, like crack-free panels, the plate was calculated such that the tensile strength is not exceeded even at maximum wind load and temperature conditions. These high demands on the surfaces are important not only to satisfaction of the optics, but also for the conviction of the bearing capacity of the textile-reinforced concrete panels. Low deformations and crack-free construction parts in use give a feeling of safer constructions. Only in the ultimate limit state of bearing capacity (safety against failure), the textile reinforcement to ensure sustainability is activated. The good alliance between textile reinforcement and concrete and the high strength provide small crack openings and significant load increases after cracking until the break starts. With the help of the experiments it was shown that facade panels at failure after cracking can accommodate about three to four times the load on the used state.

![Figure 2 View on the facade of “SchieferErlebnis” in Dormettingen (Foto: solidian) and the used textile-grid, produced by the company solidian](image)

**SANDWICH FACADES**

Sandwich elements for industrial and multi-storey buildings are constructed primarily with layers out of metal or reinforced concrete now. Textile reinforced inner and outer shells compared to those made out of reinforced concrete reduce the cost of transport and fixing and composite medium. The lightweight sandwich structures can be used either for self-supporting, vertical Sandwich facades of multi-storey buildings and factories or as structural components for modular buildings.
Parts of the facade of a new Institute at RWTH Aachen were performed as self-supporting sandwich construction with dimensions of $L \times H \times T = 3.45 \times 1.00 \times 0.18$ m$^3$ (pitches) in an EU-promoted project (Figure 4). Basis of the planning were those in various literature presented results (e.g. Hegger et al. 2007; Shams et al. 2015; Shams and Stark 2013; Shams et al. 2014). The elements consist of a load-bearing PUR rigid foam core, two thin concrete shells, which are reinforced with glass fibre and composite needles made out of stainless steel. The weight is transmitted through the inner shell with welded on the post and beam construction consoles, the wind loads are taken up by four horizontal brackets (Figure 3). The weight of the outer shell is hung in the inner shell with diagonal anchors. To ensure permanent composite, special composite needles are used, which absorb the peeling normal force stresses in the bonding fugue that result from suction, temperature and shrinkage. The sandwich structural behavior and the stress of the outer layers are substantially determined by the rigidity of the insulating core according to the theory of elastic composite (e.g. Shams et al. 2014).

In four-point bending tests on prototypes a favourable load-deformation behavior was observed, which is limited by the shear capacity of the insulating core and which occupies the potential for greater spans. The cracking of the concrete layers can be suppressed over the use load range by textile reinforcement in conjunction with short fibres effectively. The positive experiences in planning, manufacturing and assembly demonstrate the high potential for application of textile reinforced concrete for use in facades.

Figure 3 Vertical and horizontal support of the edge elements including sealing strip

Figure 4 Longitudinal view on the south facade of the new building of the Institute INNOTEX
RECONSTRUCTION OF FILIGREE CONCRETE STRUCTURES

The innovative composite of Textile Reinforced Concrete offers new possibilities for reconstruction of historical buildings. Especially delicate components, such as the historic glass concrete windows of Aachen Town Hall, benefit from the corrosion-resistant and durable textile carbon reinforcement. The old windows had to be renovate because of corroded steel reinforcement and concrete spalling. To this the landmarked glass elements, which were embedded in reinforced concrete, were separated and installed again in the renovated windows. At the same time the steel reinforcement was replaced with carbon reinforcement. Consequently the monument editions were observed and the corrosion damages in future could be avoided.

As a part of preparations for the celebrations of Charlemagne in 2014, remediation measures were carried out at the Gothic town hall, which is part of the most important medieval stately homes of the German-speaking countries. Particularly the glass concrete windows, that should reflect on the idea of the architect Graubner the appearance of quarried stone masonry, are conspicuous (Figure 6). The windows vary in their appearance and size and consist of glass elements embedded in 3,0 cm thick concrete. The 2,5 cm wide concrete webs between the lines of glass elements were used for the steel reinforcement in the horizontal direction (Rempel et al. 2014). The windows are encased in steel frames that are required in the wall for the anchoring on the one hand and served in the production as a lost formwork to the other. Before preparing the new window, which took place on the same principle as already 60 years ago, a detailed documentation of the windows was held to restore the appearance in the reconstruction. So the original position of about 15.000 glass elements could be ensured. For this the separated elements of glass were positioned on a form panel inside the frame and then filled with concrete. Carbon rovings serve as reinforcement elements, which replace the old reinforcement bars (Figure 5). The possibility of realizing sharp components enables to dispense with the surrounding frame. So the 2 m long windows were divided into portable segments and could be assembled afterwards one above the other standing. This has both advantages in manufacture as well as during assembly. The sharp edges ensure that the stacked segments seem like a monolithic created window (Figure 6).

The bearing capacity tests show that the glass elements governing the use condition. In realistic tests, the glass failed due to compressive stresses before a crack in the concrete occurred. After the failure of the glass a ductile component behaviour ceased. The load capacity of the window was almost doubled to a breaking moment of 2,5 kNm/m, corresponding to a wind load of about 14 kN/m². By means of the combination of optically high-quality concrete of the company Hering Bau with the carbon textile of the company solidian, the desired permanent solution, that even could impress the critical preservationists, originated (Figure 7).
PEDESTRIAN BRIDGE

The world's first bridge made entirely from carbon-reinforced concrete was established in Albstadt-Ebingen on 22 October 2015 (Figure 8). The bridge was built without any steel-reinforcement or prestressed steel. Especially the absence of prestressed steel is what basically distinguishes the bridge from previous bridges made from textile reinforced concrete that can be found in Oschatz, Kempten and Albstadt-Lautlingen (Michler, H. 2013 and Hegger et al. 2011).

The complete absence of steel allows a bridge construction that is both low-maintenance and durable, as corrosion damage can be ruled out. Therefore, this solution is a promising and economic way of construction for communities and townships.

The bridge has a so-called trough cross-section, produced monolithically as a prefab. The centerpiece of the construction is the carbon reinforcement "solidian GRID", characterized by a breaking stress of over 3000 N/mm². As carbon reinforcements cannot corrode, very thin concrete covers can be used. The bridge was executed with a concrete cover of only 20 millimeters. This allows the construction to realize very slim components. The trough wall is only 70 millimeters thick, the pavement only 90 millimeters. Compared to a corresponding steel-reinforced construction, this translates into a more than 50 % weight reduction. With a length of 15 meters, the bridge weighs only 14 tons. It was designed for cyclists and pedestrians but can also accommodate a 5-ton snow-clearing vehicle.

On 23 February 2016 the company in charge received the innovation prize for structural concrete products of the supplier industry for the carbon-reinforced concrete pedestrian and cycle bridge built in 2015 (Figure 7). The award honors innovative products and services from the supplier industry to the precast concrete sector.

Alongside the solidian GmbH, responsible for the development and project management, also the municipality of Albstadt as builder-owner, the Max Bögl Bauservice GmbH & Co. KG as producer of the bridge, the Institute of Structural Concrete of the RWTH Aachen University as expert for the supporting construction, KnippersHelbig for the structural engineering calculation as well as the regional authority of Tübingen for the approval in individual cases were involved in this pilot project in Albstadt-Ebingen.

Figure 8 View of the TRC pedestrian bridge in Albstadt-Ebingen (Foto: solidian)
CONCLUSIONS

Structures made of textile-reinforced concrete can be carried out more clearly slimmer than steel components due to the corrosion-resistant technical textile. In addition to high load capacity, the TRC is characterized by a very finely divided crack image with very small crack widths, when the concrete tensile strength exceeded. This new composite material is particularly suitable for high demands on the concrete surface. This is impressively illustrated by the previously realized buildings. It is not only self-supporting elements such as facade panels that have been realized, but also viable filigree structures such as shells and bridges, which were successfully built.

ABSTRACT

The high cost of reinforced concrete (RC) structures rehabilitation results in the increased utilization of non-metallic reinforcement. Glass Fibre Reinforced Polymer (GFRP) bars, due to the combination of relatively low cost (when compared to other composite materials) and a good durability, have become more popular than competitors (carbon or basalt polymer composite bars). Despite many advantages, the utilization of GFRP bars in reinforced concrete structures is still limited. This is due to the variability of GFRP bar properties among different manufacturers. To ensure wider utilization of this composite reinforcement, a better understanding of bars’ properties is needed. This research program is focused on GFRP bars’ shear properties, for both new and aged specimens. Three different types of bars from two different manufacturers were tested in shear. The aging of specimens was performed in a highly alkaline solution (pH of 13) heated to 60°C. In this aggressive environment bars were kept for 5 months. All test data were analysed and results are presented herein. The shear stress-strain relationships indicate a correlation between bars’ material properties (quality of resin, resin fiber interface, and fiber content) and the shear moduli.

KEYWORDS

Glass fiber reinforced polymers, GFRP, reinforced concrete, shear test, shear modulus, quality control.

INTRODUCTION

The usage of composite materials in civil engineering, especially FRP reinforcement, has grown significantly for the last two decades (Bakis 2002). However, when compared with conventional steel utilization of Glass Fiber Reinforced Polymer (GFRP) bars, it is still relatively limited. A reason for this can be found in the variability of mechanical properties and bars’ quality among different manufacturers. Moreover, due to patent protections and production confidentially details about resin properties or resin content are usually not available. Therefore, there is a need to establish practical and preferably simple testing protocols for the assessment of bar quality.

Shear testing of GFRP bars is relatively easy and has the potential to provide extensive information not only on bar shear capacity but also on material properties such as quality of resin, resin-fiber interface, or fiber content. During the test development additional information as, for example, shear modulus was omitted due to the nonlinearity of stress-strain relationship for direct shear (Gentry 2011). However, the analysis of the test results (shear curvatures) indicates that there is a characteristic repeatable pattern in each test outcome, which can be linked to different material properties. This research program is aimed at investigating this possibility to obtain additional information from the transverse shear test.

EXPERIMENTAL STUDY

Material description

Specimens tested in this study were provided by two companies (referred herein as Company I and Company II) operating in the Canadian market. All of the specimens were straight bars with similar diameters: #4 bars from Company I and 12M bars from Company II. Three different types of bars were tested: straight bars (SB) manufactured by the pultrusion process with additional surface treatment (Company I – sand coating; Company II – indented ribs), smooth surface bars (SSB) produced in a pultrusion process without additional surface treatment, and bent bars (BB) produced by a customized process individual for each company. Relevant material characteristics of all bar specimens as specified by the supplier and geometrical characteristics measured by us are
shown in Table 1. The nominal cross-sectional area and bar diameter are based on information provided by the supplier, while the effective cross sectional area and bar diameter were measured in this work.

**Testing procedures**

**Shear test**

Shear tests were performed according to Annex L of CSA S806-12 to determine transverse shear strength of FRP bars. Three different types of bars from both manufacturers were used in these tests: smooth surface bars (SSB) as control specimens, straight bars (SB), and straight portions of bent bars (BB). Specimens were divided into 6 sets according to bar type and diameter, and each set consisted of 8 samples. All specimens were 300 mm long. Double shear was applied to each specimen using a special shear test device (Figure 1), with stress applied at 45 MPa/min. In order to achieve this uniform stress rate and due to different bar diameters, the load control rate varied for each bar size as shown in Table 2.

</table>

The shear test device consists of two bar holders, two bottom blades unique to the outside diameter of each bar, and guides that were used to create distance between the bottom blades. All parts are connected together by threaded rods. Shear load is applied to the bar by the upper blade connected to the machine load cell.

![Figure 1 Shear test device with a sample a) before testing, b) after testing](image)

**Accelerated aging test**

The alkaline immersion test was chosen for accelerated aging. Testing methodology used in this research was developed according to the CSA S806 – 12 standard Annex M, and supplemented with information included in ASTM D7205/D7205M protocol. Bars were kept in a highly alkaline solution (pH 13, 118.5g of Ca(OH)₂, 0.9g of NaOH and 4.2g of KOH in 1 L of deionized water) heated to 60°C for five (5) months. After this period of time, bars were taken out from the bath and tested in shear.
RESULTS AND DISCUSSION

The primary test result is the nominal transverse shear stress, calculated as half of the peak failure load divided by the cross-section area (effective cross-section area reported in Table 1). The shear test consists of cutting the bar through two parallel cutting planes. Different failure modes can be observed in these tests; when both planes fail at the same time and when one plane fails after the other. The typical stress-vertical displacement curves for these cases are shown in Fig 2a and 2b.

![Failure of both planes](image1)
![Failure of the first plane](image2)

**Figure 2** Shear failure modes a) double shearing at the same time b) planes shearing consecutively

Stress-strain relationships were determined and the comparison of the most typical curves for each type of bar is shown in Figure 3a for Company I, and Figure 3b for Company II, respectively. The stress-strain relationships are calculated as stress (load divided by effective cross sectional area) versus strain (displacement divided by the effective diameter). From the obtained shear stress-strain curves (Figure 3) for all tested specimens it can be seen that the shear stiffness (shear modulus) is stress dependent. Some statistical analysis indicators are shown in Table 3 for strength and Table 4 for shear modulus.

![Stress-strain curves for bars from Company I](image3)
![Stress-strain curves for bars from Company II](image4)

**Figure 3** Stress-strain curves a) Company I b) Company II

The differences in the stress-strain relationships for bars produced by pultrusion (straight bars SB and SSB) and bars produced by customized methodology (bent bars BB) indicate that the shapes of these curve can reflect materials’ characteristics. Bent bars experience higher deformations than straight bars. This can be due to the application of different resins in bent bars’ production process as well as lower fibre content in these bars. This is true for both companies, which use different, then both straight bars, resins and lower fibre content in bent (BB) bars.

Further investigation of stress-strain relationships in shear indicates that all curves share the same characteristics: regions with similar stress-strain behaviour. Each curve can be divided into three different sections: two sections with a relatively stable shear modulus (G1 and G2) and a section with a characteristic “plateau” between two moduli, were strains increase more rapidly (Figure 4).

One can see that not only a different type of bar (SB and SSB vs. BB) but also a different type of surface finishing (sand coating and indented ribs vs. smooth surface bars) have influence on shear moduli. The largest values of moduli were obtained for smooth surface bars (SSB) for both companies. Moreover, SSB bars are also characterized by the smallest difference between two moduli (G1 and G2) with slightly higher values for the second shear modulus. In the case of straight bars (SB), samples from Company II are characterized by the same behaviour as SSB samples, while SB bars from Company I show a smaller G1. This fact indicates that sand coating surfaces have a larger influence on a shear modulus than indented ribs. This makes sense since indented ribs do not introduce a new material to the sample (as sand coating does), but they simply change the sample’s shape. The smallest shear modulus was obtained for bent bars (BB) from both companies, where G2 in this case shows the larger value.

Based on the obtained values for shear moduli and the assumptions regarding the mechanics of shearing process, it is assumed that the first shear modulus (G1) indicates resin properties, while the second one (G2) can be linked to the properties of fibers, and the plastic plateau between both moduli occurs due to the delamination process between the resin and the fibers. To investigate this speculation further, an additional shear test was performed on chemically aged bars. The bars were immersed in an alkaline solution (pH 13) for 5 months at 60°C. Since the highly alkaline solution is more severe for the glass than for the polymeric resin, it was assumed that the modulus connected with the properties of fibers (G2) would degrade more than the modulus linked with the resin properties (G1). Some statistical indicators for the alkaline aged samples are shown in Table 5 for strength and Table 6 for shear modulus.

It is noticeable that both moduli (G1 and G2) degrade significantly (see also Table 4). Comparisons of shear moduli before and after the alkaline immersion test are shown on Figure 5 a) for Company I and b) for Company II. The percentage decay of shear modulus is shown in Table 7.

Table 7 shows that, as expected, the shear moduli G2 deteriorated more than shear moduli G1. The most deterioration happened for company I for bars with smooth surface finishing. These bars do no have the beneficial protection of sand coating and thus are more susceptible to the aggressive environment. In the case of bars from Company II, both smooth bars (SSB) and straight bars (SB) do not have any additional coating and thus their deterioration in alkaline environment is similar. The smallest deterioration process occurred in the case of bent bars (BB) from Company II, which can be due to the additional polyethylene sleeve placed on bars during the production process, which works as an additional protection (similar to the sand coating on SB bars from Company II) against the alkaline solution.

As expected, all samples experienced the highest stiffness decrease for the second shear modulus (G2) (Table 7); the modulus that is influenced most by the glass fibers properties. Glass fibers are more susceptible to deterioration in the alkaline environment then the polymeric resin. This will effectively decrease the values of the G2 moduli.
CONCLUSIONS

The research program presented in this paper is focused on shear testing of GFRP bars and information that can be obtained from such testing. The results of the shear testing are reported in terms of shear strength and stiffness moduli. The shear stiffness varies, depending on the level of stress, but shear stress-strain relationships for all tested bars show certain similarities. All stress-strain relationships obtained in this research can be divided into three distinguishable regions: one linked with resin properties G1, one with fibre properties G2, and the third region, a plateau between the moduli G1 and G2, which is likely due to the delamination process.

In the comparison of the two bar types, bars (from both companies) produced by pultrusion (straight bars SB and SSB) versus bars from the customised production process (bent bars BB), show the shear test can be potentially used as an indicator for resin properties and fibre content/properties. The analysis of the results from accelerating aging tests confirm the speculation made regarding the shear stress-strain responses of the bars and their link with matrix and fibre properties.

The results presented in this paper indicate the shear test has a significant potential in determining FRP bars properties. This potential is not directly indicated in the current testing protocols (Annex L of CSA S806-12). Further research is needed for better understanding of the phenomenon and better utilization of the described shear testing for quality control of the GFRP bars.

ABSTRACT

Glass fiber reinforced polymer (GFRP) composite bars are considered durable alternative to regular steel bars for reinforcing concrete members, in corrosive environments. In concrete pavements, dowel bars are used to transfer loads between adjacent panels across construction, control, and expansion joints. Such load transfer occurs through shear action in the dowel bar. Steel dowel bars tend to corrode prematurely. GFRP bars have high corrosion resistance, however, the transverse shear properties of GFRP bar vary widely, depending on their chemical and physical properties. This paper presents comprehensive review of literature along with experimental investigation of GFRP bars for use as dowel bars in concrete pavement, at the construction and control joints. Two series of GFRP bars having diameters of 16mm and 32 mm were investigated and reported.

KEYWORDS

GFRP bars, concrete pavement, control joints, construction joints, shear resistance.

INTRODUCTION

Corrosion of internal reinforcing steel is one of the most important factors that lead to premature deterioration of concrete structure. The steel rebar in the concrete structure is generally protected by the alkalinity of the concrete to prevent corrosion. However, the area with aggressive environment, such as suffering heavy precipitation and snow, high moisture content and large amount of chlorides ions in deicing salts could reduce the alkalinity of the concrete and result in the corrosion of reinforcing steel bars and cracks in concrete. Corrosion can increase the cost of maintenance and reduce the service life of the structure. Glass Fiber Reinforced Polymer (GFRP), as a non-corroded material, is currently prompted for the industry.

In concrete pavements, dowel bars are used to transfer loads between adjacent panels across construction, control, and expansion joints. Such load transfer is secured through shear action in the dowel bar. Steel dowel bars tend to corrode prematurely, and cause deterioration of the concrete pavement joints. In order to retrofit concrete pavement with corroded steel dowel bars, GFRP composite bars are considered durable alternative for replacement of corroded steel dowel bars. GFRP bars have high corrosion resistance, however, the transverse shear properties of GFRP bar vary widely, depending on their chemical and physical properties. Investigation for shear properties of GFRP bars with different diameters will be conducted by literature reviews and GFRP bar shear resistance tests.

DOWEL ACTION

When two concrete slabs move relative to each other, the dowels are subjected to a shearing action that can be defined as dowel action. Dowel action is the secondary mechanism to resist the applied shear force when dowel bars are across a joint.

Figure 1: Deflected shape of dowel bar (Vijay 2009)
Load transfer efficiency (LTE) and Joint efficiency (E) are normally used to evaluate the performance of the dowel bar by deflections. The equation for LTE and E are shown as below,

\[
LTE = \frac{d_u}{d_l} \times 100\%
\]

\[
E = \frac{2d_u}{d_l + d_u} \times 100\%
\]

where,

\(d_u\) = deflection of the unloaded side of a joint; and

\(d_l\) = deflection of the loaded side of a joint.

According to AASHTO standards, the value of LTE is between 70 and 100 represents very good load transfer. (Vijay 2009) ACPA recommends that the value of E should be equal or greater than 75% in pavement joints. (Benmokrane et al. 2014)

**LITERATURE REVIEWS**

**Performance of GFRP Dowels for Concrete Pavements**

Eddie conducted a study on the performances of GFRP dowel bars for concrete pavements. Eddie tested three groups of GFRP bars manufactured by three different U.S. suppliers and one group of epoxy steel bars. Each group contains 3 samples. Double shear test was applied on the first two groups of GFRP dowels and the group of epoxy steel in the laboratory, and Falling Weight Deflectometer (FWD) Tests were applied in the field to record the deflections for all three groups GFRP dowels and one group steel dowels. FWD Tests were applied in the field 8 months after it was opened for traffic. The diameter of GFRP dowels is 38mm, and the diameter of epoxy steel is 31.75mm. According to the test results, shear strength of GFRP dowel is much lower than steel dowel. However, two groups of GFRP dowel bars performed similar or better than steel dowels result in joint efficiency analysis. The third group of GFRP dowel did not perform as well as the previous two groups. However, the performances were still qualified. The second group of GFRP dowels (GFRP type-2) with larger shear strength than the first group of GFRP dowels (GFRP type-1) performed better. The only concern is that GFRP dowels suffer larger deflections than steel dowels under dynamic loading conditions, which means GFRP dowels have lower joint stiffness. Also, GFRP dowels require larger diameters compared with steel dowels to achieve the same or better performance. Therefore, larger diameters and lower stiffness can reduce the bearing stress between concrete and GFRP dowels. Since bearing stress is one of the major failure causes at joints, GFRP dowels could be a better choice. Furthermore, there are no strict limitations for GFRP dowels at construction design. The larger deflection for GFRP dowels is no more a concern for applying at joints. (Eddie et al. 2001) Murison indicated in the research “Evaluation of GFRP Dowels” that Eddie performed FWD tests in the field after two years of traffic, and there is no big change on results. (Murison 2004)

Table 1 Shear strength tests for steel dowels and GFRP dowels (Eddie et al. 2001)
GFRP BAR SHEAR TESTS

Objective & Standard

The objective of this test is to determine the ultimate transverse shear strength of φ16mm and φ32mm ComBAR GFRP rebar. The test was conducted according to the procedures recommended by the ACI 440.3R-04 Committee report, section B.4 entitled “Test method for transverse shear strength of FRP bars” (ACI 440.3R-04).

For testing φ16mm ComBAR rebar, the shear test device was according to ACI 440 report, however, it had to be modified to accommodate testing φ32mm rebar. The current ACI test method presents recommended dimensions for the shear test device for testing FRP rebar of diameter up to #8 (25mm). To ensure complete shearing of the φ32mm ComBAR, the top ½ inch of the upper blade was cut before testing. The base and the blades of the shear device were made of mild (non-hardened) steel.

Equipment & Test Load Rate

A Universal compression-testing machine was used to conduct the shear test. The capacity of the testing machine is 300 kips (1334.5 kN). For the φ16mm ComBAR, the load was increased at a rate of 5.0 kips/min. (22.24 kN/min.), which is equivalent to an increase in shear stresses at a rate of 8.0 ksi/min (55.3 MPa/min). For the φ32mm ComBAR, the load was increased at a rate of 20.0 kips/min. (88.96 kN/min.), which is equivalent to an increase in shear stresses at a rate of 8.0 ksi/min. (55.3 MPa/min).

Test Procedure

Figures 3 through 11 show the ComBAR test specimens before, during and after testing. A total of seven φ16mm and seven φ32mm ComBAR specimens were tested. Figure 3 shows the test specimens.

While the ACI recommended shear test device accommodates well a φ16mm ComBAR, it needs slight modifications to accommodate the φ32mm ComBAR, as shown in Figures 5. Notice that the top of the rebar is higher than the top of the base of the shear device. Additional spacers were provided to rise the attach plates to allow for attaching the φ32mm ComBAR to the shear test device, as shown in Figure 6.

Figure 7 and 8 show a φ16mm ComBAR specimen during the test and after failure. For all the φ16mm ComBAR rebar specimens, the mode of failure was in the form of complete shearing of the rebar, as shown in Figure 8.

Figure 9 shows the φ32mm ComBAR during a test and after failure. Load was applied until complete shearing off of the ComBAR test specimens. For all the φ32mm ComBAR rebar specimens, the mode of failure was in the form of shear failure associated with partial disintegration of the 1.0 inch (25mm) wide sheared section of the test
specimen. Figure 10 shows a close-up of a sheared center section for a φ32mm ComBAR specimen. In Figure 11, a φ 32mm ComBAR rebar test specimen at failure.

Figure 10 A sheared section of a φ32mm ComBAR rebar test specimen

Figure 11 A φ32mm ComBAR rebar test specimen at failure

All specimens were tested at room temperature, at 77 °F (25 °C), and relative humidity of 47%.

Test Results

Data Analysis

During the test, the applied load was increased at a rate such that the shear stresses increased at a rate of 8.0 ksi/min (55.3 MPa/min). The ultimate applied load was recorded. Table 1 shows the test results for both the φ16mm and φ32 mm ComBAR specimens. The shear stress was determined using the following equation (3):
\[
\tau_u = \frac{P_s}{2A}
\]  

(3)

where
\[\tau_u = \text{shear strength, ksi (also given in MPa in Table 1);}\]
\[P_s = \text{maximum failure load, kips;}\]
\[A = \text{cross-sectional area of specimen, in}^2.\]

The cross-sectional area was based on the reported diameter of the specimens; 16mm, and 32mm for \(\phi_{16}\)mm and \(\phi_{32}\)mm ComBAR rebars, respectively.

Table 2 Load vs. shear stress for \(\phi_{16}\)mm and \(\phi_{32}\)mm ComBAR rebar

Based on the test results, the average shear strength of the \(\phi_{16}\)mm and \(\phi_{32}\)mm ComBAR specimens were 225.43 MPa, and 173.14 MPa, respectively. Considering a guaranteed strength as
\[V'_{u} = V_{avg} - 3(\text{Standard deviation})\]
would lead to guaranteed shear strength for \(\phi_{16}\)mm and \(\phi_{32}\)mm of 157.84 MPa and 135.13 MPa, respectively. However, given the fact that in GFRP reinforced concrete members the concrete completely surrounds the GFRP rebar, which would result in much higher GFRP shear resistance (dowel action). Therefore, the \(\phi_{16}\)mm and \(\phi_{32}\)mm ComBAR should easily exhibit shear resistance of at least 200 MPa and 150 MPa, respectively.

**Test Observations**

According to the opinion of the Principal Investigator, the shear test results of the GFRP rebars following the recommendations of the ACI 440.R3-04 report may be affected by the followings. The diameter of the semi-circles of the upper and lower shear blades may affect the mode of failure as well as the ultimate shear load. Figure 12 shows a standard upper and lower shear blades. As shown in Figure 12, the shear failure of GFRP rebar is associated with transverse (horizontal) tensile strains, and deformation of the rebar, which results in very high shear stresses near the center of the rebar and very low stress away from the center of the rebar. As GFRP rebar is transversely un-reinforced, it may experience physical disintegration during the test. Figure 13 shows upper and lower blades with semi-circles having diameters equal to that of the GFRP rebar. As the GFRP rebar cannot deform laterally, as shown in Figure 13, it should exhibit much higher shear resistance. It is important to note here that inside a reinforced concrete member, a GFRP rebar is surrounded by concrete, similar to the situation shown in Figure 13.

![Figure 12 Side-view of the upper and lower blades (with standard semi-circles)](image1)

![Figure 13 Side-view of the upper and lower blades (diameter of semi-circles equal to diameter of GFRP rebar)](image2)
Discussion

According to the data obtained in the study “Performance of GFRP Dowels for Concrete Pavements” and the shear test above, shear strength comparison for GFRP dowels with different diameters and epoxy-coated steel dowels can be summarized in the table shown below.

Table 3 Shear strength for steel and GFRP dowels

<table>
<thead>
<tr>

<tr>
<td>GFRP</td>
<td>38.1</td>
<td>119.43</td>
</tr>
</tbody>
</table>

Table 3 shows that epoxy-coated steel dowels have much higher shear strength than GFRP dowels. Even with similar diameter, the shear strength for steel dowel is more than three times higher than GFRP dowels. Furthermore, GFRP dowels with smaller diameters obtain higher shear strength. Through thickness properties variations, similar phenomenon has been also observed in tensile strength test. In addition, a modified non-standard shear test method for large diameter GFRP bars has been developed, as the standard test is not suitable for large diameter GFRP bars.

CONCLUSION

According to the other related research and the shear strength test obtained above, it can be concluded that GFRP dowel bar has much lower shear strength than steel dowel bars. However, the performance of GFRP dowels with larger diameter is similar or better than steel dowels under service loads according to the calculations for joint efficiency from the research conducted by Eddie. Therefore, GFRP dowel bar with larger diameter, as a non-corroded and low maintenance material, can be a good alternative for steel dowel bar in concrete pavement. Furthermore, non-standard shear test method for larger diameter bar has been developed.

BEARING STRENGTH OF SMALL-DIAMETER SELF-TAPPING FASTENERS IN HYBRID STEEL-FRP CONNECTIONS

T.R. Gentry¹, J. Anwar², M. Chen² and D. Scott²
School of Architecture¹
School of Civil Engineering²
Georgia Institute of Technology, USA

ABSTRACT

This paper reports on the bearing strengths of small-diameter self-tapping fasteners used to join pultruded FRP composite structural sections to thin-gage steel. Single- and double-lap shear specimens were tested with 13 fastener group patterns to assess the bearing strengths of the pultruded composite material. In addition, a set of experiments using smooth pins matching the minor diameter (4.0 mm) and major diameter (5.6 mm) of the self-tapping fasteners was completed to assess the impact of the screw threads on the composite material. These experiments indicate that the effective diameter of the self-tapping fastener can be taken as the shank diameter of the screw.

The research finds that bearing failure is the dominant failure mode in the zero degree direction for connections with up to four fasteners in a group. In 45 and 90 degree connections, a transition to net-tension failure occurs with only two fasteners in the group. The tests demonstrate that self-tapping fasteners are an economical means of joining composite materials to steel, especially for thin-wall sections of FRP and steel.

KEYWORDS

Pultruded FRP, mechanical fastening, self-tapping fasteners, bearing capacity.

INTRODUCTION

Structural members using pultruded FRP composites are produced in open and closed sections, with wall thicknesses ranging from 2 to 20 mm. Connections in larger pultruded members, with relatively thick webs and flanges, and cross-sections similar to those of hot-rolled steel members, are typically achieved with large-diameter steel bolts. The connecting elements between the FRP members are typically made of mild or stainless steel. The behavior of these bolted connections is reflected in the ASCE pultruded FRP design standard currently being developed in the United States (Mottram, 2013).

Smaller pultruded sections with thin walls are often used in applications similar to those of cold-formed steel members, such as load-bearing stud walls and roof trusses. In cold-formed steel, bolts are rarely used. Rather, most connections are completed with self-tapping fasteners (She et al., 2012). In this paper, the bearing strength of small-diameter self-tapping fasteners in FRP-steel connections is assessed, and the applicability of this fastening technique for use in FRP pultruded structures is discussed. The connection method is advantageous for these smaller-size members because the connections can be completed quickly using a torque-limiting driver/drill. Inherent in the method is the ability to work from one side of the connection, without the need to hold a nut on the back side of the connection (i.e., blind fastening). Properly design connections using this method tend to be self-aligning, as the fastening process removes a modest amount of the material from both the steel cleat and the FRP members. Applications for this fastening technique are discussed in prior work by the first author describing the design of a lightweight composite structures for photovoltaic racking system (Gentry et al., 2014).

The two preferred failure modes for mechanically-fastened FRP connections are (1) net section failure, which is generally difficult to achieve due to the large number of fasteners required, but maximizes the efficiency of the
connection and (2) bearing failure in the FRP material, which is generally provides a predictable and ductile failure mode (Bank, 2013, Bank and Arora, 2007). The shear-out, block shear and cleavage failure modes tend to occur suddenly, and are less easy predict. For this reason, edge distance and fastener spacing requirements, related to the fastener diameter and FRP plate thickness, have been established to preclude these failure modes (Tajeuna et al., 2016). Bolt rupture and pull-through failure modes are prevented by proper sizing of the bolts and washers (Mottram and Turvey, 2003).

Most of the research on the use of small-diameter fasteners in FRP composites focuses on the bonding of pre-cured plates to concrete or steel structures as a repair technique. Nevertheless, some of this work is relevant to the current study. Lamanna et al. (2004) developed a method to fasten FRP strips to concrete beams using powder-actuated fasteners and observed that the FRP strip was less likely to detach from the concrete if the FRP was predrilled before fastening.

DESIGN OF JOINTS IN PULTRUDED FRP MEMBERS USING SELF-TAPPING FASTENERS

The joint design for the FRP-steel connections developed in this research are based on the use of thin-wall steel web cleats or web splices to transfer forces across the member boundaries. Two examples of these connections are shown in Figure 1.

Figure 1 Pultruded FRP to steel connections in photovoltaic panel frame

Configuration and Installation of Self-Tapping Fasteners

The bearing condition of the self-tapping fastener used in this research differs from the conventional case of a bolt in pin-bearing for the following reason. First, the fastener installation method creates tension in the fastener and thus lateral restraint to the joint. The integral washer may add to this lateral restraint. It is likely that the joint will have higher initial stiffness than a connection in pure pin bearing, due to the torque in the fastener. As the connection is loaded it will slip into bearing as the load overcomes the friction caused by the bolt (Olmedo and Santiuste, 2012). Second, the threads of the fasteners are necessarily in the plane of the FRP material, which is generally not recommended in the case of bolted connections (Mottram and Zafari, 2011). Finally, there may be little “clearance hole effect”, because the self-tapping fastener creates a tight interface with the FRP material as it drills through the FRP. The magnitude of this effect is an important aspect of the research.

For the No. 12 fasteners used in this research, a 4 mm pilot hole in the steel and a 5 mm pilot hole in the FRP were drilled or waterjet cut. These holes were selected based on the major diameter, 5.5 mm, and minor diameter, 4.0 mm, of the No. 12 self-tapping screw. The self-tapping fastener was driven carefully with a manual torque-limiting driver to a torque of 9 N-m. The initial driving caused the threads to form in the steel. As the driving continued the parts were drawn together, and the torque in the fastener rose to the specified level. If the screw is over-driven,
two failures are possible: first, the mild steel will strip and the fastener will lose its pre-setting tension and two, the fastener will fail in torsion. For the fasteners used in this research, the failure torque is around 20 N-m. Figure 2 depicts the threading and driving torque for the fastening of a 3 mm thick FRP plate to a 1.6 mm hot-rolled mild steel plate.

![Figure 2 Self-tapping fastener torque versus slack take-up in FRP-steel joint](image)

**Observation on Fastener and Material Selection**

In addition to self-tapping fasteners, a set of preliminary experiments were conducted using self-drilling fasteners, which have an integral drill bit and do not require a pilot hole. It was found that the self-drilling fasteners tended to over-drill the FRP material, leaving a large void around the circumference of the fastener in the FRP which led to reduced bearing capacity. The 1.6 mm thick (16 gage U.S.) hot-rolled steel plate was found to be the thinnest plate which would consistently self-thread and hold the self-tapping screws. Thicker plates worked as well or better (in terms of thread forming and screw engagement) but were more than required to carry the in-plane shear loads for the connections. Though the bearing strength data below includes tests on single and two screw connections, it was found that a minimum of four screws were needed to fully-secure an FRP-steel joint using self-tapping fasteners.

**BEARING TESTING PROGRAM**

In order to assess the bearing capacity of the FRP-steel connections, a series of lap shear tests were completed. The following aspects of bearing behavior were considered important in the testing:

1. The direction of the bearing stress relative to the longitudinal axis of the composite (the direction of pultrusion).
   Tests were completed in the 0°, 45° and 90° directions.
2. The number of and pattern of fasteners used to join the FRP to the steel plate. Lap shear specimens with one to six fasteners were tested.
3. Pin-bearing resistance of smooth shank bolts of with the same diameters as the minor and major diameter of the self-tapping fasteners.
4. Effect of clamping force in the fasteners.
5. Retention of bearing capacity in hot-wet environments (not discussed in this paper).

In the discussion that follows, the bearing strength values presented here are provided as forces and not stresses, as it is not clear what diameter to use for normalizing the bearing force into a bearing stress. The bearing strength is taken as the peak force – and not the 2% bearing offset force from ASTM D5691 (2013) or the 4% offset from ASTM D953 (2010). The material properties and bearing test data represent an average of 5 specimens unless otherwise noted. Further discussion on offset bearing strength is provided with the test results, below.

**FRP Material Properties**
The pultruded FRP materials used in the test were nominal 3.2 mm thick, E-glass reinforced with layers of uni-directional roving and continuous filament mats and a fire-retardant thermosetting polyester resin. The mechanical properties are given in Table 1.

**Figure 3** Typical test article and specimen geometry (specimen SL2L2T shown)

**Bearing Test Results**

A total of 13 bearing tests sets are reported on in this paper – based on a range of configurations as discussed previously. The specimen nomenclature includes the connection type (single lap “SL” or double lap “DL”), the number of fasteners in the joint, and the fastener configuration. A typical single-lap specimen and the geometry of the lap-splice is shown in Figure 3. This single lap specimen has four fasteners, two in the longitudinal direction and two in the transverse direction. The FRP is cut in the pultrusion (longitudinal direction) as are all specimen groups unless noted. A list of the bearing tests and the test results are given in Table 3. The bearing
test results are taken as the peak force observed during the test. In addition to the peak force, the force carried by each fastener per each ply of FRP is given for comparison. The failure modes observed in the given tests series are also provided.

Figure 4 shows the typical results from single-fastener bearing tests – including the self-tapping fastener and two bolts in pin-bearing representing the minor (4.0 mm) and major diameter (5.5 mm) of the self-tapping fastener. The bolted fastener data shows a set of localized “valleys” in the load-slip relationship. These valleys correspond to the onset of bearing failure at the surface of the FRP, due to out-of-plane rotation caused by the eccentricity inherent in single-lap shear tests. These valleys are either not present or difficult to detect in the self-tapping fastener data. The smaller 4.0 mm diameter test closely matches the bearing strength of the self-tapping fastener. It is clear however that the stiffness of the self-tapping connection is much higher than the stiffness of either of the bolted joints.

</table>

This improved stiffness of the self-tapping joint is further illustrated in Figure 5, which shows the offset bearing strength of the self-tapping fastener, using the 2% offset from ASTM D5961 and the 4% offset from D953. It is
clear than the self-tapping fastener will have a higher offset bearing strength than either of the bolted connections. From the photograph, it is apparent that the self-tapping fastener demonstrates significant post-peak ductility.

The behavior of multi-fastener joints is similar to that of the single-fastener joints. For lap shear joints with 2, 3 and 4 screws in a line, the capacity increases linearly with the addition of fasteners. The 4 fastener connection shown in Figure 3 loses some capacity relative to the single-line joint, probably due to the mixture of bearing and block shear failures observed in the joint. The size of the joint needs to be increased slightly to preclude the block shear failure.

Figure 5 SL1 bearing test and offset bearing strength of self-tapping fastener joint

CONCLUSIONS

This research demonstrates the effectiveness of self-tapping fasteners as a method for joining thin-wall pultruded FRP members to steel. The techniques are applicable to achieving rapid field connections, especially in those instances where blind fastening, that is, the ability to access the back side of the connection, is required. Future publications from this research will explore the durability of the connections using these fasteners, and will demonstrate the design requirements for connections with loadings skew to the longitudinal axis of the FRP composite.

INFLUENCE OF USING PITCH-BASED ULTRA-HIGH MODULUS CARBON FIBRES ON THE STRUCTURAL BEHAVIOUR OF FRP REINFORCED CONCRETE SLABS

P. Reiter 1, B. Zwingmann 1, Y. Liu 1 and M. Schlaich 1
1 Chair of Conceptual and Structural Design,
Technische Universität Berlin, Germany, Email: bernd.zwingmann@tu-berlin.de

ABSTRACT

FRP reinforcement bars made out of glass fibres, basalt fibres or high tenacity (HT) carbon fibres have lower Young’s modulus but higher strength when compared to steel bars. Thus, the deformation of FRP reinforced concrete slabs that are designed for Ultimate Limit State (ULS) will be much higher. Limiting deformation under service load requires additional reinforcement. Therefore, unwanted costs may arise through added material, labour and space for arrangement. Ultra-high modulus (UHM) carbon fibres reach a Young’s modulus of more than 900 GPa at a high tension strength of 3.7 GPa. CFRP reinforcement bars made out of these fibres have higher extension stiffness as steel bars despite the smaller cross section. The structural behaviour of eight reinforced concrete slabs is analysed in an experimental parameter study with varying reinforcement material and quantity. The results show that UHM carbon fibres can significantly reduce the deflection under service load without losing load bearing capacity. A promising alternative to CFRP reinforcement with HT carbon fibres is demonstrated by using pitch-based UHM carbon fibres instead of highly expensive PAN-based UHM carbon fibres.

KEYWORDS

Ultra-high modulus carbon fibre, pitch-based carbon fibre, FRP RC slab, experimental study.

INTRODUCTION

Fibre reinforced polymer bars (FRP bars) have a higher strength than steel and are resistant to corrosion. Thus, concrete elements reinforced with FRP bars are highly resistant and durable. The required amount of reinforcement is smaller for FRP than for steel reinforced concrete slabs that are designed for Ultimate Limit State (ULS). Due to this fact and the low Young’s modulus of the fibres the deflection of FRP reinforced slabs under service load is unacceptable high in comparison to steel reinforced slabs. To satisfy the Serviceability Limit State (SLS) additional reinforcement is needed. CFRP bars are commonly made of HT carbon fibres (HT bars). CFRP bars based on UHM carbon fibres (UHM bars) have much higher Young’s modulus. Using UHM bars, the deflection can be reduced significantly without increasing the amount of FRP reinforcement. Figure 1 shows the deformation of a reinforced concrete slab using different types of reinforcement.

Figure 1 Concrete slabs of same load-bearing capacity reinforced with steel, HT or UHM bars
Two series of experiments were carried out to analyse the deformation behaviour and load-bearing behaviour of concrete slabs reinforced with FRP. Four different materials were used as reinforcement: steel bars, GFRP bars, HT bars and UHM bars.

**METHOD OF SOLUTION**

**Pull-out-test**

Pultruded CFRP-bars have a smooth surface, which has to be treated to create bond between the bar and the concrete. One possibility is a sand coating glued with epoxy resin. Another possibility is milling the rod’s surface. Both bar surfaces are compared to choose the most favourable bond condition for the slabs. For ComBAR® (Schöck Bauteile GmbH 2013) the second method is used to create a spindle-shaped design. Alternatively the spindle can be shaped on the surface with epoxy glue. The different bond conditions were determined by testing a sand coated and a spindle-shaped CFRP bar in comparison to a ComBAR® and a steel bar. The spindle was shaped using viscous epoxy resin Sikadur®30-normal (Sika Deutschland GmbH 2013) and tape that was placed before and removed after applying the epoxy. Figure 2 shows the tested bar surfaces.

The performed pull-out-test was based on RILEM-RC 6 (RILEM 1983). To determine the bond between reinforcement and concrete a bar with a defined diameter (Ø) has to be concreted into a cube with a defined geometry and pulled out (see Figure 3).

The model code for concrete structures (CEB-FIB 2013) defines the mean bond-stress-slip relationship of ribbed bars (see black lines in Figure 4) to evaluate the bond-behaviour. The bond-stress $\tau_b$ is calculated dividing the pull-out-force by the bonding surface. The slip is recorded underneath the specimens using a displacement transducer. The linear ascending part refers to the elastic adhesive bond, which changes to the shear-bond (curved part). This is the shear stress between the concrete corbels and the ribs. At the highest point of the graph $\tau_{b,max}$ a sustained
plateau occurs. Then the concrete corbels fail and the branch descends. The following constant curve refers to the friction-bond $\tau_{b,f}$ between the ribs and the concrete.

![Figure 4 Maximum bond-stress-slip relationships for steel bar and FRP bars](image)

For each material three specimens were tested. The results for the specimens with the maximum bond-stress of each material are shown in Figure 4. The pull-out-tests show that the maximum bond-stress is reached by the steel bar with a mean value of 23.2 MPa and a slip of 1.08 mm. CFRP-sand surface and CFRP-spindle-shaped surface have the stiffest bond with a slip of 0.39 mm and 0.29 mm. CFRP-sand reaches a mean maximum bond-stress of 17.4 MPa, which is twice as much as the CFRP-spindle-shaped with 8.0 MPa. The friction-bond of CFRP-spindle-shaped and CFRP-sand are very close to each other. In Table 1 the mean values of the test results are shown. Based on the results CFRP-sand is chosen for the reinforcement of the investigated slabs.

**Bending-test**

The concrete slab shown in Figure 5 had a length of 210 cm, a width of 30 cm and a height of 8 cm. The slab was supported like a single span beam with a span of $l_{eff} = 180$ cm. To perform a 4-point-bending test a traverse applied the load at two points. The force and displacement of the hydraulic cylinder was recorded. In addition load cells were installed below the traverse and three displacement transducers under the slab. Two additional displacement transducers recorded the strain on the front side to calculate the stress of the concrete and the reinforcement.

![Figure 5 Experimental setup for the 4-point-bending test](image)
Steel, GFRP bars, HT bars and UHM bars were used as reinforcement. The UHM bars were made out of continuous DIALEAD K13916 fibres (*Mitsubishi Plastics Inc.* 2015). They were laminated by hand, because commercially pultruded bars could not be obtained. The sand-coated UHM bar is shown in Figure 2. A concrete C50/60 was used with a maximum grain diameter of 16 mm. The properties of the materials are shown in Table 2.

$^1$Schöck Bauteile GmbH 2016  $^2$Calculated  $^3$vDijk Pultrusion Products 2014  $^4$Own test results

The concrete’s properties were obtained by material tests. The cylindrical compressive strength $f_\text{cm}$ was 61.9 MPa at a strain of 3.99 %. The tensile strength $f_\text{ctm}$ and the Young’s modulus $E_\text{cm}$ were 3.4 MPa and 29 GPa.

Two series of experiments were carried out to study the deformation behaviour and load-bearing behaviour. In the first test series (ULS<sub>eq</sub>), the slabs were designed for the same load capacity so that failure occurs at the same maximum load. The second series (SLS<sub>eq</sub>) was designed to have the same deflection at a defined load. The deflection $w$ should not exceed the limit $l_{\text{eff}}/200$. Therefore the limit deflection was designed to be between 8 and 8.4 mm for a bending moment of 1.46 kNm. The quantity of required reinforcement for both series is listed in Table 3 and 4.

**RESULTS AND DISCUSSIONS**

The moment-deflection-curves for all specimens of ULS<sub>eq</sub> are shown in Figure 6. Using guaranteed strength and safety factors instead of mean strength of the bars by mistake the ultimate moments were calculated wrongly (compare $M_\text{u}$ in Table 3 and 5). Nevertheless, the results of ULS<sub>eq</sub> show how UHM-fibres reduce deflection. Table 5 shows the ultimate moment and deflection of FRP reinforced slabs in comparison to steel reinforced slab. Values in prentices show the difference to the steel reinforced slab. The results show that for a similar ultimate moment ($\pm 20 \%$) the deflection for HT bars is much higher than for steel bars. In contrast the deflection is much lower for UHM bars. GFRP bars cause extensive deflection despite their highest ultimate moment. The fibre area of UHM bars is 3 times bigger but the deflection is almost 6 times lower compared with HT bars. None of the FRP bars provides ductility.

In Figure 6 the moment-deflection-diagram for $ULS_{eq}$.

In Figure 7 the concrete slabs of $ULS_{eq}$ are shown during the test with the same moment ($M = 2.57$ kNm). The deflections of slabs reinforced with GFRP bars and HT bars are much higher than those of steel bar and UHM bar reinforced slabs. In addition to low deflection the cracks are evenly distributed with small widths when using UHM bars. This is caused by the stiff bond (see Figure 4) and the high Young’s modulus.

Figure 6 Moment-deflection-diagram for $ULS_{eq}$

Figure 7 Deflection of the $ULS_{eq}$-slabs with the same bending moment
Test results for SLS$_{eq}$ are shown in Figure 8 and Table 6. The slabs with the four different reinforcement materials show similar deformation behaviour such as planned for SLS$_{eq}$ (scaled up view in Figure 8). For a moment of 1.46 kNm the slabs deflect approximately 5 mm (see Table 6) which is lower than the calculated value of 8.8 mm. UHM bars require less than 50 % of HT fibre cross section and 13 % of glass fibre cross section for the same deformation. The required amount of GFRP and HT reinforcement to achieve low deformation leads to an unnecessary high ultimate moment. An adequate balance between deformation and ultimate moment is achieved by the usage of UHM bars. The load-bearing behaviour is similar to the steel reinforced slab.

CONCLUSIONS

This paper shows that CFRP-bars made out of UHM carbon fibres can significantly reduce the deformation of concrete slabs in comparison to other FRP bars. Less reinforcement can be used and unnecessary high ultimate moments can be avoided. Pitch-based carbon fibres can be an advantageous alternative for the highly expensive PAN-based carbon fibres to produce UHM bars.

ABSTRACT

In recent years, the development and use of Fibre Reinforced Polymer composite materials in infrastructure have gained increasing attention worldwide. More specifically, natural mineral fibres such as basalt are currently being developed and are showing promising properties. Within an appropriate polymer matrix, their use as reinforcement in concrete structures offers performance benefits related to their environmentally friendly and non-corrosible nature. In particular, BFRPs have the potential to replace conventional internal steel rebar and thus, to be the next generation material in concrete reinforcement applications. A detailed literature review indicates that a careful selection of the appropriate manufacture technique and design methodology are required in order to prevent brittle failure on a concrete structure reinforced with FRP composite material. This paper reports on how to use the additional helical reinforcement and the braid configuration in order to increase strength, structural ductility and long term durability. Moreover, this study outlines the development of an analytical numerical model to predict the longitudinal elastic modulus of braided composites, as well as its validation by comparison of the results with available data from the literature.

KEYWORDS

Fibre Reinforced Polymer (FRP), basalt fibre, braiding technique, infrastructure, concrete reinforcement, BFRP rebars.

INTRODUCTION

The long-term durability of steel reinforced concrete (RC) structures, subjected to repeated loading and aggressive environmental factors, has become a major concern in the civil engineering construction industry. Degradation of both mechanical properties and durability performance due to corrosion severely affects service lives and the safety of steel RC elements. This in turn raises the need for their effective rehabilitation (Hollaway 2010; Afifi et al. 2015; Fiore et al. 2015; Elgabbas et al. 2015). It is noteworthy that maintenance costs related to steel reinforcement corrosion are significant worldwide, with an estimated repair cost of over $12.8 billion per annum for bridges in the United States alone (Behnam and Eamon 2013). The use of fibre reinforced polymer (FRP) composite materials as a potential replacement for traditional steel in internal concrete reinforcement, has recently received a great deal of attention by civil engineering scientists, as well as industry (Hollaway 2010; Afifi et al. 2015). The advantages of FRP composite materials over steel include excellent corrosion resistance, good fatigue properties, damage tolerance, low specific gravity, non-magnetic properties, light weight, low energy consumption during fabrication, and the potential real-time monitoring of their behaviour (Portnov et al. 2013; Pastore and Ko 1999). In addition, these innovative materials are considered to offer an overall more economical option for construction applications (Fiore et al. 2015; Behnam and Eamon 2013). Summarising, the optimum development of a reinforced concrete type in which the usual internal steel rebars are replaced by FRP composite materials is consider to be an ongoing research topic worldwide, but the structural safety associated with this composite material is still not fully understood (Afifi et al. 2015; Elgabbas et al. 2015; Wang and Belarbi 2010).

The aim of this work is to design and develop novel BFRP rebars for manufacture using a braiding technique. They consist of basalt fibres and a thermosetting polymer matrix (epoxy resin), and the relation between braiding parameters and rebar properties is assessed. Theoretical calculations by means of numerical simulation are also presented to determine the stiffness properties of manufactured braided BFRP composites; model data is then compared with results available from the literature. It should be noted that these innovative rebars give a unique surface texture for better interfacial interactions with concrete; this feature will be further investigated in the next phase of the research.
LITERATURE REVIEW

Fibre Reinforced Polymer for concrete reinforcement

According to the literature, FRP composites consist of high tensile fibres (e.g. carbon, glass, basalt) embedded in polymer matrices (thermosetting or thermoplastic) leading to improved mechanical properties of the system (Fiore et al. 2015; Behnam and Eamon 2013). In particular, basalt fibre, an inorganic, natural fibre made from molten basalt rock at diameters ranging from 9 to 20 μm, has the potential to become a promising reinforcing material for FRP composites in infrastructure applications. This is due to its excellent properties, such as high tensile modulus, good alkali resistance and environmentally friendly origins (Ahmadi et al. 2012; Parnas et al. 2007; Banibayat and Patnaik 2014). It is broadly accepted that FRPs can be a viable alternative for replacing steel as internal concrete reinforcement in a cost effective manner, as these materials are competitive in terms of life-cycle costs (Whitehead and Ibell 2005). In addition, they have several performance benefits namely the corrosion resistance, high tensile strength, fatigue resistance and many more. However, a direct substitution between FRP and steel reinforcing bars is not possible due to various differences in their physical and mechanical properties. The linear stress-strain behaviour up to failure, the lack of ductility and energy absorbing capabilities are the main limitations that prevent the use of FRP rebars on a large scale (Portnov et al. 2013; Pastore and Ko 1999; Whitehead and Ibell 2005; Ibell et al. 2009). If FRP reinforcement is to be used successfully and widely in concrete structures, it must be used to its full potential (Ashour and Habeeb 2008; Whitehead and Ibell 2005). When FRP bars are simply placed in concrete as a direct substitute for steel bars, it is impossible to achieve this aim, as the concrete tensile strain capacity is low compared with the high capacity of FRP (Portnov et al. 2013). Therefore, it is clearly understood that, only through the rational and efficient use of FRP composite materials that can meet strength, ductility, stiffness, as well as reliability and cost demands, both construction industry and engineers, as well as manufacturers of these products, will gain the greatest benefit (Behnam and Eamon 2013; Wang and Belarbi 2010; Ibell et al. 2009).

Due to the growing interest on the use of FRP composites in construction, a small number of design guidelines, codes and specifications for their efficient use in civil engineering applications were developed during the last decade. Special publications by ACI - the ACI Guide for the Design and Construction of Structural Concrete Reinforced with FRP Bars, ACI-440.1R – and various other international standards, including the Japan Society of Civil Engineers, the British Standards Institution, the Canadian Standards Association International - CSA-S806-02 - that directly address the use of FRP, are available so far. However, the use of FRP for reinforcement instead of steel is far from widely accepted in the conservative construction industry, mostly because of the lack of familiarity with this material, the high initial costs and the lack of structural ductility. Moreover, design codes are slowly developing for FRP rebars compared to the well-established ones for the use of steel bars in concrete members (Afifi et al. 2015; Fiore et al. 2015; Elgabbas et al. 2015; Behnam and Eamon 2013).

To date most of the FRP reinforcement used in concrete has been manufactured by pultrusion, a low cost method providing composites with a constant cross section and a smooth surface (Fiore et al. 2015; Ahmadi et al. 2009). Recently there has been increasing interest among researchers in braiding techniques for FRP composite fabrication, aiming for improved mechanical properties and multiaxial orientation (Pereira et al. 2008, Tang and Postle 2001). The basic principle of the braiding technique is the interlacing of yarns in a way that they cross each other in a diagonal direction (Pastore and Ko 1999). Braiding angle – the angle between braid yarns and axis of braid structure- is an important parameter that affects mechanical properties of braids and is usually adjusted by changing the take-up speed in braiding machine, obtaining a range between 20 and 85° (Ahmadi et al. 2009; Branscomb et al. 2013). It should be noted that braided FRP rebars could obtain higher flexural & shear strength, increased durability and improved crack resistance, compared to pultruded ones that exhibit low bending strength, mostly due to uni-directional structure. Although the braiding method is less common as it is more expensive, it does present significant advantages in special civil engineering applications, mostly relating to the additional ductility provided and the increased bond between FRP and concrete, which has a direct influence on both the serviceability and the ultimate load-carrying capacity of the structure (Pereira et al. 2008; Ashour and Habeeb 2008).

EXPERIMENTAL WORK

In this paper, a theoretical approach for the prediction of the elastic modulus of braided BFRP rebars is established, based on numerical simulation and mathematical modelling after analyzing the manufacture of the braided preforms. Comparisons are made between the values predicted from the present model and the literature data. In addition, a braided BFRP helix configuration for internal concrete reinforcement is attempted to be produced with epoxy resin impregnation.
Manufacturing design and process

The goal of this research activity is to develop an understanding of the mechanical behaviour of braided composite bars and correlate it with textile processing conditions. An important challenge, that needs special attention when designing textile composite materials, is the complex nature of the processing parameters, such as yarn size, number of carriers in the braiding machine, braid angle, in order to ensure optimum behaviour of the final product and obtain the desired physical and mechanical properties for its end-use. The development of braided BFRP preforms for use as rebars in concrete reinforcement after proper impregnation in epoxy resin and the influence of the braiding angle and the number of braiding layers are the main fields investigated within this study. The objective of these trials is the production of braided BFRP rebars, consisting of a braided core (~ 3mm) and surrounded by two layers of PET material (Figure 1). These are introduced to promote resin flow, and an outer finishing braiding layer is added to complete the required dimensions. Basalt fibres are the reinforcing material and the matrix is epoxy resin. The target outer diameter of samples is 5.0 mm (Figure 2). Table 1 exhibits in detail the fundamental material properties of basalt, PET fibres and epoxy resin used on the trials.

Numerical analysis

Simplified theoretical approaches for FRPs often presume a layup of only unidirectional reinforced layers and homogenization approaches for the prediction of structural properties. However, different kinds of fabrics and manufacture techniques are often applied for the layup of FRP materials (Tang and Postle 2001). Several studies report the use of classical lamination theory (CLT) approach for the analysis of braided FRP laminated structure, and these formed the basis for this work (Valentino et al. 2013; Srikanth and Rao 2014; Bank 2006).

For each layer of every BFRP sample, the four independent engineering parameters affecting their stiffness behaviour (longitudinal/ \( E_x \), transverse/ \( E_y \), shear/ \( E_s \), modulus and Poisson’s ratio/ \( \nu \)) were estimated using the following equations:

\[
E_x = \varphi_f E_f + (1 - \varphi_f) E_m
\]

\[
E_y = \frac{E_x \left(1 - \sqrt{\varphi_f(1-\varphi_f)}\right)}{E_m}\nu_x \nu_y E_x
\]

\[
E_s = \frac{E_x}{2(1+\nu)}
\]

\[
\nu_x E_y = \nu_y E_x
\]

where \( \nu_x \) and \( \nu_y \) are the major and minor Poisson ratio respectively, \( E_f \) and \( E_m \) are the Young’s modulus of fibre and matrix respectively and \( \varphi_f \) is the fibre volume content given by Eq. 5.

\[
\varphi_f = \frac{U_f}{U_c}
\]

where \( U_f \) and \( U_c \) denote the volume of fibre and composite respectively. The fibre volume content is an indicator for the achieved quality and serves as a base for the prediction of braid’s mechanical properties.
Then, the on-axis stiffness matrix \([Q_{ij}]\) for each braid layer is calculated, defining the six off-axis stiffness coefficients along with braid angle. The stiffness matrix \([A–B–D]\) and the cofactor expansion matrix \([C]\) for each BFRP sample can be obtained from terms \(A_{ij}\), \(B_{ij}\), \(D_{ij}\), expressing the extensional, flexural and extensional-bending coupled response respectively, as follows.

\[
A_{ij} = \sum_{k=1}^{n} Q_{ij}^{k} h_{k}
\]

(6)

\[
B_{ij} = \sum_{k=1}^{n} Q_{ij}^{k} (-z_{k} h_{k})
\]

(7)

\[
D_{ij} = \sum_{k=1}^{n} Q_{ij}^{k} (h_{k}z_{k}^2 + \frac{h_{k}^3}{12})
\]

(8)

where \(z_{k}\) is the midplane distance for each layer \(k\) and \(n\) the total number of layers in each sample.

Finally, Eq. 9 forms the basis for the evaluation of the elastic properties of braided BFRP rebars.

\[
E_{x_{FRP}} = \frac{DET([A–B–D])] / DET([C])}
\]

(9)

RESULTS AND DISCUSSIONS

Braided BFRP rebar preforms were produced varying the number of layers and the parameters of braiding process to achieve the desired structural geometry and meet the performance characteristics of existing rebar reinforcement. More specifically, the production of the core focused on two configurations: a single layer of 600 tex Basalt and a 2-layer version using 300 tex Basalt. Two approaches were also used for the PET flow mesh. The first approach was the production of a sleeve using 32 threads, whereas the second was over braiding of the core using 24 threads. The outer layers were produced using 600 tex Basalt with the target braid angle of ±45° (Table 2). A complete braided sample, made in Burgmann Packings Ireland, is shown in Figure 3.

Note: All values are an average of readings taken at several locations of manufactured BFRP samples; OD: Outer diameter (mm); Braid yarns: Basalt (tex), PET Monofilament; Angle (°).

The three selected braided preforms were then tested in SuperTEX Austria to evaluate their suitability for epoxy resin impregnation in a helical configuration. Each sample was found to give similar infusion results, with sample n°3 observed to exhibit the best behaviour (Figure 4).

The effective longitudinal in-plane modulus \(E_{x_{FRP}}\) was also calculated using CLT and Equations 1 – 9. This approach produced theoretical values of 25.80, 27.21 and 27.54 GPa for BFRP samples 1, 2, 3 respectively. The validity of this numerical investigation was assessed by a direct comparison with reference values of pultruded BFRP rebars from the literature (Elgabbas et al. 2015; High et al. 2015; Hui et al. 2012). This showed that the numerically determined elastic moduli using the CLT approach are largely similar, with BFRP 3 performing slightly better. Although the modulus values are relatively low, it should be noted that the small diameter braiding
process leads to relatively low fibre volume fractions. The limitation in braiding carriers in order to meet the diameter demands for helical configuration is considered to be the main factor that prevents higher rates compared to BFRP rebars produced by pultrusion technology, which can obtain experimental values of modulus around 40 – 50 GPa according to the literature. This can be addressed by using larger diameter samples, with higher fibre contents in the outer layers. It should also be noted that the braiding technique can offer significant performance benefits in specific structural applications in which additional ductility or/ and increased bond between FRP and concrete is needed.

For the next stage of this research experimental tests regarding physical and mechanical properties of braided BFRP rebars will take place at University College Dublin. These aim to verify the validity of the CLT numerical approach for accurate prediction of the properties of three-dimensional braided composites.

**CONCLUSIONS**

This paper demonstrates research that is currently in progress concerning the development of braided BFRP bars for concrete reinforcement. The described preliminary work has been conducted to understand the behaviour of braided fabrics and the influence of geometrical factors and processing conditions on physical & mechanical properties of braided rebars. The aim of this study is to successfully produce a braided BFRP helix for internal concrete reinforcement and to evaluate the stiffness of this braided composite using CLT approach. In particular, the mechanical response and the stiffness of braided BFRP composites have been estimated with numerical analysis and, in a further step, this theoretical model was validated using reference data showing a good agreement. The findings of this work include a useful tool for the design of BFRP rebars manufactured using braiding, capable of being applied to other braided geometries. Areas of future work within this project include the detailed investigation of FRP influence on structural reliability and an in-depth research on their strength, response and durability in order to obtain an optimized design and determine how this promising material can contribute to a more durable infrastructure.

ABSTRACT

This paper presents the results of an experimental investigation of the axial behaviour of circular geopolymer concrete columns longitudinally and transversely reinforced with glass fibre reinforced polymer (GFRP) bars and spirals, respectively. Three full-scale short columns with a slenderness ratio \( L/r \) of 8 were fabricated and tested: one unconfined column and two confined columns with spiral pitch \( s \) of 50 mm and 100 mm on-centers. The GFRP spirals have a nominal diameter, tensile strength, and tensile modulus of 9.5 mm, 1184 MPa, and 62.6 GPa, respectively. Based on the experimental results, the GFRP spirals enhanced the compression performance of the unconfined column. The well-confined column \( s=50 \text{ mm} \), yielded the largest load-carrying and deformation capacities, approximately 22\% and 174\%, respectively, higher than that of the unconfined column. This column also showed better compression performance such as less brittle failure, higher ductility (67\%), and greater confinement efficiency (28\%) compared to the column with wider spiral pitch \( s=100 \text{ mm} \). Finally, the tested columns showed relatively superior ductility and confinement efficiency compared to the conventional concrete columns reinforced with GFRP bars and spirals.

KEYWORDS

Geopolymer concrete columns, GFRP bars, GFRP spirals, ductility, confinement efficiency.

INTRODUCTION

Glass fibre-reinforced polymer (GFRP) bar and geopolymer concrete are two emerging building materials that are normally substituted for steel bar and ordinary concrete, respectively, to deal with the corrosion-induced durability problems and cement sustainability issues, respectively, of the conventional reinforced concrete (RC) system. Aside from being corrosion resistant, GFRP bars have high tensile strength, lightweight, electromagnetic neutral, and non-conductive, with the added benefits of ease of transportation and fabrication. Geopolymer concrete, on the other hand, is a sustainable construction material because its binder, the geopolymer, can be manufactured using alkali-activated silica- and alumina-rich industrial waste materials and its production process consumes low energy and emits low CO\(_2\) in the atmosphere. It is also resistant to elevated temperatures, highly stable in aggressive environments, and can develop high mechanical strength at a short period.

Several studies reported that both the GFRP bars and geopolymer concrete were suitable for the fabrication of compression members. The study conducted by Tobbi et al. (2012) showed that the GFRP bars contributed 10\% of the column capacity, which was practically analogous to steel’s contribution (12\%). Furthermore, the more recent experimental investigation done by Afifi (2013) and Mohamed et al. (2014) showed that the compression performance of circular columns reinforced with GFRP bars and spirals was similar to that of the traditional RC columns. They also reported that the GFRP spirals effectively enhanced the ductility of the columns, provided good confinement of the concrete core, and provided sufficient restraint against buckling of longitudinal bars. On the other hand, the research works done by Sumajouw and Rangan (2006) and Sujatha et al. (2012) revealed that the crack pattern, failure mode, and compression behaviour of geopolymer concrete columns were similar to that of the ordinary-concrete columns. It was also reported that the design procedures (Sumajouw and Rangan 2006) and analytical equations (Sarker 2009) for the typical RC column were also applicable to steel-reinforced geopolymer concrete (S-RGC) columns. With the stated advantageous characteristics of the GFRP bars and geopolymer concrete, combining them would offer a promising technology, herein called GFRP-reinforced
geopolymer concrete (GFRP-RGC), in fabricating new compression members with high durability, high sustainability, and adequate structural integrity. In this study, the axial behaviour of geopolymer concrete columns reinforced with GFRP bars and spirals was investigated. The compression contribution of longitudinal GFRP bars was quantified, the effects of the presence and pitch of spirals were evaluated, and the overall behaviour of GFRP-RGC column was compared to that of the GFRP-reinforced concrete (GFRP-RC) columns.

EXPERIMENTAL PROGRAM

Materials & Test Specimens

High modulus sand-coated GFRP bars and spirals with nominal diameters of 15.9 mm and 9.5 mm, respectively, were used as longitudinal and transverse reinforcement (Figure 1). The bars were manufactured through a pultrusion process wherein the E-glass fibres are impregnated with a modified vinyl ester resin. The properties of the bars, as specified by the manufacturer, were summarised in Table 1. A patented geopolymer concrete made up of 10-20 mm coarse aggregates, fine and medium sands, water, plasticizer, and a geopolymer binder made up of alkali-activated fly ash and slag was used in the study. The unique feature of this geopolymer concrete is that it can be cured in ambient conditions and it has a low heat of hydration, approximately 15°C (Aldred n.d.), which is just 12% of the glass transition temperature (T_g) of GFRP bars. Following the ASTM C39/C39M-15a (2015), the average compressive strength (f'_c) and elastic modulus (E_c) of the geopolymer concrete were 38 MPa and 33 GPa, respectively. Three full-scale short columns with a slenderness ratio (L/r) of 8 were cast and tested. The diameter (D) and height (L) of the column were 250 mm and 1000 mm, respectively. Each column was longitudinally reinforced with six 15.9 mm GFRP bars, yielding a reinforcement ratio (\(\rho_f\)) of 2.43%. The first column, the control specimen, was fabricated without transverse reinforcement in the tested region. The second and third columns were transversely reinforced with GFRP spirals pitched (s) at 50 mm and 100 mm on-centers, respectively, which translate to transverse reinforcement ratios (\(\rho_{ft}\)) of 3.13% and 1.57%, respectively. The specimens were labelled as follows: GGC-s. The first three letters (GGC) stand for “GFRP-reinforced geopolymer concrete column” followed by the corresponding spiral pitch (s). Figure 2 shows the details and configurations of the tested columns.

Methods

Figure 3 shows the test setup employed in the study. The columns were confined at both ends with two pairs of 10 mm thick steel clamps to prevent end crushing and to ensure that failure occurs at the test region. In addition, 3 mm thick neoprene rubber were provided between the specimen and the support plates to ensure uniform load distribution across the cross section. Chicken wire was wrapped around the column specimens for safety purposes. The monotonically increasing axial loads were applied in displacement control mode using a hydraulic jack to allow for the observation of both the pre- and post-peak behavior. The magnitude of the applied loads was measured with a 3000 kN capacity load cell, whereas the corresponding deformations were measured with a string pot. The location of the electrical strain gauges are shown in Figure 2 depicts. Three strain gauges were mounted onto longitudinal bars and another three were attached to the geopolymer concrete surface, aligned with the bars. Four strain gauges set 90° apart were also used to capture the strains in the transverse reinforcement. The strain, load, deformation, and deflection readings were recorded using a data logger attached to the machine, while the failure modes were documented with a video recorder.
RESULTS AND DISCUSSION

Load-Deformation Relationship

Figure 4 shows the load-deformation response of the tested columns. The load-deformation curves of the unconfined and confined columns consisted of a relatively similar linear ascending segment, with an average stiffness of 311 kN/mm. This can be expected since, at this stage, the columns’ behavior was governed predominantly by the geopolymer concrete’s compressive properties with little or no significant contribution from the GFRP ties. After exceeding the peak load level, GGC-00 failed suddenly and did not show any post-peak behavior. This load represents the gross capacity of the unconfined geopolymer concrete column ($P_g$). GGC-50 and GGC-100, however, continued to carry additional loads, owing to the still-intact concrete core confined by spirals. The confined columns yielded two peak loads. The initial peak load embodies the $P_g$ of the confined column that marks the beginning of concrete cover spalling. The second peak, on the other hand, corresponds to the maximum load capacity of the confined geopolymer-concrete core ($P_c$) that signifies the initiation of geopolymer-concrete core crushing failure.

Failure mode

Figures 5 shows the post-failure overview of the tested columns. As can be expected, the specimens exhibited a compression-type of failure, suggesting the effectiveness of the design and construction procedure employed in the study. The simultaneous crushing of the geopolymer concrete and global buckling of the GFRP bars governed the failure of GGC-00. A well-formed cone on both ends (Figures 5a) characterized GGC-00’s post-failure configuration. GGC-50 (Figure 5b) and GGC-S100 (Figure 5c), on the other hand, failed in a relatively ductile and more complex manner compared to the control specimen and characterized by the formation of an inclined failure plane, depicted by red lines. The failure can be described as the sequential occurrence of the following mechanism: local buckling and compression rupture of GFRP-bars, geopolymer-concrete core crushing, and rupture of the GFRP spirals, specifically at the intersection of the longitudinal and transverse reinforcement (Figure 6).

Table 2 summarizes the $P_g$ and $P_c$ of the tested columns. The compression contribution of the unconfined geopolymer concrete was determined by subtracting the GFRP bars’ contribution ($P_{gb}$) from GGC-00’s $P_g$ (1772 kN) and then dividing the remaining load by the difference between the geopolymer concrete gross area ($A_e$) and the total bar area ($A_b$), ($P_g-P_{gb}$)/($A_e-A_b$). The result was equivalent to 34.42 MPa, which was approximately 90% of the average compressive strength of the standard geopolymer concrete cylinders used in the study. Interestingly, this ratio was higher than the commonly used value of 85% for estimating the theoretical capacity of ordinary-concrete column sections, which tends to support Maranan et al.’s (2015) conclusion that geopolymer concrete has better mechanical properties than ordinary concrete of the same grade such as higher elastic modulus (leading to its better compatibility with GFRP bars compared to normal concrete), greater ultimate compressive strain (as much as 4800 με), and larger tensile strength. The use of spirals improved the $P_g$ of GGC-00. The $P_g$ of GGC-50 (1838 kN) and GGC-100 (2063 kN) increased by 4% and 16%, respectively, owing to the activation of the lateral confining pressures of the spirals. The $P_c$ of GGC-50 was lower than that of GGC-100, which could be due to the presence of closely spaced ties that caused discontinuity of the geopolymer concrete between the cover and core, making the column more susceptible to early concrete-cover spalling. Only GGC-50 and GGC-100 yielded $P_c$.

equivalent to 2160 kN, and 1717 kN, respectively, which were 118% and 82% of their respective \( P_c \). As can be expected, the well-confined column (GGC-50) yielded \( P_c \) that was higher than its \( P_f \). Table 2 also summarizes the GFRP bars’ compression contribution at \( P_c \) load level (\( P_{gb} \)), which was determined by multiplying the measured average longitudinal bar strain (\( \varepsilon_{gb} \)) with the total nominal area (\( A_t \)) and elastic modulus (\( E_t \)) of the GFRP bars. GGC-00 yielded the lowest \( P_{gb} \) of 123 kN which translates to a \( P_{gb}/P_c \) of 6.9%. GGC-100 yielded a \( P_{gb}/P_c \) of 7.1% that was marginally higher than GGC-00 while GGC-50 produced a much higher \( P_{gb}/P_c \), equivalent to 8.6%. These results were higher than De Luca et al.’s (2010) findings, with a \( P_{gb}/P_c \) of just 5%, which made them to conclude that the bar contribution could be ignored in evaluating the nominal capacity of the column. This could be related to the lower longitudinal reinforcement ratio (1.0%) and inferior mechanical properties of the GFRP bars they employed in their study.

Table 2 provides the axial deformation at \( P_c \) and \( P_f \), load levels (\( \Delta_c \) and \( \Delta_s \), respectively). The transversely reinforced columns produced \( \Delta_s \) values that were either higher than or equal to that of GGC-00 (7.2 mm), depending on the degree of confinement. GGC-50 had denser arrangement of reinforcement that produced planes of weakness between the cover and core, and hence, this column yielded a larger axial deformation than GGC-100. The \( \Delta_c \) of GGC-50 (19.7 mm) and GGC-100 (11.4) were approximately 2.46, and 1.57 times that of their corresponding \( \Delta_s \), respectively. Obviously, the column with higher volumetric ratio or lower tie spacing demonstrated better deformability performance compared to those with lower volumetric ratios.

**Strains in Geopolymer Concrete and GFRP reinforcement**

Figure 7 shows the relationships between the axial load and the average axial strains in the geopolymer concrete, longitudinal GFRP bars, and GFRP spirals. As can be expected, the geopolymer concrete and GFRP bars yielded comparable strains at same load level. Table 2 shows the maximum average strains in the geopolymer concrete at the \( P_c \) load level or the average concrete strain before the cover spalling (\( \varepsilon_{gc} \)). The average \( \varepsilon_g \) (\( \varepsilon_{g-ave} \)) of confined columns was equivalent to 2002 \( \mu \varepsilon \) and was higher than that of GGC-00 (1424 \( \mu \varepsilon \)), owing to the transverse reinforcement that prevented the premature cracking within the specimen and prevented the early buckling of the GFRP bars. Table 2 also summarises the strains in the longitudinal GFRP bars at \( P_c \) load level (\( \varepsilon_{fg} \)). The \( \varepsilon_{fg} \) of GGC-00 was 1647 \( \mu \varepsilon \), which is equivalent to 8.7% of the GFRP bars’ ultimate tensile strain (\( \varepsilon_t \)). GGC-50 and GGC-100 developed \( \varepsilon_t \) of 2116 \( \mu \varepsilon \) and 1967 \( \mu \varepsilon \), respectively, which translate to strain development of 11.2% and 10.4% of \( \varepsilon_t \), respectively. The average \( \varepsilon_{fg} \) (\( \varepsilon_{fg-ave} \)) of the confined columns was 2041 \( \mu \varepsilon \) and was relatively comparable to \( \varepsilon_g-ave \), suggesting the compatibility between the bars and the geopolymer concrete. Hence, equivalency between these materials could be assumed for design and analysis purposes. Furthermore, this average strain value was higher than the design strain limit of 1000 \( \mu \varepsilon \) proposed by Zadeh and Nanni (2013) to avoid exaggerated deflections. In general, marginal transverse strains (\( \varepsilon_{gb} \)) were recorded at lower loads. After exceeding the load equivalent to GGC-00’s \( P_c \), however, relatively higher strains were obtained from GGC-50 (968 \( \mu \varepsilon \)) because of the early spalling of its concrete cover compared to GGC-100 (730 \( \mu \varepsilon \)). At \( P_c \) load level, the results were reversed. The \( \varepsilon_{fc} \) was 13131 \( \mu \varepsilon \) for GGC-8-S100 while GGC-50 produced \( \varepsilon_{fc} \) of 7765 \( \mu \varepsilon \).

**Confinement Efficiency and Ductility Index**

In this study, the column ductility index (\( DI \)) was defined as the ratio of the displacement at 85% of \( P_{peak} \) to the displacement that corresponds to the elastic behavior limit (\( \Delta_{S5}/\Delta_1 \)), as shown in Figure 8. The procedure for determining these displacements was based on Pantelides et al.’s (2013) recommendations. The confinement efficiency (\( CE \)), on the other hand, was computed as the ratio of the compressive strength of the confined column to the compressive strength of the unconfined column (\( f'_{cc}/f'_{cc} \)). The \( f'_{cc} \) was calculated as the peak load divided by the area of the confined geopolymer concrete, which is represented by point C in Figure 9. The \( f'_{cc} \), on the other hand, was equivalent to 0.90\( f'_{cc} \). Table 3 summarises the \( DI \) and \( CE \) values of the tested columns. Based on the experimental results, the ductility index and confinement efficiency increases as the amount of transverse reinforcement increases. Interestingly, these results are consistent with Afifi et al.’s (2013) and Sharma et al.’s (2005) findings for GFRP-RC and conventional RC columns, respectively.

CONCLUSIONS

This study investigated the behavior of geopolymer concrete spiral columns reinforced longitudinally and transversely with GFRP bars. From the experimental results, the following conclusions were drawn:
The compression contribution of the GFRP bars (with a reinforcement ratio of 2.43%) with respect to column capacity varied from 6.9% to 8.6%, with an average value of 7.5%.

The column with a smaller spiral pitch (50 mm on-center) yielded higher load carrying capacity and failed in a more ductile manner compared to the column with a larger spiral pitch (100 mm on-center). In addition, the former column yielded ductility index and confinement efficiency that were 67% and 28%, respectively, higher than that of the latter column.

The GFRP-RGC circular columns yielded a relatively higher normalized strength (96.4%) compared to GFRP-RC circular columns (88.6%). This could be attributed to the higher elastic modulus of geopolymer concrete (33 GPa) compared to normal concrete (29 GPa) of the same grade (38 MPa), resulting in a better compatibility in the GFRP-RGC system than in the GFRP-RC system. Further studies, however, are needed to validate this generalization.

It can be inferred, therefore, that the GFRP-RGC system could be adopted for the fabrication of compression members, particularly when corrosion resistance, electromagnetic transparency, material greenness, durability, and sustainability are sought.

ACKNOWLEDGMENTS

The authors would like to express their special thanks to V-ROD® Australia for providing the materials as well as to the Natural Science and Engineering Research Council of Canada (NSERC) and the technical staff of the structural lab at University of Southern Queensland.

ABSTRACT

The experimental investigations conducted to study the behaviour of ultra-high performance steel fibre concrete (UHPSFC) reinforced with fibre reinforced polymer (FRP) material is presented in this paper. The investigations include the compressive behaviour of UHPSFC confined with FRP tubes and flexural behaviour of UHPSFC beams reinforced with internal FRP bars. 6 cylindrical specimens of UHPSFC confined with Carbon FRP (CFRP) and Basalt FRP (BFRP) tubes were tested under compression. Two full scale UHPSFC beams of 3250mm span reinforced with CFRP and Glass FRP (GFRP) bars were tested under four point bending. The compression behaviour of UHPSFC is significantly improved by the confinement provided by FRP material in terms of both strength and ductility. The compressive strength of UHPSFC confined with FRP tubes is 1.35 times greater the unconfined UHPSFC cylinders. The ultimate failure strain of FRP confined UHPSFC cylinders is found to be 3 to 4.5 times greater than the unconfined ones. The beams reinforced with FRP bars found to have greater load capacity than the steel bar reinforced beams with same percentage of reinforcement. The experimental results reflect the potential of FRP composites to build hybrid structural members with UHPSFC material.

Ultra-high performance concrete, FRP, confinement, UHPC beams.

INTRODUCTION

Ultra-high performance steel fibre concrete (UHPSFC) is an advanced cement composite material, which is characterised by high strength, ductility, durability and fracture toughness. The higher strength characteristics of the material enables to design innovative structures with significantly smaller cross-sections (Graybeal 2005) and without conventional steel bar reinforcement (Voo et al. 2012). In last decade, several studies investigated the material properties (Graybeal 2007, Hassan et al. 2012) and structural applications of UHPSFC (Yang et al. 2010, Fisher et al. 2002). Very few studies investigated the compressive behaviour of confined UHPSFC. The improvement provided by the confinement of normal strength concrete in terms of strength and ductility is well understood. It is also well known that due to the low dilation capacity of high strength concrete the confinement leads to insignificant improvement in its strength and ductility (Mandal et al. 2005). The UHPSFC has a considerable dilation capacity which is provided by the internal steel fibres, considering which Zohrevand and Miriran 2011 investigated the compressive behaviour of FRP confined UHPSFC. It was found that FRP confinement lead to significant improvement in strength and strain capacities of UHPSFC. It was reported that the available stress strain models developed for FRP confined normal strength concrete are not reliable to predict the stress strain behaviour of FRP confined UHPSFC. It was recommended that further research is required to investigate the behaviour of FRP confined UHPSFC which includes the practical confinement ratios to develop reliable FRP confined stress strain models of UHPSFC.

In past few years, the new type of reinforcing materials in the form of fibre reinforced polymer (FRP) bars emerged as an effective way to enhance the corrosion resistant of structures. The replacement of steel bars with FRP material is found to have several advantages such as high corrosion resistance, high strength to weight ratio, non-conductivity and ease of handling (Ehsani et al. 1997). Due to their high strength, the use of FRP bars with UHPSFC can provide a new way of optimizing the structural members. The objective of this study is to investigate the behaviour of hybrid members made up of two advanced materials of FRP and UHPSFC subjected to flexural and compressive loadings. To study the flexural behaviour, the composite beams of UHPSFC reinforced with
different materials such as glass FRP bars, carbon FRP bars, and conventional steel bars were tested. The load displacement behaviour, cracking pattern and failure modes of the beams with different rebar material is compared. To investigate the compressive behaviour of FRP confined UHPSFC, 6 cylindrical specimens of UHPSFC confined with Carbon FRP (CFRP) and Basalt FRP (BFRP) tubes were tested.

EXPERIMENTAL PROGRAM

Test Specimens and materials

To investigate the compressive behaviour of FRP confined UHPSFC, a total of 6 cylinders of 100mm (diameter) x 200mm (height) were tested. Additionally 3 unconfined cylinders of identical dimensions were also tested. The tubes were made by using manual wet layup procedure and cured for 7 days before the concrete casting. 4 circumferential layers of FRP material was provided to the confined specimens either in the form of carbon FRP or basalt FRP. The properties of the CFRP and BFRP fabric used are shown in Table 1, which is extracted from the coupon tests. The specimens are designated according to the FRP material used for confinement. The unconfined specimens are denoted with a letter U followed by the number, which denotes the identical specimen number such as U-1 is unconfined cylinder specimen number 1. Similarly confined specimens are designated as CC-1 or CB-1 as confined cylinder with CFRP or BFRP material, respectively.

* reported by manufacturer

To investigate the flexural behaviour of UHPSFC beams reinforced with FRP rebar material, 2 full-scale beams were tested. Additionally 1 full scale beam as a control specimen with identical cross section and span with steel rebar as reinforcing material was also tested for comparison purposes. The details of all the test beams are given in Table 2. All the beams were of 250 x 250mm cross-section with a span of 3250mm. The beams were designated with a first letter as “UHB” followed by a letter representing the name of the rebar material used and then followed a number representing the diameter of rebar used as tensile reinforcement. The letter “ST”, “GF”, and “CF” represents the reinforcing bar material as steel bar, GFRP bar, and CFRP bar. For example the beam with steel rebar of 20mm diameter is designated as UHB-ST-20. To assure the flexure failure mode of the beam, the shear reinforcement was also provided which consisted of 8mm diameter stirrups spaced at 90mm centre to centre up to the load points as shown in figure 1. The properties of the reinforcing bar materials as reported by manufacturer is shown in Table 1.

UHPSFC Mix

In this study, two type of UHPSFC mix were used. The mix were developed at The University of Adelaide using locally available raw materials. The UHPSFC mix-1 consists of specially graded sands so as to optimize the packing density of the mix. The UHPSFC mix-2 utilises only materials commonly used in the manufacture of
conventional normal strength concrete with the purpose of minimising material costs, the details of which can be found in (Sobuz et al. 2016). The detail proportioning of materials for the UHP SFC mix adopted in this study are given in Table 3. The binder consisting of sulphate resistant cement and silica fume was used in both the mix. The sands used in mix-1 were in the form of silica powder with an average size of 50μm and silica sand grade 30/60 with an average size of 400μm. For mix-2, river washed sand from local quarry was used as filler and no coarse aggregates were used in both the mix. The third generation liquid based High range water reducing admixture (HRWR) of Sika Viscocrete was used to achieve the workability. The steel fibres used were hooked end steel fibres of 35mm in length with aspect ratio of 64 and yield strength of 1100MPa reported by the manufacturer. The amount steel fibre added was 2.25% by volume.

All the dry constituents were electronically weighed and mixed in dry state in horizontal pan mixer for at least 3 minutes. The water and HRWR were mixed together and added into the material and allowed to mix until the materials turns into a flow-able consistent paste. The steel fibres are then added and mixed for further 5 minutes.

Fabrication

The FRP tubes were manufactured using manual wet layup process by wrapping the epoxy resin impregnated sheets around the cylindrical shape Styrofoam which had a diameter of 101mm and 220mm height. The fabrics of width 205mm were cut to a total length of 4 layers with an additional overlap length of 100mm. The epoxy resin is applied to whole length and on both sides of the fabric with the help of a roller brush and wrapped to the Styrofoam tube in the hoop direction. After 24 hours the hardened FRP tubes were removed from Styrofoam cylinders and cured for 7 days at room temperature. The UHPSFC was filled into the tubes and after 24 hours the specimens were placed and cured in a fog room for at least 56 days until testing.

The beams are fabricated one at a time due to the large amount of material required. The horizontal mixer of 1 ton capacity installed at The University of Adelaide is used for the onsite manufacturing of the structural members. The wooden formwork is built for the casting of the beams and all the beams are casted horizontally. The specimens required for the material tests are also casted for each batch of concrete. After 2 hours of casting all the specimens are covered with wet hessian and plastic sheets for at least 24hours. The formwork is then removed and the beams are cured with wet hessian covered with plastic sheets for at least 28 days before testing.

Instrumentation and Testing procedure

Compression test

All the confined and unconfined cylindrical specimens were provided with 2 electrical strain gauges of 30mm length to record the axial strains. Four equally spaced 5mm strain gauges were also attached to the confined specimens to measure the lateral/hoop strains in the FRP material. Additionally 4 linear variable differential transformers (LVDT) were used to measure the platen-to-platen displacement so as to measure the strains of the whole specimen. The uniaxial compressive load was applied at a constant rate of 0.05mm/minute throughout the test for which a universal testing machine of 5000kN capacity was used. The load, strain and displacement data were recorded continuously at the rate of two readings per second.

Beam Test

The beams were subjected to two equal concentrated loads applied symmetrically at a distance of 250mm from the mid span as shown in figure 1, so as to induce pure bending stresses in the beam between the load points. The load was applied through a single hydraulically actuated jack to the steel section placed on the top face of the beam with its supports 500mm apart. The beams were tested until collapse with monotonically applied load and the corresponding deflections and strains were recorded simultaneously.
TEST RESULTS AND DISCUSSION

Compressive behaviour

Table 4 presents the summary of tests results in terms of ultimate strength and strains of unconfined and confined specimens. The unconfined compressive stress strain curve obtained from experimental tests for the UHPSFC is shown in figure 2a. The average compressive strength of the UHPSFC is 140MPa and the corresponding axial strain is 0.4%. It can be seen (figure 2a) that the stress strain relation is almost linear up to the peak load followed by a sudden drop of load until a stable stress plateau is attained. Figure 2b shows the compressive stress strain curve of CFRP confined cylindrical specimens along with the unconfined ones. The CFRP confined specimens follows the same trend of linear stress strain up to the attainment of peak strength as is found in unconfined cylinders. The peak strength is increased by 36% by the CFRP confinement when compared to the unconfined compressive strength. A drop in strength after attaining the initial peak strength can be seen in the stress strain plots (Figure 2b), which is due to the softening of the inner core. The behaviour is similar to the high strength concrete (HSC) reported by (Xie and Ozbakkaloglu 2015, Mandal et al. 2005) which is caused by the brittle nature of HSC and ultra HSC. The softening leads to 8% decrease in the strength which is followed by the hardening branch of stress strain curve. The stress plateau of the hardening branch attains almost similar strength as that of initial peak strength followed by similar trend of softening and hardening until the rupture of CFRP tube.

The ascending branch of stress strain curve of BFRP confined specimen (Figure 2c) remains linear typically up to 85% of the unconfined strength after which it follows curvilinear path to attain the peak strength followed by the softening branch. The BFRP confined specimen shows 16% gain in strength when compared with the unconfined ones. At softening the strength drop is almost equal to 16% of the peak strength which means that the softening occurs till the strength is reduced to the unconfined strength of the material. After softening the material is unable to recover its peak strength which is attributed due to the less confinement effectiveness of BFRP because of its low elastic modulus compared to CFRP. The strength increase provided by the BFRP confinement is not significant in comparison to the CFRP confinement. In terms of ductility, BFRP confinement showed superior performance than CFRP. The results show that the compressive stress strain behaviour of CFRP confined UHPSFC is very similar to the elasto-plastic behaviour of steel. Such a behaviour is extremely desirable for the design of compression members located in the regions of high seismicity.

Flexural behaviour

The deflection is measured at mid span for all the beams. Figure 3 shows the load versus mid span displacement relationship obtained from the tests. The load-displacement curves indicate that the relation can be divided into three to four distinct regions, namely initial linear zone before first cracking, yield load at the yielding of rebar, peak load and collapse load of beam. The first stage of load displacement curve corresponds to the high bending stiffness of the uncracked section response of the beams. The first cracking load for beam UHB-ST-20 is 20kN and for UH-BG-20, UH-BC-12 is 26kN. After the first cracking load, the reduction in bending stiffness is observed due to the initiation of micro cracks. The load displacement curve observed to be linear with reduced stiffness until the yield load is attained. The reduction in stiffness is found to be dependent on the stiffness provided by the reinforcing bar material that is a factor of elastic modulus of bars and percentage of reinforcement provided.

The failure of beams UHB-ST-20 and UHB-CF-12 initiated due to the yielding of the reinforcing bars, whereas beam UHB-GF-20 yielded due to the crushing of concrete. The beams with steel bars is found to have long ductile plateau after the yield load is attained with the final collapse is due to the rupture of the reinforcing bars. The beam UHB-CF-12 with CFRP rebar observed to have negligible ductility after the yield load and the beam failed in a sudden manner due to rupture of CFRP bars. The failure of beam UHB-GF-20 initiated with the crushing of concrete. Although the beam has less ductility, the load drop is gradual as the crushing of UHPSFC is progressed which is different to the sudden and brittle failure observed for cylindrical specimens under pure compression.

Table 5 summarises the experimental results obtained from the beam tests. The results indicate that only 1.5% of reinforcement is required for high modulus GFRP material to obtain the compression failure mode of the beams whereas the beam with same percentage of steel bar reinforcement showed tension failure mode due to the rupture of rebar. The beam UHB-CF-12 with only 0.5% of reinforcement attained the similar stiffness as of beam UHB-GF-20 with 1.5% of reinforcement. The load carrying capacity of UHB-CF-12 is found to be 18% greater than UHB-ST-20 which has 3 times reinforcement percentage when compared to UHB-CF-12.

CONCLUSIONS

The behaviour of UHPSFC reinforced with FRP materials in the form of tubes and reinforcing bars subjected to compressive and flexural loadings is investigated in this study. The compression behaviour is investigated by testing 6 FRP confined UHPSFC cylinders and flexural behaviour is investigated by testing 3 large scale beams. The following conclusions are drawn from the experimental investigations:

The compressive strength of UHPSFC was increased by 36% and 16% when confined with CFRP and BFRP material, respectively. The FRP confinement significantly improved the ductility of UHPSFC where the ultimate axial strains were increased by a factor of 3 for CFRP confinement and by a factor of 4.5 for BFRP confinement.
The UHPSFC beams reinforced with conventional steel rebars exhibit very ductile failure. The fibres resisted the opening of the cracks and contributed toward the increased load carrying capacity of beams even after the steel bars are yielded. The beams reinforced with FRP materials had reduced stiffness when compared with beams with steel rebars. However, the cracking pattern was observed to be similar for both type of reinforcing materials. Due to the high strength of FRP materials it was found that only 1.5% of reinforcement is required by GFRP rebars to obtain the compression failure mode of the beam, whereas the beam with same percentage of steel bar reinforcement showed tension failure mode due to rupture of rebar.

The beam with 0.5% of CFRP reinforcement had tension mode of failure whereas the stiffness achieved is identical to the beam with 1.5% of GFRP reinforcement and 18% greater load capacity than the beam with 1.5% of steel reinforcement. Further tests are required to obtain the percentage of CFRP reinforcement required to change the mode of failure from tension to compression. The experimental results reflects the potential of FRP composites to build hybrid structural members with UHPSFC material.

EXPERIMENTAL AND NUMERICAL STUDY ON THE SHEAR BEHAVIOUR OF
GEOMETRICALLY SIMILAR FRP RC BEAMS

ABSTRACT

This paper discusses an experimental study examining size effect in GFRP RC beams with overall height varying from 260 mm to 460 mm, but otherwise similar in geometry and material properties. All beams were unreinforced in shear and designed to ensure shear failure. 3D DIC was employed alongside strain and displacement transducers to gain additional insight into the development and degradation of shear resisting mechanisms. The experimental measurements will be used to calibrate a numerical model and validate its reliability and performance. The results of this study can assist in improving existing shear design recommendations for FRP RC beams.

FRP, RC beams, shear, size effect, experimental study, numerical analysis.

INTRODUCTION

The shear performance of reinforced concrete (RC) members is governed by the development of a complex set of mechanisms. Shear stresses can, in fact, be transferred through a section of an element by the portion of concrete in compression, aggregate interlock, friction along a diagonal shear crack, dowel action of the longitudinal reinforcement and, when provided, the transverse shear reinforcement. Various studies have examined the shear behaviour of steel RC beams and have shown that member size directly affects the magnitude of the shear resisting mechanisms. In particular, Kani (1967) examined the performance of a series of beams by varying the depth of their cross section, \( d \), while keeping the steel reinforcement ratio constant. The results of this study (Figure 1a) show that the normalised shear strength of the tested beams decreased with the increase of \( d \). Such a trend, however, seemed to be less pronounced in slender beams. Various researchers (Shioya et al. 1990, Collins and Kuchma 1999, Frosch 2000 and Lubell et al. 2004) proved that size effect may be attributed mainly to a reduction in the resistance offered by aggregate interlock as a result of the larger cracks that develop in larger elements (Figure 1b). It was also found that crack widths increase linearly with crack spacing and that there is a direct relationship between crack spacing and depth of the beam (Shioya et al. 1989).

Over the past decades a great deal of attention has been put on fibre reinforced polymer (FRP) bars, which moved rapidly from being a novel alternative to steel reinforcement to a well-established practice. FRP bars are characterized by a linear elastic mechanical response and, consequently, the structural behaviour of FRP RC is different than that of steel RC. Although shear in FRP RC beams is transferred through the development of the same resisting mechanisms as for steel RC, their magnitude and individual contributions to overall shear capacity needs to be carefully reassessed. In particular, under similar loading conditions FRP RC elements can develop much higher deformations, thus exhibiting wider cracks than their equivalent steel RC counterparts. In turn, these larger deformations result in a reduced portion of concrete in compression resisting shear and in a weakened aggregate interlock along the cracks. In addition, due to the low transverse shear resistance of the FRP bars, the contribution of dowel action is negligible (Razaqpur et al. 2004).

While the overall shear behaviour of FRP RC is well documented (e.g., Guadagnini et al. 2006, Yang et al. 2015), research on the effect of element size on shear strength is still limited (Alam and Hussein 2012, Ashour and Kara 2014). This paper discusses the results of the first stage of a larger testing programme that aims to examine size effects in FRP RC beams.
EXPERIMENTAL PROGRAMME

Three geometrically similar beams were tested as part of an experimental programme designed to investigate the size effect in shear FRP RC beams without shear reinforcement. The longitudinal reinforcement ratio, $\rho_{lf}$, and shear span to depth ratio, $a/d$, were similar for all specimens (Table 1), while the overall depth, $d$, varied from 260 mm to 460 mm (Figure 2). The longitudinal reinforcement consisted of 12.7 mm GFRP bars in tension, while 6 mm basalt FRP (BFRP) bars were used as compression and skin reinforcement. The overall length of the all beams was 2500 mm. All of the specimens were cast using the same batch of ready mix concrete and the average concrete strength, $f_{cy}$, for each beam is also reported in Table 1 as measured on the day of testing.

Two tests were performed on each of the specimens. During the first test (Phase I, tests GB54 and GB58) the position of the load was selected so as to induce shear failure along the shorter of the shear spans, $A$ in Figure 2 (top), while maintaining relatively low average shear stress levels along the adjoining shear span ($B+C$) to ensure that this would remain relatively undamaged. Before the re-tests (Phase II, tests GB55 and GB59), the damaged portion of each beam (shear span $A$) was cut, and post-tensioned metal straps (PTMS) were wrapped along span $C$ to provide the required additional shear strength and avoid failure in this zone (Figure 2, bottom). Given that the two shear spans of specimens GB56 and GB57 were similar, PTMS were used in each phase of testing to strengthen one of the shear spans and ensure failure of the instrumented shear span.

Material properties

The summary of geometric and material properties of the test beams is presented in Table 1, where $a$ is the shear span, $f_{cy}$ is the concrete cylinder compressive strength (taken as 80% of the compressive strength obtained from testing 100 mm cubes), $E_f$ is the GFRP modulus of elasticity, $\rho_{lf}$ is the longitudinal reinforcement ratio, $F_{ult}$ is the ultimate applied load, $V_{exp}$ is the corresponding shear load at failure, $V_{norm}$ is the shear strength at failure normalized by the concrete compressive strength, and $\delta_{max}$ is the maximum deflection under the loading point.

Instrumentation

The applied load was measured using the internal force transducer in the actuator, while displacement and strains were recorded using LVDTs and strain gauges, respectively. The displacement was measured under the load point, where the maximum deflection was expected, and at the supports to determine the net deflection of each specimen.
Strain gauges were placed along the longitudinal reinforcement on the test side of the beam, which was also monitored with Digital Image Correlation (DIC). All details of the instrumentation are presented in Figure 2.

![Figure 2 a) Reinforcement scheme; b) load setup and instrumentation arrangement of the FRP RC beams without shear reinforcement (dimensions in mm)](image)

**DIC setup**

DIC was employed to obtain the full field strain deformations within the shear span of the beams, and in particular, a three dimensional (3D) configuration was used to eliminate the effects of possible out of plane displacement of the specimens during testing (i.e., generation of apparent strains) (Di Benedetti et al. 2015). Images were acquired with two CMOS (complementary metal-oxide semiconductor) digital cameras having a 4272×2848 pixel resolution (Canon EOS 1100D) and equipped with zoom lenses with F-number and focal length of 3.5-5.6 and 18-55 mm, respectively (Canon EF S 18 55mm f/3.5 5.6 IS II). The two cameras were rigidly connected and positioned 2 m apart from the specimen and a light-emitting diode (LED) lamp was used to uniformly illuminate the measurement surface. The stereo vision system was calibrated by taking images of a known pattern with different positions and orientations. During the load test, the shutter was remotely triggered three times every 10 seconds by the data acquisition system recording the point wise sensors in order to synchronize all data. The field of vision (FOV) was selected to accommodate the whole test shear span (Figure 2, A and B in Phase I and II, respectively), extending below the specimens to account for the expected maximum deflection at failure. After whitewashing the beams, speckles with an approximate diameter of 1 mm were spray painted in the region of interest.

**EXPERIMENTAL RESULTS**

**Moment capacity and shear strength**

The summary of the test results is listed in Table 1. In general, an increase in the ultimate moment capacity was observed with an increase in the overall depth of the members, \(d\) (solid lines in Figure 3a). The second test on each beam (dashed lines) resulted in overall higher capacity, which can be attributed to the fact that shortening the clear span of the beams to remove the damaged portion of the specimen after the first test (GB54 and GB58), partially changed the internal resisting mechanisms affecting both stiffness and ultimate behaviour. For example, in the test of GB55, the short span (\(C\) in Figure 2) contributed to the overall shear capacity by engaging a strut-and-tie action, resulting in a much higher shear resistance than that provided by GB54 (first test).

The experimental shear strength \(V_{exp}/bd\) was normalized by the concrete strength, \(\sqrt{f_{ck}}\), and was plotted against the members’ effective depth, \(d\) (Figure 3b). The results show that the normalized shear strength decreases with an increase in \(d\), which is in good agreement with available literature (Ashour and Kara 2014). In particular, a drop in shear strength of about 60% was observed between tests GB59 and GB56, when overall depth increases from 260 mm to 460 mm, respectively. This could be explained by the opening of wider diagonal shear cracks causing a reduction of shear resisting mechanism provided by mechanical interlocks.
In order to gain a more in-depth understanding of the shear cracking mechanism, and how it affects shear resistance, the DIC measurements taken along the test shear span of beams GB54 and GB56 are shown in Figure 4a and 4b, respectively. In both specimens, the critical diagonal cracks developed from the tip of the vertical flexural crack closer to the support (extensometers 3 and 2 in Figure 4a and 4b, respectively), and propagated towards the loading point at increasing load levels.

The width of the shear crack was measured at eight points perpendicularly to the crack direction (ext. 1-8 marked on the counter map inserts showing horizontal strains) and plotted against the percentage of the ultimate load of each respective beam. Flexural cracking at the monitored location started at a load of about 40% of ultimate, as evidenced by the increase in crack width captured by the DIC system. With a further increase in the applied load, the flexural crack turned gradually into an inclined crack and progressed towards the point of application of the external load. Just before failure occurred (at 87% and 93% of the ultimate load of beams GB54 and GB56, respectively), the inclined crack extended backward below the tip of the original flexural crack resulting into a significant increase in maximum crack opening (ext. 1-5). The results show that the largest crack opening at failure occurred above the tip of the flexural crack and was equal to 1.2mm (ext. 2) for beam GB56, while a maximum crack width of 1mm was observed in beam GB54 (ext.3).

**NUMERICAL INVESTIGATION**

The tests on GB54, GB56 and GB58 were numerically simulated using FEMIX, a finite element program that implements a 3D multidirectional fixed smeared crack model (Gouveia 2011). The specimens were discretized using 8 node plane-stress finite elements with a Gauss-Legendre (GL) integration scheme of $2\times2$ integration points (IP). An energy tolerance of $1\times10^{-3}$ was used as convergence criteria and a maximum of 2 sets of cracks in each
IP was allowed to form. The reinforcement was simulated with perfectly bonded, 2-node 2D embedded cable elements and a GL integration scheme of 2 IP. All analyses were executed with a modified Newton-Raphson iterative algorithm where the stiffness matrix was updated in the first iteration of each load increment. The load was applied in displacement control, with the arc-length technique, up to the ultimate beam’s deflection, at which stage it was no longer possible to ensure convergence. Poisson’s ratio ($\nu = 0.20$), initial Young’s modulus ($E_c = 24830$ MPa), parameters of the trilinear softening curve ($\xi_1 = 0.006$, $\alpha_1 = 0.5$, $\xi_2 = 0.1$, $\alpha_2 = 0.05$, $G_{f,1} = 0.05$ N/mm, Figure 5a), parameters of the shear softening curve ($\beta = 0.5$, $\tau_{cr} = 0.5$ MPa, $G_{f,s} = 0.025$ N/mm, Figure 5b), and the threshold angle ($\theta_{th} = 30^\circ$) were maintained constant for all analyses. Conversely, the concrete compressive and tensile strength varied for the three beams to reflect the values obtained from the experimental characterization. The modulus of elasticity of the reinforcement was 46 GPa.

Figure 5 Concrete softening diagram for fracture mode: (a) I and (b) II

Figure 6 shows a comparison between experimental and numerical analyses. In particular, Figures 6a-c show the deflection calculated under the loading point as a function of the applied load, while Figures 6d-f compare the crack patterns observed experimentally at failure with those obtained numerically (only fully open cracks are represented, i.e. their energy exceeded the specific fracture energy).

Figure 6 Comparison of experimental and numerical results: Load – deflection curves for beams (a) GB58 (b) GB54 (c) GB56, Crack pattern (d) GB58 (e) GB54 (f) GB56

The experimental shear failure was well captured by the numerical simulations while the stiffness of the overall load-deflection response was generally over-estimated. The higher predicted initial stiffness can be attributed to the fact that a certain degree of initial cracking was already induce in the specimens during the setup operations.
In the elasto-cracked stage, the stiffness of specimen GB58 (smallest effective depth) was well captured, while the stiffness of specimens GB54 and GB56 deviated from the experimental results. In particular, the higher the effective depth, the higher the deviation between numerical and experimental stiffness, suggesting that this phenomenon was not being well captured by the constitutive model. To account for this effect, the parameters defining the crack shear softening diagram, mainly fracture mode II, should directly consider the crack opening.

CONCLUSIONS

The results from a first phase of an experimental programme on size effect of shear critical FRP RC beams have been reported in this paper. A 3D-DIC was employed to enable a more accurate assessment of the local cracking and deformation behaviour throughout the whole load history. A FEM numerical model was developed to try and capture the behaviour of the tested beams as well as the crack development.

The experimental tests confirmed that beam depth plays an important role in determining the shear behaviour of FRP RC beams, which can already be significant for a change in overall depth from 260 mm to 360 mm (typical of most laboratory tests).

Although only preliminary results were presented for the analysis of crack development using DIC, this promising measuring technique can enable a better understanding of local deformation phenomena and could be used to obtain critical damage parameters to inform the development of more reliable numerical models, which still to date cannot simulate the complex behaviour of concrete elements subjected to brittle failure modes.

ABSTRACT

Recently, much research efforts has been directed towards investigating the shear behavior of concrete beams reinforced with fibre reinforced polymer (FRP) bars. However, there is still a demand for more studies to solve this issue, especially in the case of high strength concrete (HSC) members. This paper presents an experimental study about the shear behavior of HSC beams longitudinally reinforced with carbon fibre reinforced polymers (CFRP) bars. A total of thirteen simply supported HSC beams with or without steel stirrups were fabricated and tested under four-point monotonic loading until failure. A rectangular cross section of width (b=120 mm) and effective depth (d=224 mm) is adopted for all beams. The main investigated parameters include the shear span-to-depth ratio (a/d), the longitudinal reinforcement ratio (ρf%), the transverse reinforcement ratio (ρv%), and the longitudinal reinforcement type (conventional steel bars or CFRP bars). All beams were designed so that failure would occur due to shear. The mode of failure, the cracking load, the ultimate shear strength, and the midspan deflection are presented. It was found that the shear failure of HSC beams reinforced with CFRP bars occurs without warning; this may be attributed to the low elasticity modulus of CFRP bars. Addition of longitudinal steel bars to the flexural reinforcement of the tested beams improved both their ultimate shear capacity and their ductility. The ultimate shear capacity is basically dependent on a/d and ρv%.

CFRP bars, high strength concrete, shear, experimental, monotonic loading.

INTRODUCTION

The use of fibre reinforced polymer (FRP) bars in reinforced concrete (RC) members has become extremely popular in the last decades as they provide anticorrosive alternative for steel reinforcement in addition to their high strength-to-weight ratio. FRP bars have superior tensile strength compared to steel; they behave in a linearly elastic manner up to failure (ACI 440.1R-06). This makes the concrete reinforced with FRP bars more susceptible to brittle failure especially when used in high strength concrete (HSC) members. The use of HSC is rapidly increasing in buildings, bridges, and other structures due to its superior strength and stiffness. The use of HSC in combination with FRP reinforcement allows a better use of high stress and strain properties of FRP bars. However, an increase in the strength of the concrete produces an increase in its brittleness and smoother shear failure surfaces leading to a reduction in the contribution of aggregate interlock and hence a reduction in the shear force carried by concrete. These combined effects can ultimately lead to brittle shear failures. Several studies on the shear capacity of FRP reinforced members without shear reinforcement have indicated that the shear strength is influenced by the stiffness of the tensile reinforcement, the shear span to depth ratio, the tensile strength of concrete and the depth of the member (Sonobe, et al., 1997; Michaluk, et al., 1998; Tureyen; Frosch, 2003; Gross, S., Yost, et al., 2003; Ashour, A., 2006; Alam, M. S., 2010; El-Sayed, 2006b and Razaqpur, et al., 2011). The behavior of FRP bars is brittle with no yielding at failure. Since the shear capacity prediction is essential in the design of FRP reinforced concrete members, the ACI 440.1R-06 guide recommends that such members be designed as over reinforced sections and recognizes that the shear behavior of FRP reinforced concrete members should be carefully studied. Generally, the shear behavior of FRP-RC members is similar to that of steel-RC ones except for some differences attributed to the difference in properties of both materials. Differences include the modulus of elasticity, E, surface bond characteristics and the anisotropic nature of the material. Due to relatively low modulus of elasticity of FRP bars, concrete members reinforced with FRP bars develop wider and deeper cracks than members reinforced with steel having the same amount of reinforcement. Finally, the overall shear capacity of concrete members reinforced...
with FRP bars as flexural reinforcement is lower than that of concrete members reinforced with steel bars with the same amount of tensile reinforcement.

**RESEARCH SIGNIFICANCE**

With the increased popularity of using FRP bars in HSC members, a better understanding of the behaviour of such structural elements is emerging to achieve powerful and economical design methods. This study explores experimentally the effect of using HSC with FRP bars on the shear behavior of HSC beams with/without transverse shear reinforcement (stirrups). This was obtained through the experimental observations and test results related to the cracking behavior, shear failure mechanisms, ultimate shear strength $V_u$, and the midspan deflection.

**EXPERIMENTAL INVESTIGATION**

The experimental program in this paper includes thirteen HSC beams. CFRP and conventional steel bars were used in reinforcing the concrete beams. All beams have high strength concrete ($f_c = 47.07$ MPa). Beams were designed according to the ACI 440.1R-06 to fail due to shear not due to flexure. All beams were simply supported and tested under four-point monotonic loading until failure. The main investigated parameters include the shear span-to-depth ratio (a/d), the longitudinal reinforcement ratio ($\rho_f \%$), the transverse reinforcement ratio ($\rho_v \%$), and the longitudinal reinforcement type (conventional steel bars or CFRP bars).

**Materials**

Locally produced materials are used: fine aggregates composed of harsh desert sand, crushed bazalt, ordinary Portland cement, and tap drinking water. A high range water reducing admixture (Sikament R2008) was used to enhance workability and increase the early strength. Moreover, silica fume was used to get high strength concrete mixes. The target compressive strengths of the concrete were 47.1 MPa after 28 days. Table 1 gives the proportions of the mix used in this study. Six concrete cubes 150 x 150 x 150 mm were cast from each concrete batch and cured under the same conditions as the test beams. Three cubes were tested in compression after 28 days, while the other three ones were tested at the same day of testing beams. At the age of beams testing, the average compressive strength of the cubes was 58.9 MPa (equivalent to cylinder strength, $f_c = 47.1$ MPa). High-grade deformed steel bars were used as longitudinal reinforcement, while normal mild steel bars were used for stirrups. The used CFRP bars in this study were provided with ribs during manufacturing as shown in figure 1 in order to enhance the bond between the bars and concrete. CFRP bars were in two sizes (10 and 12) mm diameter. The characteristics of the CFRP and steel reinforcement used in this study are summarized in Table 2. Tests were carried out to determine the properties of the used materials according to the standard specifications, the obtained results were compared with the limits given in these specifications.

SPECIMEN DETAILS AND TESTING

The tested beams were arranged into four groups according to the variables. The group details are presented in Table 3. All beams had a rectangular cross section of width \(b_w=120\) mm and effective depth \(d=224\) mm. All beams had a 200 mm overhang length behind the supports on each side as anchorage length to avoid premature bond failures as presented in Figure 2. The shear span for group (1) ranged from 225 to 675, providing \(a/d\) of (1, 1.5, 2, and 3). Mild steel was used for transverse shear reinforcement for group (2) with ratios \((\rho_v\%) = 0.0, 0.22, 0.41,\) and \(0.64\). Group (3) consisted of four cases of main longitudinal reinforcement bars (Steel, CFRP, 2 CFRP +1 Steel and 1 CFRP +2 Steel). CFRP and steel were mixed in these tests in order to take the advantage of the higher stiffness of steel while keeping at the same time the higher tensile strength of CFRP. The beams of group (4) had a different longitudinal reinforcement ratio \((\rho_i = 0.584, 0.841, 1.262\) and \(1.682\%\)).

Midspan vertical deflections of beams were measured with LVDT installed at the front side at the middle of the beam. The LVDT were mounted on a metal frame clamped to the lower portion of the bottom of the beam and distributed to obtain the deflection profile of each beam. Concrete strain gages were installed at the maximum compression location of the specimen to monitor the compressive strain during testing. All instrumentations were checked and zeroed prior to the start of testing. The beams were subjected to a four-point monotonic loading up to failure at a rate of 0.5 V/min. During the tests, the development of crack patterns was marked on the beam surfaces with a black felt pen. Photographs were taken before and after failure. Loads, deflections and strains were scanned automatically until the end of the test by the data acquisition system.

Crack Patterns and Modes of Failure

During the test, the growth of cracks was marked for each beam. This was carried out to identify the direction of cracks propagation and to determine the differences in cracks patterns of the beams. The slope of the inclined crack at failure is listed in Table (4). For all beams, the first flexural cracks initiated at the bottom of the beam in the constant moment region, where the flexural tension stress was maximum and the shear stress was zero. The observed flexural cracks propagated vertically upward to the level of the neutral axis, which reflected the absence of shear stresses. As the load increased, additional flexural cracks developed within the shear span. Due to the presence of shear stresses, these flexural cracks became progressively more inclined and propagated towards the load points. These types of cracks are known as flexural-shear cracks. These cracks extended rapidly through the beam leading to the so-called a diagonal-tension failure. The duration between the formation of an inclined crack and failure of a beam was small. This behavior was observed for most of the beams in the current study. For beams with different a/d, the slope of the inclined crack decreased as a/d increased. This is attributed to that at a certain shear load, the moment as well as the flexural stress increase as a/d increases. Higher flexural stress could lead to the reduction in the inclination of shear cracks. Hence, the horizontal projection of the inclined cracks increased with an increase in a/d. The loads of initial flexural cracks and initial shear cracks decrease as a/d increases. The cracking and the ultimate loads increase as a/d decreases. The increase of steel stirrups ratio ($\rho_v$%) enhances the ductility of beams and changes the mode of failure from brittle failure to ductile one. A secondary concrete splitting failure within the shear span at the level of the longitudinal reinforcement was observed in beam "1C2S-1.5-V1-R3". This phenomenon of longitudinal splitting along the main reinforcement occurred immediately after the formation of the critical diagonal shear crack. Due to the smoother surface of the shear crack of HSC beams, the
contribution of aggregate interlock in transferring shear stresses becomes less significant resulting in higher dowel forces in the longitudinal reinforcing bars crossing the crack. These higher dowel forces cause higher vertical tensile stresses in the concrete surrounding the bars. These tensile stresses combined with the existing bond stresses result in concrete splitting failure along the longitudinal bars.

**Cracking and Ultimate Loads**

Figure 4 and Table 4 show that the ultimate shear capacity increased significantly with decreasing a/d. It can be noticed from the figures that the increase in a/d from 1.0 in beam "C-1.0-V1-R2" to 3.0 in beam "C-3.0-V1-R2" caused a reduction in the ultimate shear capacity by approximately 72%. The decrease in the ultimate shear strength with increasing a/d can be attributed to the fact that the tied arching action becomes less effective with increasing a/d because of the reduced angle between the inclined strut and longitudinal axis of the beam. The decrease in a/d reduces the distance between the supports and the applied loads and hence increases the effectiveness of the arching mechanism by transmitting a greater part of load directly to the support by diagonal compression. This was confirmed by many authors (Razaqpur, et al., 2004, El-Sayed, et al., 2006a, and Razaqpur, et al., 2011). From Table 4 and Figure 4 it is observed that the values of the ultimate shear strength increased linearly as ρv% increased. This increase in the shear strength was due to the improvement in the shear transfer mechanisms. It was unexpected to observe that the ultimate shear capacity of the beam reinforced with steel were slightly lower than that of the counterpart reinforced with CFRP bars as shown in Figure 4 and Table 4. This result contradicts the general expectation, that due to the relatively low modulus of elasticity of FRP bars, the FRP-reinforced concrete beams experience reduced shear strength in comparison to those of beams reinforced with the same amount of conventional steel bars. In fact, the modulus of elasticity was not the only difference between the steel and FRP bars used in this investigation. There was another parameter which may cause this result. This parameter was the difference between the tension strength of CFRP and conventional steel bars. As a result, the arch action developed in the FRP-reinforced beams was more efficient than that developed in the steel-reinforced beams. The more efficient the arch action is, the higher the ultimate shear strength will be. The efficient arch action in the FRP-reinforced beams was to the extent to overcome the difference in the modulus of elasticity between FRP and steel bars, resulting in slightly higher ultimate shear strengths in the beams reinforced with CFRP bars than those of the beams reinforced with steel. The increase in reinforcement ratio by approximately 188% (from 0.584 to 1.682%) increased the ultimate shear strength by 43%. This increase in shear strength was due to the improvement in the shear transfer mechanisms. Increasing the reinforcement ratio decreased the penetration depth in the compression zone of the shear cracks and decreased their width. This, in turn, increases the contribution of aggregate interlock as well as the contribution of un-cracked concrete by increasing the area of concrete compression zone. In addition, increasing the reinforcement ratio increased the dowel capacity of the member by increasing the dowel area, thereby reduced the tensile stresses induced in the surrounding concrete. This was in agreement with a previous work by El-Sayed, 2006b

**Load Deflection Behavior**

The measured values of midspan deflection at the bottom surface of the tested beams were plotted against the corresponding applied load from zero to failure as shown in Figure 2. Table 4 gives also the values of the midspan deflection at failure for each beam. It is observed that the shear load deflection behavior of all tested beams was linear. This linear behavior continued until failure because of the stiffness of the beams remained constant while the formed cracks grew and new cracks developed in the shear span zone. This is due to the linear elastic characteristic of CFRP bars. It is observed that, decreasing a/d in beams from 3.0 to 1.0 led to a reduction in the maximum midspan deflection from 9.5 mm to 4.0 mm. Also, the lower the a/d, the steeper the load-deflection curve. This may be attributed to the fact that when a/d decreases, the beam becomes more rigid. It is observed also that the cracking and ultimate load values and the maximum deflection decrease as ρv% decreases. This means that as the stirrups increased in the beam, the ductility of that beam increases. At the same load level, and as expected, the deflection of the beams decreased as the axial stiffness of the reinforcing bars increased, irrespective of the reinforcement type.

**CONCLUSIONS**

The present study investigated the shear behavior of HSC beams reinforced with CFRP bars. The experimental study carried out included testing thirteen high strength concrete beams to investigate the factors affecting the shear behavior of HSC beams reinforced with FRP bars. The major test variables were: the shear span to depth ratio, (a/d); the longitudinal reinforcement Ratio (ρl %); the shear reinforcement ratio (ρv %) and longitudinal reinforcement type (CFRP and High tensile steel). Based on the experimental observations and the analysis of the test results, the following conclusions were drawn:
1) The increase in a/d from 1.0 to 3.0 led to a reduction in the ultimate shear capacity by approximately 72%.
2) For beams with different a/d, the slope of the inclined crack decreased as a/d of the beam increased.
3) The increase in $\rho_v$% enhances the ductility of beams and changes the mode of failure from brittle failure to ductile one.
4) It was unexpected to observe that the ultimate shear capacity of the beam reinforced with steel bars were slightly lower than that of its counterpart reinforced with CFRP bars. This may be attributed to the higher tensile strength of CFRP bars.
5) The increase in reinforcement ratio by approximately 188% (from 0.584 to 1.682%) increased the ultimate shear strength by 43%.
6) Using steel bars at the same time with CFRP bars as longitudinal reinforcement enhances the ultimate shear capacity of the tested beams and enhances their ductility.
7) The decrease in a/d from 3.0 to 1.0 led to a reduction in the maximum midspan deflection from 9.5 mm to 4.0 mm. Moreover, the lower the a/d, the steeper the load-deflection curve.
8) As $\rho_v$% increases, the ductility of the beams increases.
9) As expected, the behavior of beams with steel reinforcement was different from the other beams that reinforced with CFRP. A yield stage occurred in beams with steel reinforcement due to the yielding of steel reinforcement, while in beams that reinforced with CFRP the load deflection curve was linear. This is due to the linear elastic characteristic of CFRP bars.
10) Generally, HSC beams reinforced with CFRP bars can achieve shear strength values comparable to or higher than that of similar steel-reinforced beams.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the sincere assistance provided by Dr. Mohamed Fathy Fahmy, the assistant professor at Assiut University, Egypt (Currently, a research Fellow, International Institute for Urban Systems Engineering, Southeast Univ, Nanjing, China). Dr. Mohamed's effort in importing CFRP bars from China is highly appreciated.

ABSTRACT

With the increasing traffic loading and large variation of environmental temperatures, deteriorations of expansion joints between simply supported spans cause structural repeated maintenance and high repair costs. The focus of this study is to study the behaviour of a link slab element, which can be used as a joint between two adjacent structural components. In this joint system, a ductile Engineering Cementations Composites (ECC) link slab reinforced with Fibre Reinforced Polymer (FRP) grid is proposed for replacing the conventional expansion joint. The requirements on the link slab in terms of material properties and reinforcement with FRP grid. This research herein describes the study of mechanical performance of different mixtures ECC specimens and the mechanical properties of FRP grid. The experimental variables include the volume of different type powder, sand ratio, water-cement ratio and tensile strength of FRP grid. Subsequently, the test results of the flexural behaviours of reinforced ECC test specimens were presented and discussed. It was shown the ductility and cracking behaviour of ECC.

ECC, FRP grid, link slab, mixing procedure, ductility.

INTRODUCTION

Large scale highway and superhighway infrastructure remains a backbone of national and international trade supporting the economies of both highly developed and developing nations worldwide. However, to allow the condition of infrastructure is allowed in many continue to become exceedingly poor, mainly due to a persistent lack of funding, increasing traffic volumes, and heavier loads on road ways (Lepech M.D. 2009). Many highway bridges are composed of multiple span steel girders simply supported at piers or bents. A mechanical joint is typically employed at the end of the simple span to allow deck deformations imposed by girder deflection, concrete shrinkage, and temperature variations (Yun Y.K. 2004). Many infrastructure maintenance and repair meth-odds have been proposed and instituted, ranging from the use of high strength concrete (Kim et al.2001) to the use of epoxy coated reinforcing steel (Zahrani et al.2002) on bridge decks, each with varying degrees of success. However, none of these solutions target the inherent shortfall of concrete brittleness, which results in cracking with the applied load. The crack width is difficult to be controlled in a reliable manner, typically allow salt water to contact the reinforcing steel, could cause series structural deterioration subsequently. It is well known that it is costly to install and maintain bridge deck joints (Wolde-Tinsae et al.1987). Deterioration of joint functionality due to debris accumulation can lead to severe damage in the bridge deck and substructure. Alampalli and Yannotti found that the jointless deck construction practice is generally more efficient than integral bridge construction practice (Alampalli, S et al.1998).

Engineered Cementitious Composite (ECC) is a high performance fiber reinforced cementitious composite designed to resist tensile and shear force while retaining compatibility with normal concrete in almost all other respects (Li. 2002). Recent research on ECC has shown that this material is highly durable and well suitable for
large infrastructure applications. After first cracking, the composite undergoes plastic yielding and strain-hardening to a tensile strain of 3.7% prior to developing a macroscopic crack. The tensile strain capacity of ECC is about 380 times that of normal concrete. Especially, crack width of ECC material develops between 50μm and 70μm during early strain hardening stages and remain at that width under additional tensile strain up to failure. The goal of this research is to provide a cost-effective solution to bridge deck deterioration problems associated with joints, by developing durable and maintenance-free ECC link slabs used in jointless bridge decks. Thus, the introduction of ECC to link slab construction is proposed for its ability to control crack widths and its processing flexibility. Link slab of ECC reinforced with FRP grid is shown in Figure 1.

![Figure 1](image)

Figure 1 Link slab of ECC reinforced with FRP grid

This research herein describes the study of mechanical performance of various ECC specimens with different mixtures, mechanical property tests of CFRP grid and flexural properties of slabs. The experimental of bending variables include the volume of different type of powder, water-cement ratio, the mechanical property of FRP grid. In this article, the ECC reinforced with FRP grid was discussed through bending tests to find out advantages of the combination of these two materials.

**EXPERIMENTAL PROGRAMME**

**Properties of PVA Fiber and Tensile Test of FRP Grid**

Large scale laboratory testing of ECC link slabs was conducted by Kim et al. (2001) to investigate the load capacity and fatigue performance of ECC link slabs, along with the development of cracking on the tensile face of the ECC link slab (Wang et al. 1997). Kim found that ECC material was a suitable choice for construction of link slabs to replace conventional mechanical expansion joints. In order to obtain higher corrosion resistance and durability, polyvinyl alcohol (PVA) fiber was used in this article. It was found that the high modulus polyvinyl alcohol (PVA) fiber have remarkable effect on the improving strain-capacity of ECC than polypropylene (PP) fiber (HR Pakravan et al. 2016). The fibers are produced by the company of Kuraray and properties of PVA fiber are shown in Table 1.

![Table 1 Properties of PVA fiber](image)

![Figure 2](image)

Figure 2 FRP Grid

![Figure 3](image)

Figure 3 Tensile Test
In order to develop new type of anti-cracking technique for ECC link slabs, a new cementitious composite reinforced by a combination of carbon textile and PVA fiber was proposed. FRP grid was placed along the direction of principal stress so that the reinforcing effect can be significantly enhanced. The FRP grid used in this test was shown as Figure 2. The tensile behaviour of this FRP grid was obtained by the direct tensile test (see Figure 4). The maximum tensile strength of the FRP grid is 1.56 N/mm² according to the test results.

**Mixing Process and Mix Proportions of ECC Specimens**

The dispersion of fiber is one critical factor for the workability of ECC. The mixing process of ECC in this paper is illustrated in Figure 2, which is beneficial for the dispersion of fiber. In the process of mixing, adding superplasticizer and water should be in advance to make sure the degree of dispersion of PVA fiber. Thereafter, PVA fiber was added evenly into the cement-sand mortar to make sure the magnitude of the stirring.

![Figure 4 Mixing process of this test](image)

Based on the property requirements of ECC material for link slabs, a number of mix proportions were adopted based on the design criteria, as shown in Table 2. The experimental variables include the volume of different type powder, sand ratio and water-cement ratio. At the same time, a control group of concrete was set up. The compressive strength is 35MPa.

![Figure 5 Steel framework of ECC slabs](image)  
![Figure 6 Three-point loading test](image)

**Specimen Preparation and Bending Test**

According to the previous experimental studies (Alp Caner et al. 1998), the link slab is in bending and behaved similar as a flexural component rather than a tension member and the crack at the center of slab did not extend to
the bottom face of the slab. In order to analyze the bending performance of link slab, a series of ECC slabs were designed and tested. The size of ECC slab was determined to be 15mm × 100mm × 400mm (see Figure 5) based on the research in the literatures. In the study, a three-point loading test was carried out to investigate the bending behaviour of all the ECC slabs according to the ASTM code (see Figure 6).

**DISCUSSION OF EXPERIMENTAL RESULTS**

**Flexural Properties of Concrete and ECC Slabs**

The bending test results show that ECC slab possesses ultra high flexural ductility, as shown in Figure 7, and have saturated multiple-cracking capability than concrete slab. The mid-span deflection of ECC slab is 133 times than concrete slab (see Figure 8). In addition, the volume of limestone flour has an effect on the deflection of mid-span. Increasing 10% limestone flour in the mixing resulted in 18.8% enhancement of the flexural capacity of ECC slab (see Figure 9). On the other side, as shown in Figure 10, the use of silica fume result in an increase of the cracking load by 46.3% and improve the cracking behaviour of pure bending zone, but declined the flexural capacity by 9.5%. Therefore, it can be summarised that the application of mineral powder (limestone and Silica) has a significant effect on the ductility of ECC materials, which is also presented by other researchers (Shuxin Wang et al. 2007). It is necessary to develop a further study of the influence of mineral powder on the micro-crack and bending capacity of ECC link slab.

**Influence on FRP Grid on the Behaviour of ECC Slabs**

Figure 11 illustrates the comparison of load vs. deflection response of the ECC slab reinforced with FRP grid in the middle layer and that without any reinforcement. It is found that the increase of flexural capacity of the reinforced ECC with FRP grid is 1.7% (see Figure 11). As shown in Figure 12, ECC reinforced with FRP grid can improve the cracking behaviour of ECC, cracks of slabs become finer and the spaces between closer. In addition, it is shown that average crack width of reinforced ECC slab is 78.8μm in pure bending zone, while the average crack width of ECC slab is 118.2μm (see Figure 13). It is found that the using of FRP grid as reinforcing material resulted in increasing the corrosion resistance and bending stiffness of ECC component.
CONCLUSION

This study is to investigate the potential of a durable concrete bridge deck system with the use of ECC material in link slabs. These trial mixes confirmed that large scale mixing of ECC material is possible and could result in a material that maintained its high performance in large quantity processing with conventional ready-mix equipment. According to the result of experiments, mineral powders determine the bending capacity and the micro crack develop of ECC slabs. It is evident in the test results that the application of mineral powder (limestone and Silica) has a significant effect on the ductility of ECC materials, increasing 10% limestone flour in the mixing resulted in 18.8% enhancement of the flexural capacity of ECC slab. ECC with high volume limestone flour have better work performance compared to that with small volume limestone flour. The use of silica fume could increase the crack load by 46.3% and improve the cracking behaviour of pure bending zone, but decline the flexural capacity by 9.5%. ECC slab reinforced with FRP grid results in better cracking behaviour observably, but have finite influence on ductility. The application of FRP grid as a reinforcing material in ECC slabs has a beneficial effect on the structural behaviour of this structural component.

REUSE OF WASTE GFRP COMPOSITES AS COARSE AGGREGATES FOR CONCRETE

L.C. Bank, A. Yazdanbakhsh, C. Chen and Y. Tian
Department of Civil Engineering
Grove School of Engineering
City College of New York
New York, NY, USA

ABSTRACT

The use of production waste FRP fully-cured parts (not scrap fibers or resin systems) as replacements for large (coarse) aggregate in concrete mixes is discussed in this paper. A preliminary study consisting of two series of tests using production waste pulltruded FRP reinforcing bars were conducted. FRP Bars ranging from 6 mm to 25 mm in diameter were cut into cylindrical aggregate-sized pieces and used as a replacement for the coarse aggregate in normal strength (~30 MPa) and high strength (~40 MPa) mixes in natural aggregate replacement percentages of 5, 10, 40 and 100%. Mixes were graded according to ASTM standards. 100 × 200 mm and 150 × 300 mm standard test cylinders were produced and tested for compressive strength, tensile (splitting) strength, and compressive stiffness. Strength and stiffness data are presented and compared with ACI and EU2 predictions. Images of failure modes and failure surfaces as a function of the replacement percentages are provided. The significance of these results on the possible use of aggregate pieces obtained by processing GFRP waste from FRP wind turbine blades and FRP boats are discussed.

KEYWORDS

FRP waste, FRP recycled aggregates, FRP rebars, concrete strength, concrete stiffness.

INTRODUCTION

In recent years there has been an increasing body of research, and industry concern, related to recycling or reuse of FRP composites (Job, 2013; Bank and Yazdanbakhsh, 2014; Oliveux et al., 2015). Three primary methods to dispose of FRP composites exist at the present time, (1) disposal in a landfill, (2) incineration, and, (3) reusing all or part of the composite material in a secondary process or application. Methods (1) and (2) are already prohibited in a number of countries. Reuse can consist of (a) recovery of the constituent fibers or the resins by thermo–chemical methods, (b) use of small pieces or particles of FRP material itself by cutting and grinding, or (c) use of large parts or even the entire FRP part in a different application. This paper focuses on method (b) and exclusively on glass fiber reinforced thermosetting polymers (GFRP).

In the near future significant FRP waste will come from the wind power industry (Cherrington et al., 2012, Ortegon et al., 2013) and the marine industry (Marsh, 2013). The rapid growth in wind energy technology in the last 15 years has led to a commensurate rapid growth in the amount of FRP materials used in this industry. The Global Wind Energy Council (GWEC) reports that 432 GW of wind power was installed as of the end of 2015; China 145 GW, USA 74 and Germany 44 leading the world. One wind blade of a typical 2.5 MW turbine is 50 m long, contains approximately 8 tonnes of FRP material, and costs about $150,000. By 2035, 4.2 million tonnes of wind blade (based on a 2015 installed capacity of 432 GW of wind power) will need to be recycled.

In this study GFRP waste from commercially produced GRFP reinforcing bars for concrete structural members were used as coarse aggregate for structural concrete as a replacement for natural aggregate. The use of FRP recyclates in concrete as ground filler has been studied for a number of years (Yazdanbakhsh and Bank, 2014). However, very little work has been reported on the use of large (5 mm to 25 mm) aggregates from recycled FRP in concrete. The benefits of using larger FRP aggregates from FRP waste are hypothesized by the authors to be due to (1) the ability to grade the aggregates when they are cut to specific sizes, (2) the ability to preserve the composite nature of the FRP which is lost when it is ground to a fine power to be used as filler, (3) the ability to save on energy cost when reducing FRP waste parts to larger pieces, and, (4) the ability to reduce environmental
pollution due to pulverizing or incinerating the FRP material. The reported study represents the initial phase of this work in which waste FRP reinforcing bars were used as coarse aggregates. Current work using waste FRP in different shapes and sizes from end–of–life wind turbine blades, boats and pultruded profiles is underway.

**EXPERIMENTAL INVESTIGATION**

**Mix Designs**

Two separate series of test programs were conducted. Series 1 consider of concrete mixes with high percentages (100, 40) of FRP Recycled aggregate (FRP–RA) and Series 2 consider of concrete mixes with low percentages of FRP–RA. In Series 1 both high strength and normal strength concrete mixes were considered. The mix designs are shown in Table 1. Note that different compositions (sizes of aggregates) of the FRP–RA were used in different mixes to investigate different aspects of behavior in this preliminary study.

The results show that in Series 1 the compressive strength of the FRP–RA specimens is reduced by 13 to 21% relative to the NA control for both the normal and high strength concrete, while the splitting strength is reduced by 25 to 35% for the normal strength mix and only 11 to 20% for the high strength mix. In Series 2 the
Compressive strength reduction was between 3 and 6% and the splitting strength between 9 and 0%. Counter to expectations the reductions were larger for the 5% replacement than the 10% replacement which casts doubts on the integrity of the Series 2 results. In Table 2 the predicted splitting strengths shown in green color indicate that the measured strength is conservative while the red color indicates an unconservative prediction. It can be seen that Series 2 results were unconservative even for the NA mix designs. This also raises some question about the integrity of the results of series 2. Notwithstanding the results of Series 2 are reported since the mix proportions were quite different from Series 1 and the cylinder sizes were bigger so the results of are some interest. Images of the failed compression test specimens are shown in Figs. 4 to 6.

In Series 2 strain gages were bonded to the specimens to measure the compressive modulus of the specimens. The results are shown in Table 3 with comparison to the ACI predictions.

From Table 3 it is seen that the stiffness for the control mix (NC2) in Series 2 was less than the ACI prediction for compressive stiffness calculated from the measured compressive strength given in equation 3. The predictions for the FRP–RA mixes were conservative (and larger than the control mix). It appears the control mix was not well made.

$$E_{ACI} = 4,700 \sqrt{f'_c} \text{ (MPa)}$$  \hspace{1cm} (3)

Images of the splitting specimens are shown in Figs. 7 to 9 below. The darker color of the Series 2 specimens is due to the fact that they were wet before the photographs to provide visual contrast.

**DISCUSSION**

Detailed discussion of the test results for Series 1 are presented in Yazdanbakhsh et al., 2016. The reduced strength in the concrete with the FRP–RA is attributed to the bond in the interfacial transition zone (ITZ).
between the FRP–RA and the cement paste. Although the test results show a decrease in the compressive and the splitting strength when FRP-RA is substituted for NA in the specimens this is in a similar range, in many reported tests, to the decrease in strength seen when NA is replaced with conventional Recycled Concrete Aggregate (RCA) obtained from construction and demolition waste (CDW). In these series of tests, FRP reinforcing bars with helical wraps and sand-coated longitudinal surfaces, which are especially produced for developing bond to the concrete, were used. In cases where boat parts or wind blade parts need to be cut up and graded to produce FRP-RA all the surfaces are likely to be smooth. Engineering solutions to resolve this design issue will need to be developed in the future. Finally it is also important to point out that this research has not yet addressed the subject of the durability of the FRP–RA concrete.

ABSTRACT

Carbon Fibre Reinforced Polymer (CFRP) is an advanced composite material with advantages of high strength, lightweight, no corrosion and high fatigue resistance, which makes it suitable to be made into cables and replace steel cables in cable structures. However, anchoring CFRP cables is problematic, because CFRP is an orthotropic material, whose strength and modulus perpendicular to the fibre direction are considerably smaller than those in the fibre direction. To avoid the anchoring problem, a novel design, i.e. CFRP continuous winded band system, is proposed in this paper. Cables used in such system are CFRP continuous bands, which will be wound through all the intermediate nodes and only anchored at the both end nodes or which will form closed loops without any anchorage. The greatest advantage of the CFRP continuous winded band system is minimising necessary anchorages and thus exploiting to the full favourable conditions of CFRP cables and avoiding the unfavourable ones.

CFRP, cable, anchorage, continuous band, winding.

INTRODUCTION

Reviewing the history of cable structures, it can be found that the development of cable materials can significantly promote the development of structures (Liu 2015). Carbon Fibre Reinforced Polymer (CFRP) is an advanced composite material with advantages of high strength, lightweight, no corrosion and high fatigue resistance, which makes it suitable to be made into cables and replace steel cables in a broad range of applications (Schlaich et al. 2015).

The application of CFRP cables is now driving the progress of cable structures (Liu 2015). However, the CFRP is a typical orthotropic material, that is, its mechanical properties, such as the strength and the modulus, perpendicular to the fibre direction is considerably lower than those in the fibre direction. This makes CFRP cables difficult to be anchored.

This paper proposes a novel design, i.e. CFRP continuous winded band system, so as to avoid the anchorage problem of CFRP cables. The CFRP continuous bands are adopted in this system. They are wound through all the intermediate nodes and only anchored at the both end nodes or form closed loops without any anchorage. Several possible forms of such system are illustrated in this paper. In addition, state of the art and theoretical basis are first introduced.

STATE OF THE ART

Existing CFRP Cable Structures

Studies on CFRP cable structures can be dated back to the 1980s (Meier 2012). As early as in 1987, a CFRP cable-stayed bridge with a main span of 8400 m crossing the Strait of Gibraltar was proposed (Meier 1987). However, the first practical use of CFRP cables in a real cable structure was in 1996 in the Tsukuba FRP Bridge (Karbhari 1998). From then to now, there have been 10 CFRP cable structures over the world, even though all of them were built more or less as prototypes. The existing CFRP cable structures are listed in chronological order of completion in Figure 1 (Liu 2015).
In the above figure, No. 1 is the Tsukuba FRP Bridge (photo credit: Iwao Sasaki), which is a pedestrian cable-stayed bridge completed in 1996 and located in Tsukuba, Japan; all stay cables of this bridge are made of CFRP. No. 2 is the Stork Bridge completed in 1996 and located in Winterthur, Switzerland (photo credit: EMPA); it is a highway cable-stayed bridge and two of its stay cables are made of CFRP. No. 3 is the Neigles CFRP Footbridge (photo credit: Tokyo Rope); it is a pedestrian suspension bridge completed in 1998 and located in Fribourg, Switzerland and its two main cables are made of CFRP. No. 4 is the Herning CFRP Bridge completed in 1999 and located in Herning, Denmark (photo credit: COWI), which is a pedestrian cable-stayed bridge with all cables made of CFRP. No. 5 is the Laroin CFRP Footbridge (photo credit: Freyssinet), which is a pedestrian cable-stayed bridge with 16 CFRP stay cables and 2 steel back stays; it was completed in 2002 and is located in Laroin, France. No. 6 is the Jiangsu University CFRP Footbridge completed in 2005 and located in Zhenjiang, China (photo credit: Kuihua Mei), which is a pedestrian cable-stayed bridge with all cables made of CFRP. No. 7 is the Penobscot Narrows Bridge, which is a highway cable-stayed bridge completed in 2006 and located in Penobscot, Maine, USA (photo credit: MOT); in 2007, six steel strands in the stay cables of this bridge were replaced by CFRP strands. No. 8 is the EMPA Bowstring Arch Footbridge completed in 2007 and located in Dübendorf, Switzerland (photo credit: Urs Meier); all the bowstrings of this bridge are made of CFRP. No. 9 is the TU Berlin CFRP Stress-Ribbon Footbridge completed in 2007 and located in Berlin (photo credit: Achim Bleicher); all stress-ribbons in this bridge are made of CFRP. No. 10 is the Cuenca Stress-Ribbon Footbridge completed in 2011 and located in Cuenca, Spain (photo credit: Mike Schlaich); it is a pedestrian stress-ribbon bridge with all stress-ribbons made of CFRP.

Future Trend of CFRP Cable Structures

As seen from the above section, the existing CFRP cable structures are all cable bridges. Moreover, majority of them are cable-stayed bridges. Up to now, there is not yet any CFRP cable roof or facade in the world. Furthermore, studies on CFRP cable roofs or facades are also very few (Feng et al. 2007) (Liu et al. 2015).

However, cable roofs and facades are ideal structures for CFRP cables, because most of them are orthogonally loaded by external loads. In orthogonally loaded cable structures, the structural stiffness is mainly comprised of the geometric stiffness, which is induced by the pre-tension force in the cables. The elastic stiffness generated by the elastic modulus of cables is less important. For such cable structures, increasing the tensile strength of cables to increase the pre-tension force is a more efficient way to raise the structural stiffness than increasing the elastic modulus of cables. Using CFRP cables, whose tensile strength is considerably greater than that of steel cables (Schlaich et al. 2015), in orthogonally loaded cable structures can improve the economic efficiency, although the elastic modulus of CFRP cables is smaller than that of steel cables and their unit price is also much higher (Schlaich
et al. 2015). Consequently, using CFRP cables in cable roofs and cable facades should be a trend for future buildings.

To investigate the feasibility of applying CFRP cables to cable roofs and cable facades, a small CFRP spoked wheel cable roof was built at TU Berlin in 2013, which is shown in Figure 2 (Schlaich et al. 2014).

![Figure 2 CFRP spoked wheel cable roof prototype](image)

In this prototype, the radial cables are loop-shaped CFRP tension members and the tension ring is a closed octagon CFRP loop. The cross section of the radial cable and the tension ring is 30 mm × 1.2 mm, which can bear nearly 80 kN tension force. Both types of CFRP structural elements were manufactured at TU Berlin by hand through laminating a continuous carbon fibre tow coated with epoxy resin on a rotating form and using vacuum technique to harden. The material of the compression ring, pillars and nodes is aluminium. To pre-tension the CFRP cables, each node of the tension ring was separated into two semilunar parts, which are linked together by four bolts. By tightening the bolts and hence shortening the distance between these two parts, the CFRP cable system of the spoked wheel cable roof was pre-tensioned to a sufficient level and a very stiff system was achieved.

**THEORETICAL BASIS**

*“Pin-Loaded” Concept*

As noted earlier, the key problem facing the application of CFRP cables in cable structures is how to anchor them. The advantages of CFRP cables can only be valid if their mechanical properties (i.e. strength and modulus) are fully exploited (Schlaich et al. 2012).

The conventional CFRP cable anchorages can be classified into two types, i.e. clamp anchorage and bond anchorage (Liu 2015). The clamp anchorage, as its name suggests, is a type of anchorage relying on the clamp function, or more specifically, the friction force and/or the mechanical interlocking force, to anchor the CFRP
cables. The bond anchorages rely on the bond force to anchor the CFRP cables. Usually, the bond materials used are the resin-based mortar (e.g. epoxy resin) or the cement-based mortar (e.g. high-expansion cement). These two types of CFRP cable anchorages have already been used in some projects, such as 6 existing CFRP cable stayed bridges (Figure 1). However, these anchorages are usually large, complicated and expensive. This makes them unfavourable for some CFRP cable structures, especially for cable roofs and cable facades, which usually require relative small and cheap anchorages.

The pin-loaded anchorage is a relatively new anchorage system for CFRP cables, which is different from the clamp or bond anchorage, as shown in Figure 3 (Liu 2015).

As can be seen from the above figure, the main part of pin-loaded anchorage is only a pin or a thimble. CFRP cables are anchored through winding on the pin. With such “pin-loaded” design concept, the anchorage structure can be greatly simplified and the length of anchorage can be considerably shortened. Moreover, when the anchored CFRP cable is subjected to tension, the pressure will be generated between the CFRP cable and the pin, which will generate an extra friction force and help to anchor the CFRP cable. The pin-load anchorages are particularly well suited for anchoring CFRP cables in cable roofs and cable facades, where the structural spaces are usually too limited to place the clamp anchorages or the bond anchorages. Moreover, beams and columns with round cross sections in such cable structures can be pins themselves for the pin-loaded CFRP cable anchorages and thus leading to even smaller anchorage sizes and simpler anchorage structures.

“Continuous Winded Band” Concept

The “continuous winded band” is a novel form of using CFRP. This idea was inspired by the pin-loaded anchorage. However, the CFRP cable used in such system is the CFRP continuous band, which will be wound through all the intermediate nodes and only anchored at the both end nodes (see Figure 4) or which will form closed loop without any anchorages (see Figure 6). The greatest advantage of the CFRP continuous winded band system is that the number of anchorages is minimised and thus exploiting to the full favourable conditions of CFRP cables and avoid the unfavourable ones.

TYPICAL FORMS OF CFRP CONTINUOUS WINDED BAND SYSTEM

There are several possible forms of CFRP continuous winded band system. Two typical forms are introduced in this section. Apart from these two examples, the CFRP continuous winded band system is well suited for many other cable structures.

One Typical Form: Anchored at End Nodes
First, one typical form in which the CFRP continuous band is anchored at end nodes is illustrated in Figure 4, which is the cable system of the cable membrane roof for a swimming pool. The details of the CFRP continuous band used and the nodes are illustrated in Figure 5. (Liu 2015)

![Figure 4 Swimming pool cable roof with CFRP continuous winded band system](image)

As can be seen from the above figures, only one cable, i.e., a CFRP continuous band, is used in the structure. This makes the structure concise and aesthetically pleasing. Furthermore, the CFRP continuous band is wound through every intermediate node and only anchored at end nodes with pin-loaded anchorages.

**Another Typical Form: Closed Loop**

Another typical form in which the CFRP continuous band forms a closed loop without any anchorage is illustrated in Figure 6. The structure is a spoked wheel cable roof. The details of the CFRP continuous band used and the nodes are shown in Figure 7 (Liu 2015).

![Figure 6 Spoked wheel cable roof with CFRP Continuous Winded Band System](image)
As can be seen from the above figures, there are only two cables in the structure, i.e. a CFRP continuous band acting as the spoke cables and a CFRP inner ring. This CFRP continuous band forms a closed loop and is wound around all nodes without any anchorages.

**CONCLUSION AND PROSPECTATION**

This paper mainly presents the conceptual design of the CFRP continuous winded band system. Adopting such system, the number of the required anchorages will be significantly reduced or eliminated and thus making the best use of the advantages of CFRP cables and bypassing their disadvantages. Furthermore, cable structures with the CFRP continuous winded band system are very concise and aesthetic. Admittedly, except for the advantages, the CFRP continuous winded band system also has some disadvantages. For example, the failure of a single segment of the CFRP continuous band may result in the failure of the whole system; therefore, the safety factor for the CFRP continuous band might be set higher than that for ordinary cables.

In general, the CFRP continuous winded band system is an interesting and promising way of using CFRP in cable structures. More researches including the static and dynamic properties and the construction methods should be done for its realisation.

NEW FRONTIERS FOR THE USE OF FRP REINFORCEMENT IN GEOMETRICALLY COMPLEX CONCRETE STRUCTURES

2 Department of Architectural, Environmental and Civil Engineering, University of Miami, US
e-mail:s.spadea@bath.ac.uk

ABSTRACT

The development of flexible formwork has made it possible to cast optimised geometrically complex and thin walled reinforced concrete structures. At the same time, advanced composite materials offer the opportunity to solve the problem of steel corrosion, which can affect aging of concrete structures. With the goal of achieving sustainable design, being able to combine optimised geometries with durable construction materials is a major challenge for civil engineering.

New research at the University of Bath and the University of Miami aims to completely replace internal steel reinforcement in geometrically complex concrete structures with durable and ready-to-use cages made of fibre reinforced polymer (FRP) reinforcement. By fabricating the reinforcement in the desired geometry, it will be possible to provide the required strength exactly where needed, thereby reducing the amount of concrete required to resist internal forces and capitalizing on the extraordinary possibilities offered by both concrete and FRP construction materials.

The design of such optimized elements and the automated process of manufacturing the Wound FRP (W-FRP) reinforcement are presented in this paper.

KEYWORDS

W-FRP, RC beams, optimization, fabric formwork.

INTRODUCTION

Since its early age, concrete has been cast in rigid formwork, normally in the form of rectangular prismatic solids. Recent research has shown that nearly 40% of concrete that is currently used in building structures has little contribution to structural capacity, only adding extra self-weight to the building (Orr, Darby et al. 2011). Flexible formworks rely on the use of a system of flexible sheets of fabric to allow complex shapes to be easily cast, thus facilitating the construction of optimised concrete structures (Orr, Darby et al. 2011, Veenendaal, Coenders et al. 2011). This is crucial for the sustainable design of concrete structure, provided that the saving in material use directly lead to saving in embodied energy.

In addition to the great possibilities of building unconventional concrete geometries and reduce the material consumption, the use of fabric formwork offers a technological advantage. By casting concrete into a permeable fabric membrane, excess pore water is allowed to bleed from the concrete during curing. The resulting reductions of water/cement ratio in the surface zone of concrete elements bring improvements in durability (Price 1999, Orr, Darby et al. 2013).

Nevertheless, the need to assemble quite complex reinforcing cages together with the low durability of steel reinforcement in thin walled structures, are some of the reason why a large-scale deployment of this technology has not occurred yet.

The use of FRP as internal reinforcement can help to overcome these kind of issue. The substantial disadvantage inherent in the use of FRP reinforcement is related to onsite flexibility. Whereas steel reinforcement can easily be bent into an extensive range of geometries at the construction site, FRP reinforcement needs to be carefully shaped during manufacture according to the final demand. This challenge turns in favour of the pursuit of material
optimization, which require an increase in the level of control during the design and construction phases to produce complex geometries. Moreover, the terrific lightness of composite reinforcement suggests the opportunity to deliver prefabricated reinforcement cages to site, ready to be positioned and cast.

With all this in mind, coupling the geometric flexibility given by novel formworks systems with the enhanced durability offered by FRP reinforcement, gives the opportunity to depict a new paradigm of design for the reinforcement of concrete structures, aiming to pursue the sake of sustainability in the construction process. Further savings in emissions can be achieved using low-carbon cements, which further reduce the embodied energy of concrete. In fact, such cements cannot readily be used with steel reinforcement as they also reduce the alkalinity of the concrete mix. By contrast, a reduced alkalinity environment makes no difference when using a non-corrosive reinforcement, allowing the potential to achieve embodied energy savings through both geometry and material choices.

The present research aims to explore the possibility of fabricating FRP reinforcement in complex geometries by mean of an automated manufacturing system, in order to provide tensile strength exactly where it is needed by optimized RC structural elements. This will be transformative for concrete construction, as it will greatly simplify the design of more efficient, thin walled and architecturally daring concrete structures.

DESIGN PROCEDURE

Literature Review

FRP has excellent tensile properties in the direction of the fibres. Unlike steel, which exhibits yielding and plastic flow, it has a linear elastic stress–strain relationship. The Young’s modulus of FRP reinforcement is usually lower than steel as it is primarily dependent on the stiffness of fibre used (Nanni 1993). For this reason the serviceability limit states, rather than the ultimate limit states, are normally governing the design of FRP reinforced structures. In particular, the control of deflection is very often the most decisive check in the design process (Ascione, Mancusi et al. 2010, Nanni, De Luca et al. 2014). Additionally, the lack of yielding of the FRP reinforcement suggests the design of over reinforced sections, in order to obtain concrete crushing flexural failure and prevent sudden FRP rupture. This circumstance produces, in any case, an overall less ductile behaviour of FRP RC members as compared to steel RC members.

Another relevant design problem is modelling the mechanisms of shear resistance in FRP reinforced concrete members. Shear failure of reinforced concrete structures is brittle and it can be tremendously sudden and dangerous when dealing with FRP shear reinforcement (Matta, El-Sayed et al. 2013, Ascione, Razaqpur et al. 2014, Razaqpur and Spadea 2015). Furthermore, the most up-to-date design codes do not provide specific guidance to analyze the shear strength of non-prismatic concrete members (Orr, Ibell et al. 2014).

In order to develop a model that can efficiently predict the structural behaviour of such structural elements and consequently perform the structural optimization of fabric–formed concrete beams reinforced with FRP, a method of analysis with broad applicability was developed into a Matlab code. The geometry of the fabric formed member and the distribution of the reinforcement was modelled in a closed form allowing for considering variation in section dimensions along the members. The optimization criteria aim to obtain the minimal mass of concrete and observing the capacity design requirements as per the mostly recognized design codes (CSA S806 2012, CSA S6 2014, ACI 440.1R 2015).

Computational Method

The computational procedure followed can be briefly outlined as below:
1. Setting static scheme, structural materials, geometric limitations, design standard, capacity design requirements.
2. Finding the applied bending moments and shear stresses from the given loading.
3. Optimization for strength is carried out to find the profile of the beam which satisfy the ultimate limit states for flexure and maximize concrete contribution to shear strength. This is done dividing the section geometry and layout of the longitudinal reinforcement for each section.

At this point, a FRP RC fabric formed beam without shear reinforcement, optimized for flexure, is obtained.

4. The serviceability behaviour of the member is then assessed (elastic deflection, crack width and time dependent behaviour checks).
5. If the member fails to meet serviceability limit state conditions, the applied bending moments and shear stresses are virtually increased by a scaling factor, and the computational procedure go back to point 3 until point 5 is satisfied.

The reason for increasing the design stresses rather than performing a specific optimization process for serviceability is related to the willingness of observing the capacity design rules. At this point, a FRP RC fabric formed beam without shear reinforcement, optimized for flexure, and meeting the serviceability limit state conditions is obtained.

6. Optimization for shear strength is carried out to find the best geometry and the minimal quantity of web reinforcement which satisfy the ultimate states for shear. The web reinforcement geometry is limited to shapes that can be obtained by fibre winding, hence they may result in being a certain type of spirals. Also in this case the method is based on a sectional analysis.

At this point, a FRP RC fabric formed beam, optimized for flexure and shear strength, and meeting the serviceability limit state conditions, is obtained. The code is able to produce a STereoLithography (.stl output file) of the designed beam, which is suitable to embed all the information pertaining the geometry of the designed structural elements.

MANUFACTURING METHOD

As described in the following paragraphs, a computer controlled winding of impregnated carbon fibres around a set of FRP bars gave us the opportunity to obtain durable, lightweight, and ready-to-use reinforcement cages.

The manufacturing of web reinforcement is operated by means of a process based on the filament winding fabrication technique, which consist on wrapping continuous fibres under tension over a rotating mandrel. While the mandrel rotates, a wind eye on a carriage moves horizontally, laying down the fibres in the desired pattern. In the wet winding method, the fibre picks up resin either by passing through a resin bath or from a metered application system. In the dry winding method, the reinforcement is in the pre-impregnated form. After several layers are wound, the component is cured and removed from the mandrel. This method of manufacturing provides a great control over fibre placement and uniformity of the material structure and it is generally used to produce continuous hollow shapes with constant cross section.

In the present application, slightly curved CFRP bars, responsible for providing the flexural strength to the concrete beams, are attached to the mandrel according to the prefigured reinforcement geometry. A refined system of control allows the winding of a number of carbon tow layers in the form of spirals with variable cross section. After the winding and curing process occurs, the reinforcing bars are maintained in the curved configuration by the wound reinforcement.

The filament winding prototype, specifically designed and constructed at the University of Bath with the aim of producing this new class of reinforcing cages, is shown in Figure 1. The design includes the possibility of implementing either wet-winding, by means of a resin bath, or a dry-winding method.

In this work a continuous 50k carbon fibre tow (C T50-4.0/240-E100) produced by Sigrafil (SGL group) is adopted. The SGL Carbon tow is used in combination with Fyfe Tyfo S two-component epoxy to implement a wet-winding process. This class of epoxy resin, suitable for the wet-layup of external strengthening of structural members, can be applied at room temperature and air cured. Both are considerable advantages for this application as the resin bath does not need to be heated and the curing process can be simply operated by storing the cages at standard lab conditions for 48h-72h.

FLEXIBLY FORMED BEAMS

With the aim of validating both the optimization procedure and the W-FRP reinforcement cages manufacturing method, six FRP fabric formed beams were designed and cast. The beams are currently being tested at the University of Bath.
Assumptions

The adopted static scheme is a simply supported beam with three meters span and half-meter overhang on each side. The entire beam is subject to a uniformly distributed load.

Two different study cases were taken in consideration:

1) The first set of beams (Set I) is intended to simulate a precast fabric formed joist supporting a lightweight floor (e.g. all-FRP or wood floor).
2) The second set of beams (Set II) aims to reproduce the use of a precast fabric formed beam with an in-situ casting of a concrete floor. In the experimental work described below, the beam and the slab elements were cast together for ease of construction.

Additionally, the following assumptions were made for design purposes:
- The dead load and the live load are 2.5 kN/m and 7.5 kN/m, respectively;
- The strength class of concrete is C30/37;
- The bottom and top reinforcement are respectively #3 Carbon and #3 Glass FRP Aslan bars produced by Hughes Brothers.

Optimization Results

Table 1 shows a comparison of the most relevant details of the beams. A 3D visualization of the beam’s Stereolithography, as generated by the design code, is also shown in Figure 2.

Each set is composed of three beams having identical concrete geometry and longitudinal reinforcement but different W-FRP shear reinforcement. Whereas they all satisfy the points 1 to 5 of the above-mentioned computational procedure, only beams x.3 have the requested shear strength (point 6). In fact, beams x.1 and x.2 are purposely designed to exhibit a premature and sudden shear failure.

**Construction**

The essence of flexible construction is to secure the fabric on a supporting frame in order to achieve the desired form once the formwork is filled with concrete. In the present work, the fabric is draped into a plywood supporting frame to shape the non planar lateral surface of the stems whereas the control over the beam elevation is achieved using a keel, pre-cut to the desired elevation (Figure 3a).

Figure 3b shows the W-FRP cage of beam II.2 instrumented with strain gauges and installed into the fabric formworks before concrete casting.

EXPERIMENTAL INVESTIGATION

The experimental setup (Figure 4) consists of two simple supports and seven hydraulic jacks attached to a rigid frame, each one instrumented with a load cell. Five jacks are equally spaced on the 3000 mm beam span and powered by the same oil circuit, as to apply a load $P$. The remaining three jacks are installed at the ends of the cantilevers (500 mm long), and powered by a separate different hydraulic circuit in order to apply a load equal to $0.5 \cdot P$. This loading scheme allows to simulate a uniformly distributed load.

Seven displacement transducers are installed: one at the beam midspan, two at the supports, two at the quarters span and two at the ends of the cantilevers. Five cross-sections of the beams are instrumented with uniaxial strain gauges installed on the reinforcing bars and on the concrete (cyan sections in Figure 4) in order to monitor the flexural curvature of the beams. The wound reinforcing cages of beams x.2 and x.3 are instrumented with uniaxial strain gauges mounted on each leg included between the supports and the closer point load in the span (magenta areas in Figure 4). The front face of each beams is painted with a dotted bi-chromatic pattern. High resolution pictures, perpendicular to the observed surface, are taken at each 2kN increment throughout the entire loading cycle to enable subsequent analysis using Digital Image Correlation (DIC).

REMARKS AND FUTURE WORK

This paper presents an analytical tool able to show the potential of using bespoke CFRP reinforcement in RC optimised beam and the automated process of manufacturing the FRP reinforcing cages. Such structures have complex geometries, which are difficult to reinforce with conventional steel. The technical developments in this paper provide the basis for a novel alternative reinforcement technique that is well suited to automation and mass production.

The experimental validation is under development; hence some of the results will be presented during the CICE 2016 conference, in Hong Kong.

PERFORMANCE AND STRENGTH OF PULTRUDED GFRP ANGLE STRUTS
SUBJECT TO CONCENTRIC COMPRESSION

ABSTRACT

This paper aims to investigate performance and strength of glass-fiber reinforced polymer (GFRP) pultruded equal leg angles subject to short-term concentric compression. The background theory for a perfect angle strut is presented and the critical buckling stresses for two different boundary conditions are compared with those obtained with Generalized Beam Theory (GBT), showing good agreement. It is shown that, for typical pultruded GFRP with relatively low shear modulus, the influence of the flexure about major axis, shear and local deformations are negligible. The real column behavior is discussed and a column strength equation combining beam-column and classical plate theories is proposed to address the problem. Finally, the experimental results available in literature are compared with the lower-bound strength curve, leading to the conclusion that the method is adequate to predict ultimate load of angle struts, although more tests are needed for calibration of imperfection parameters.

KEYWORDS

GFRP, angle, column strength curve, flexural-torsional buckling, flexural buckling.

INTRODUCTION

Extensive research has been conducted worldwide on the behavior of pultruded columns and different strength curves have been proposed in literature (Barbero and Tomblin, 1994, Barbero and DeVivo, 1999, Seagatith and Sriboonlu, 1999, Puente et al., 2006, Cardoso et al., 2014a). However, major effort has been directed toward the performance of doubly symmetric sections, where an interaction between local and flexural global buckling modes governs the behavior. To date, few works have been focused on the compressive behavior of monosymmetric or asymmetric cross-sections and no provisions for these sections have been included in the current Italian code for design of pultruded members (CNR, 2008) and in the Prospect for the New Guidance in the Design of FRP (Ascione, 2016). The work of Zureick and Steffen (2000) remains the only dedicated to investigate the performance of pultruded angle struts, despite their intensive use as truss members (e.g. footbridges and braced frames). In that work, the authors tested 25 equal-leg angle columns having different width-to-thickness (b/t) ratios and lengths and recommended the nominal strength to be determined as the lesser of material compressive strength, flexural buckling and flexural-torsional buckling critical stresses. Additionally, the authors proposed design factors computed from reliability analysis of their experimental results. Their findings have been included in the draft for the future ASCE Pultruded Fiber Reinforced Polymer (ASCE, 2010). Although simple, this method does not represent the actual behavior, where imperfections are present and second-order stresses have to be considered. A recent approach proposed by Dinis et al. (2015) for design of steel thin-walled angle columns, for instance, take into account imperfections and interaction between buckling modes. This paper aims to complement Zureick and Steffen’s (2000) work by describing the real column behavior and proposing a strength curve that can be used to predict a lower bound member capacity.

PERFECT COLUMN

The term ‘perfect column’ adopted in this work refers to perfectly straight and undistorted members subject to a concentric compression force. For a perfect angle strut, three distinct and uncoupled failure modes may occur: flexural-torsional buckling, flexural buckling and material compressive failure. The two first modes are associated with instability limit state, while the latter occurs if the column material compressive strength is exceeded prior to buckling.
Crushing

The term ‘crushing’ generally refers to all collapse modes that may occur at the constituent material level of a fibrous composite material: elastic microbuckling, plastic microbuckling and fiber crushing (Fleck, 1997). Comprehensive closed-form equations for GFRP material crushing strength ($F_{cr}$) have been presented by Barbero (1998) and Barbero et al. (1999), but input data for the method are rarely presented in data sheets, tables and manuals provided by manufacturers. Recently, Cardoso et al. (2014b) proposed an empirical expression based on linear regression of mean experimental results obtained by various authors. Design codes usually specify minimum material compressive strength for structural application.

Flexural Buckling

The flexural buckling ($F$) about the minor axis may occur in relatively long struts and the critical stress, $F_{cr,Fy}$, is given according to the so-called Euler buckling equation:

$$F_{cr,Fy} = \frac{\pi^2 E_t}{(K, L/r_t)}$$

in which $E_t$ is the cross-section representative modulus of elasticity; $L$ is the column length; $K$ is the flexural buckling coefficient about the minor axis; and $r_t$ is the radius of gyration. It is important to mention that this expression does not consider shear deformation influence.

Flexural-Torsional Buckling

Flexural-torsional buckling ($FT$) is mainly characterized by a natural coupling of flexural buckling about major axis and torsion about shear center. This mode is likely to occur for thin-walled open cross-sections with low torsional rigidity and with shear center not coinciding with the centroid, e.g. angles and channels. The flexural-torsional buckling critical stress, $F_{cr,FT}$, for a monosymmetric section is given as (Timoshenko and Gere, 1961):

$$F_{cr,FT} = \frac{F_{cr,Fy} + F_{cr,T}}{2}\left[1 - \frac{4F_{cr,Fy}F_{cr,T}[(1-(x_0/L_t)^2)]}{(F_{cr,Fy} + F_{cr,T})^2}\right]$$

in which $x_0$ is the distance between the shear center and the centroid; $L_t$ is the cross-section polar radius of gyration with respect to the shear center; $F_{cr,Fy}$ is the flexural buckling stress about major axis; and $F_{cr,T}$ is the torsional buckling critical stress. For equal-leg angles with negligible transverse shear deformation, $F_{cr,Fy}$ and $F_{cr,T}$ can be determined according to Eqs. 3 and 4, respectively (Zureick and Steffen, 2000):

$$F_{cr,Fy} = \frac{\pi^2 E_t}{(K, L/r_t)}$$

$$F_{cr,T} = \frac{\pi^2 E_t}{12(1-\nu_{LT}\nu_{TT})}\left(\frac{t}{K, L}\right)^2 + G_{LT}\left(\frac{t}{b_t}\right)^2$$

where $K$ is the flexural buckling coefficient about the major axis; $K$ is the torsional buckling coefficient, respectively; $r_t$ is the radius of gyration about the major axis; $b_t$ and $t$ are angle leg width and thickness, respectively; $E_t$ is the wall flexural modulus in longitudinal direction; $G_{LT}$ is shear modulus; and $\nu_{LT}$ and $\nu_{TT}$ are the major and minor in-plane Poisson’s ratio, respectively. It is important to mention that $E_{LT}$ is highly dependent on the roving layers distribution throughout wall and may be considerably lower than $E_t$ for thinner sections. For thicker sections, the difference becomes negligible (Cardoso et al., 2014b).

For typical pultruded GFRP material, shear modulus is very low in order that torsional buckling ($T$) governs the behavior. Zureick and Steffen (2000) assert that $F_{cr,FT} \sim 0.9F_{cr,T}$. However, it can be shown that the simply assumption of $F_{cr,Fy} \sim F_{cr,T}$ is sufficiently accurate for most of the cases. This hypothesis – $FT \sim T$ – is assumed in this work and the differences are discussed in the following section.

Figure 1 presents a typical cross-section with nomenclature and reference axes adopted in this work. The cross-section deformations for the buckling modes discussed previously are also illustrated.
Signature Curve

Although the dominant modes are flexural-torsional and flexural, angle sections may also exhibit local bending and shear deformation (Dinis et al., 2010). To evaluate the accuracy of Eqs. 1 and 4 \( F_{cr,FT} \sim F_{cr,T} \), a comparison was made with the results obtained with the Generalized Beam Theory (GBT) (Schardt, 1994), implemented using the software GBTul (Bebiano et al., 2008), for two usual end conditions: pinned-ends with simply supported walls (PP-SS), for which \( K_x=K_y=K_t=1.0 \); and fixed-ends with clamped walls (FF-CC), where \( K_x=K_y=K_t=0.5 \). In Figure 2, critical buckling stress is plotted against the column length – the so-called signature curve – using Eqs. 1 and 4 for a 127x9.5 mm angle section and typical material properties. Values obtained with GBTul including global, local and shear deformation modes are also plotted for certain lengths. A maximum localized difference of 8% was observed, which indicates that the equations adopted are sufficient accurate for a design approach. Other important conclusions can be drawn from GBTul analyzes: i) modes associated with wall transverse bending do not play important role and their influence may be neglected; and ii) shear deformation modal participation was about 18% and 14% for short pinned and fixed-ended columns, respectively, but this seems not to influence importantly the critical stress. A similar difference can be observed for other cross-sections.

**Signature Curve** \( F_{cr} \times L \)

- \( b_x = 122.3 \) mm
- \( t = 9.5 \) mm
- \( E_{L,f} = 21,000 \) MPa
- \( E_L = 21,000 \) MPa
- \( G_{LT} = 4000 \) MPa
- \( (1-\nu_{LT}\nu_{TL}) = 0.95 \)

Figure 2 Critical stress versus length (signature curve) for an angle strut 127x9.5 mm (FT = flexural-torsional; T = torsional; F = flexural).

REAL COLUMN

Real columns are those affected by geometric and material imperfections. Applied compressive force produces second-order bending moments that result in increased lateral deflections and, therefore, reduced critical capacities compared to those described as perfect columns (Batista, 2004). A similar behavior is expected for the column constituent plates, which experience second-order effects associated with wall imperfections.
To derive a strength equation, it is initially considered the only influence of the flexural-torsional mode. Assuming that this mode can be approximately described by a cross-section rotation about the shear center ($F_{c,FT} - F_{c,T}$), the constituent plates can be isolated and analyzed with a classical plate theory. The following hypotheses are considered: i) stretching in the middle plane and post-buckling behavior are neglected; ii) material behavior is linear elastic; iii) mechanical properties and thickness are uniform throughout the plate; and iv) residual stresses are negligible. An analytical model similar to the one presented by Cardoso et al. (2014a) can be developed and the following normalized flexural-torsional strength ($\chi_{FT}$) equation can be obtained:

$$\chi_{FT} = \frac{F_x}{F_{pp}} = \frac{1 + \alpha_{FT} + \lambda_{FT}^2 - \sqrt{(1 + \alpha_{FT} + \lambda_{FT}^2)^2 - 4\lambda_{FT}^2}}{2\lambda_{FT}^2}$$

(5)

where $F_{o,FT}$ is the ultimate load associated with the flexural-torsional mode; $\lambda_{FT} = (F_{Lc}/F_{c,FT})^{1/2} - (F_{Lc}/F_{o,FT})^{1/2}$ is the FT-mode relative slenderness, and $\alpha_{FT}$ is the FT imperfection factor. Although $\alpha_{FT}$ can be written in terms of the wall geometry, initial imperfection, plate stiffness and strength parameters, this factor can also be determined experimentally or empirically derived to cover the experimental results (Cardoso et al., 2014a).

It is interesting to note that Eq. 5 has the same form as the typical column strength curves developed for steel, such as those defined by Perry-Robertson (Ziemian, 2010) and Dutheil (1961). As expected, for perfect plates ($\alpha_{FT} = 0$) the strength reduces to $F_{Lc}$ for $\lambda_{FT} \leq 1.0$ and to $F_{c,FT} - F_{c,T}$ for $\lambda_{FT} > 1.0$.

To consider the influence of the flexural buckling mode, the following hypotheses are assumed: i) column bending stiffness remains constant until failure, i.e., bending stiffness is not affected by flexural-torsional buckling; and ii) failure occurs when the compressive stress reaches its capacity, taking into account the reduction associated with flexural-torsional. An analytical model based on the beam-column theory similar to the one presented by Cardoso et al. (2014a) can be developed and the following final normalized strength equation can be obtained:

$$\chi = \frac{F_x}{F_{pp}} = \frac{1 + \alpha_{F} + \lambda_{F}^2 - \sqrt{(1 + \alpha_{F} + \lambda_{F}^2)^2 - 4\lambda_{F}^2}}{2\lambda_{F}^2}$$

(6)

in which $\chi$ is the normalized strength; $F_x$ is the ultimate load taking into account combination of flexural (F) and FT modes; $F_{pp}$ is the ‘perfect plate’ strength given as the lesser of $F_{Lc}$ and $F_{c,FT}$; $\alpha_{F}$ is the column imperfection factor; $\lambda_{F} = (F_{pp}/F_{c,F})^{1/2}$ is the F-mode relative slenderness; $\rho_{FT} = \chi_{FT}/\chi_{FT,0}$ represents the reduced capacity with respect to the perfect condition for the FT-mode; and $\chi_{FT,0}$ is the perfect plate normalized strength, i.e., $\chi_{FT,0} = 1.0$ for $\lambda_{FT} \leq 1.0$ and $\chi_{FT,0} = 1/\lambda_{F}^2$ for $\lambda_{FT} > 1.0$. $\alpha_{F}$ can be written in terms of the column geometry and initial imperfections or determined experimentally to cover the experimental results (Cardoso et al., 2014a).

Once more, the equation derived is similar to typical column strength curves. It is important to note that, as expected, for perfectly straight columns ($\alpha_{FT} = 0$) the strength reduces to $\rho_{FT}F_{pp}$ for $\lambda_{F} \leq 1.0$ and to $F_{c,X}$ for $\lambda_{F} > 1.0$. If no imperfections are present (perfect column condition), $\rho_{FT} = 1.0$ and the ultimate load reduces to the lesser of $F_{o,FT}, F_{o,c,F}$ and $F_{Lc}$. The proposed expression allows determination of angle-strut ultimate load based on flexural-torsional and flexural slendernesses and imperfection factors.

**COMPARISON WITH EXPERIMENTAL RESULTS**

In this section, the experimental results reported by Zureick and Steffen (2000) are used to evaluate the method. Computation of relative slenderness, $\lambda_{FT}$, for all struts tested by these authors resulted in values greater than 2.0, indicating that all angles tested were slender with respect to flexural-torsional buckling mode. For an arbitrarily assumed imperfection factor $\alpha_{FT} = 0.1$, it can be seen that reduced capacity factors, $\rho_{FT}$, are similar for all columns (average $\rho_{FT} = 0.98$). In Figure 3, a normalized strength curve with $\alpha_{FT} = 0.45$ is proposed and it can be seen that all test results but one are adequately covered.

To understand the influence of flexural-torsional and flexural slendernesses in the member capacity, a contour plot of the reduced strength factor with respect to the perfect column condition, $\rho = F_x/\min(F_{Lc}, F_{c,FT}, F_{o,FT})$, as a function of $\lambda_{F}$ and $\lambda_{FT}$ is presented in Figure 4. Zureick and Steffen’s (2000) results are also shown in the ‘map’ with their corresponding $\rho_{exp}$. Two important conclusions can be drawn from this plot: i) the maximum reduction of capacity is expected for columns having $\lambda_{F} = \lambda_{FT} = 1.0$; and ii) there is a lack of experimental data in this critical region, indicating that more tests are needed.

**CONCLUSIONS**

This paper presented a brief review on the behavior of perfect with orthotropic material. Critical buckling equations were compared with the results obtained from a GBT analysis, showing that flexure about major axis, wall
Transverse bending and shear deformations do not affect significantly the critical loads for typical pultruded material and their influence can be neglected.

The concepts associated with the behavior of a real angle strut were also presented and a column strength equation derived from classical plate and beam-column theories was proposed (Eq. 6). The approach is simple and considers the influence of both flexural-torsional and flexural slendernesses and the imperfection factors associated with each mode. Although these imperfection factors can be explicitly written in terms of imperfections, geometric and material properties, it seems convenient to obtain them experimentally.

The method was validated using experimental results available in literature. In this study, arbitrary imperfection factors were used in the evaluation. Finally, a contour plot of the reduced capacity with respect to the perfect condition is presented, showing that maximum reduction occurs for columns having $\lambda_F = \lambda_{FT} = 1.0$. Moreover, more tests with different slenderness combination are needed to augment the available data and to obtain reliable imperfection factors. An experimental program is currently underway at Pontifical Catholic University of Rio de Janeiro with this purpose.

ASCE Fiber Composites and Polymers Standards Committee (2010). Pre-standard for load & resistance factor design (LRFD) of pultruded fiber reinforced polymer (FRP) structures. Final Report submitted to American Composites Manufacturers Association (ACMA), ASCE. Reston VA USA.

ABSTRACT

The rotational behavior of the web-flange junctions (WFJs) of a pultruded GFRP bridge deck system was investigated. The rotational response of three WFJ types was characterized. An experimental procedure based on three-point bending and cantilever experiments conducted on the web elements and simple analytical models was used. The WFJs generally exhibited non-rigid and nonlinear behavior. The overall moment-rotation relationships, rotational stiffness, strength and failure modes differed depending on the web type, the location of the WFJ within the deck profile, the initial imperfections and the direction of the bending moment applied. Simplified expressions to model the WFJ rotational behavior were derived. The validity of the experimental and idealized rotational responses was assessed by means of numerical simulations of full-scale experiments conducted on the GFRP deck.

KEYWORDS

GFRP, pultrusion, bridge deck, web-flange junction, rotational stiffness, mechanical testing.

INTRODUCTION

Pultruded glass fiber-reinforced polymer (GFRP) bridge decks are one of the most developed and extended applications of FRP materials for load-bearing structural members in the civil engineering domain. GFRP bridge decks fulfill two structural functions: (i) distribution and transmission of the traffic loads applied to the bridge to the underlying superstructure; (ii) participation in load transfer in the bridge’s longitudinal direction by acting as the top chord of the main girders when there is sufficient composite action between the girder and deck. For pultruded GFRP deck systems, exhibiting orthotropic structural behavior, the performance concerning the two aforementioned functions is influenced by the deck’s behavior in its transverse-to-pultrusion direction.

In a previous study (Yanes-Armas et al. 2016a), the transverse behavior of a GFRP deck with trapezoidal cell geometry, DS (DARPA 2000), was experimentally investigated. The slab cross section, the loading configuration and the load-deflection response are illustrated in Figure 1(a) and (c). The load transfer mechanism, failure mode and system transverse in-plane shear stiffness were studied. The deck exhibited a frame-governed behavior whereby the load was mainly transmitted by local shear and bending moments in the web and flange elements. Progressive cracking occurring in the web-flange junctions (WFJs) resulted in a stiffness reduction without leading to the deck’s final failure. A non-brittle failure occurred and a sustained load-bearing capacity under the development of large displacements was recorded. A basis for evaluating the deck’s performance was established; additional local features, particularly the rotational behavior of the WFJs, required further evaluation.

The objective of this work was to characterize the rotational behavior of the DS WFJs. Three WFJ types, in two bending moment directions each, were investigated. A method based on three-point bending and cantilever experiments conducted on the web elements and simple analytical models was used. Simplified expressions to model the WFJ rotational behavior were derived. Lastly, their validity was assessed by means of numerical simulations of full-scale experiments conducted on the deck.

EXPERIMENTAL PROGRAM

Experimental Approach

Each DS WFJ may be defined by three convergent elements (one web and two flange segments). The typical fiber architecture of the WFJ area, consisting of E-glass fiber reinforcements embedded in an isophthalic polyester resin, is illustrated in Figure 2. Based on the fiber architecture, the flange can be considered as being continuous across
the WFJ. On the other hand, the web’s end may exhibit a certain rotational flexibility due to: (i) the lack of fiber continuity towards the flange; (ii) the change of direction of the prolonged fabrics; (iii) the roving core/resin-rich area, see Figure 2. The end condition of the web can thus be considered as a semi-rigid joint whose rotational behavior is described by the relationship between the local bending moment applied to the web’s end, $M$, and the relative rotation between the web and the flange elements, $\phi$. Hence, the web’s end can be modeled in the form of a rotational spring responding to the moment-rotation ($M-\phi$) relationship.

Figure 1 Experimental configuration for DS deck specimens subjected to transverse (a) three-point bending and (b) in-plane shear; measured and calculated load-displacement behavior under (c) three-point bending and (d) in-plane shear.

Figure 2 Fiber architecture and structural idealization of WFJs with (a) inclined and (b) vertical webs; dimensions in mm.

The complete $M-\phi$ relationship characterizing the rotational stiffness of the WFJs can be determined from three-point bending beam and cantilever experiments conducted on the web element. The rotational stiffness can be derived from the experimental responses obtained by using two simple analytical models: that of a simply supported beam under three-point bending and that of a cantilever with semi-rigid end condition, whose rotational stiffness equals that of the WFJ.

Figure 3(a) illustrates a simply supported beam of $L_{pb}$ span length subjected to symmetric three-point bending, which can be considered as two cantilevers of $L_{cant} = L_{pb}/2$ length with fixed end and symmetrically placed about mid-span, see Figure 3(b). Equal deflections under the load application point are obtained for both the three-point bending ($\delta_{pb}$) and the cantilever ($\delta_{cant}$) configurations given that $P_{cant} = R_{pb}$, i.e., $P_{cant} = P_{pb}/2$:

$$\delta_{cant,f}(P_{cant}) = \delta_{pb}(2P_{cant})$$

Figure 3(c) illustrates a cantilever beam with semi-rigid end condition, which is modeled as a rotational spring. The deflection of the partially fixed cantilever under the load application point, $\delta_{cant,ir}$, can be formulated as:

$$\delta_{cant,ir}(P_{cant}) = \delta_{cant,f}(P_{cant}) + \delta_e(P_{cant})$$
where $\delta_{cant,f}$ = deflection of the fixed end counterpart; $\delta_{\phi}$ = deflection caused by the rotation in the semi-rigid end. Operating with Eqs 1 and 2, $\delta_{\phi}$ can be expressed as:

$$\delta_{\phi}(P_{cant}) = \delta_{cant,sr}(P_{cant}) - \delta_{3pb}(2P_{cant})$$

(3)

Additionally, $\delta_{\phi}$ can be calculated as a function of the rotation in the semi-rigid end, $\phi$, as:

$$\delta_{\phi} = L_{cant}tg(\phi)$$

(4)

Therefore, by replacing Eq. 3 in Eq. 4, $\phi$ can be formulated as a function of the deflections, under the load application points, in the simply supported beam and the semi-rigid end cantilever configurations as:

$$\phi = arctg\left(\frac{\delta_{\phi}(P_{cant})}{L_{cant}}\right) = arctg\left(\frac{\delta_{cant,sr}(P_{cant}) - \delta_{3pb}(2P_{cant})}{L_{cant}}\right)$$

(5)

The bending moment acting in the semi-rigid end, $M$ (see Figure 3(c)), can be calculated as:

$$M = P_{cant}L_{cant}$$

(6)

In accordance with the preceding explanations, the $M-\phi$ relationship of the WFJ can be obtained from the recorded loads, measured deflections and set-up geometry of three-point bending beam and cantilever experiments performed on the web element, providing that $L_{cant} = L_{3pb}/2$. First, the web is subjected to three-point bending with simply supported end conditions and a $L_{3pb} = 130$-mm span length. Subsequently, the web-cantilever experiment is conducted with a $L_{cant} = 65$-mm lever arm – the WFJ is considered as a rotational spring and the experiment responds to the model illustrated in Figure 3(c). Finally, the WFJ $M-\phi$ relationship is calculated from the load-deflection data, by applying Eqs 5 and 6 throughout the whole $P_{cant}$-$\delta_{cant,sr}$ range and the corresponding $P_{3pb}$-$\delta_{3pb}$ $(2P_{cant}$-$\delta_{3pb})$ range.

**Specimens, Experimental Set-ups and Procedure**

Two groups of WFJs can be differentiated in the DS deck depending on the corresponding web geometry: vertical (V) and inclined (I). The latter can be classified into two types according to the closer (c) / farther (f) location of the adhesively-bonded profile-to-profile joint in the flange in relation to the web, see Figure 4(a).

The rotational stiffness of the three WFJ types (Ic, If, V) was investigated. The tensioned side of the web towards the obtuse/acute angle (I-WFJs) or towards the double / single flange laminate (V-WFJs) is denoted by o/a and d/s, respectively, see Figure 4(a). The experimental program was performed on three specimens from each of the six series. The specimens’ overall geometry (nominal width $b_o$ of 50 mm) is shown in Figure 4(a); their location within the deck panel of the preceding beam experiments (Yanes-Armas et al. 2016a) is shown in Figure 4(b). The visual inspection of the specimens revealed that partially bonded areas were apparent in the adhesive layer of the V-WFJs and that a small crack (referred to as “pre-crack” in the following) existed in the flange of every Ic specimen, see Figure 2(a). Differences in the actual fiber arrangement of the If- and Ic-WFJs were observed, despite their identical fiber architecture design; these are detailed in Yanes-Armas et al. (2016b).

Figure 4 (a) WFJ specimens; (b) location of WFJ specimens within DS deck panel when subjected to transverse bending (local bending moments in webs are shown); dimensions in mm
First, the webs of the WFJ specimens were loaded in a symmetric three-point bending configuration with simply supported end conditions and a 130-mm span length ($L_{pb}$), see Figure 5(a). The rotations and the vertical deflections along the specimen’s web were measured by means of a video extensometer. All experiments were performed under displacement control at a rate of 0.01 mm/s. The specimens were loaded until the strain in the web reached a limit value of 0.6% and were subsequently unloaded at a 0.02-mm/s rate. Then, cantilever experiments with a 65-mm lever arm ($L_{cant}$) were performed. A single test rig was designed and manufactured so that the web-cantilever experiments could be conducted on the six WFJ series using a universal testing machine, see Figure 5(b). The specimen’s flange was laterally clamped on both sides of the WFJ; the 20.3-mm-thickness flange area close to the WFJ remained unclamped. A video extensometer was used to measure the rotations of the specimen’s flange and web and the vertical deflections along the length of the latter. All experiments were conducted under displacement control at a 0.01-mm/s rate up to failure.

![Figure 5 Set-up for (a) three-point bending and (b) cantilever experiments](image)

**EXPERIMENTAL RESULTS AND DISCUSSION**

The average $M$-$\phi$ curves obtained for all series by applying the aforesaid procedure are shown in Figure 6 (see $exp$ curves). The normalized $M$ values (moment per unit width, $M/b$) are displayed. The ultimate bending moment of the WFJ ($M_{ult}/b$), the corresponding rotation ($\phi_{M,ult}$) and the initial tangent rotational stiffness, $K_{0,ult}/b$, defined as the slope at the origin of the $M$-$\phi$ curve, were calculated. The If-$w$WFJs initially displayed perfectly rigid behavior ($K_{0,ult}/b = \infty; \phi = 0$), irrespective of the direction of the local bending moment applied to the web element, almost up to their maximum ultimate bending moment. Their rotation at failure was negligible. The maximum moment capacity of both series was similar regardless of the examined bending direction. Nevertheless, after the peak moment, a sudden moment decrease occurred in the If-$o$ specimens while the If-$a$ specimens showed a progressive softening branch. A nearly constant post-peak (residual) moment capacity followed in both series, which was approximately 10% higher in If-$a$ than in If-$o$, although it developed up to an around 40% smaller maximum rotation. On the other hand, the Ic-$w$WFJs initially exhibited semi-rigid ($0 < K_{0,ult}/b < \infty$), nonlinear behavior preceding the maximum moment capacity, which occurred at rotation values significantly larger than in the If-$w$WFJs. The rotational flexibility of the Ic-$w$WFJs was related to their lower stiffness and initial nonlinearity in the cantilever configuration, associated with the flange’s pre-crack (see Yanes-Armas et al. 2016b). The Ic-$o$ specimens, where the applied local bending moment produced tension in the WFJ’s obtuse angle and hence opening of the pre-crack, displayed a more pronounced nonlinearity and an approximately 30% lower rotational stiffness. The Ic-$a$ specimens exhibited an approximately 40% higher peak moment than the Ic-$w$ specimens and a relative rotation at failure 3.3 times greater. The V-WFJs showed a non-rigid, slightly nonlinear initial $M$-$\phi$ response with comparable rotational stiffness irrespective of the bending moment direction – a 17% difference in $K_{0,ult}/b$ was found between the V-$d$ and V-$s$ series. However, the V-$s$ specimens exhibited a more pronounced nonlinearity and significant stiffness reduction as from approximately 70-80% of their maximum moment. A roughly constant post-peak moment capacity was exhibited by both the V-$d$ and the V-$s$ specimens. The average value of the residual moment-bearing capacity was approximately 30% higher in the V-$d$ series than in the V-$s$ series, although it developed up to an about 20% smaller maximum rotation. Differences in the rotational stiffness and/or strength of the six WFJ specimen types indicated that their characterization should be considered separately and that prospective modeling should take the dissimilarities into account.
MODELING

Empirical Modeling of Rotational Stiffness of Web-Flange Juncions

Based on the average $M$-$\phi$ curves obtained from the three-point bending and cantilever experimental results (see exp curves in Figure 6), two idealized models were derived for the moment-rotation behavior of the WFJs: (i) a rigid-plastic model (RP) and (ii) a trilinear model (TL). The RP model, see Figure 7(a), presumes that no relative rotation exists for moments lower than the assumed maximum bending capacity, $M_{pl}/b$. Increasing rotation takes place at a constant $M_{pl}/b$ moment and up to a $\phi_{max}$ rotation at which failure occurs. The peak bending moment ($Ic-o$, $Ic-a$) or the upper boundary of the post-peak capacity ($If-o$, $If-a$, $V-d$, $V-s$) of the experimental $M$-$\phi$ curves was taken as $M_{pl}/b$; the maximum rotation of the series’ average plot was taken as $\phi_{max}$. In the TL model, see Figure 7(b), a three-segment ($OA$, $AB$, $BC$) piecewise linear function, composed of two ascending branches and one softening, descending branch, is used to represent the moment-rotation behavior. The average exp $M$-$\phi$ curves from Figure 6 and their corresponding $K_{pl}/b$, $M_{ult}/b$, $\phi_{ult}$ and $\phi_{max}$ are used as input parameters. The following assumptions were made: (i) the idealized initial rotational stiffness is equal to $K_{pl}/b$; (ii) the $M_{ult}/b$ and the corresponding $\phi_{ult}$ are respected – they define the softening initiation point $B$; (iii) the $\phi_{max}$ value is respected – it defines the $\phi$ coordinate of point $C$, taken as the softening end; (iv) $AB$ and $BC$ slopes are defined on the basis of the energetic balance between the idealized and the average $M$-$\phi$ experimental curves up to the $\phi_{ult}$ and $\phi_{max}$ rotations, respectively. The RP and the TL models for the $M$-$\phi$ relationships are represented in Figure 6(a)-(c).

In order to support the WFJ moment-rotation relationships calculated from the experimental results and validate the idealized models derived, two-dimensional finite element (FE) models were established of full-scale DS deck specimens subjected to three-point bending (Yanes-Armas et al. 2016a) and in-plane shear (Gürtler 2004) in their transverse-to-pultrusion direction. The experimental configurations modeled and the corresponding experimental results are shown in Figure 1. The FE-software SAP2000 and the Frame element were used. The web-to-flange connections were modeled as rotational springs whose behavior corresponded to the moment-rotation relationships shown in Figure 6, except for the external webs’ junctions in the three-point bending experiments (their behavior was not studied). Three models were established for each configuration to separately consider the experimentally-based $M$-$\phi$ curves (exp) and the idealized relationships (RP and TL). Displacement-controlled nonlinear static analyses considering geometric nonlinearities were performed.
Figure 1(c) shows the comparison of the measured load-displacement (P-δ) behavior of the deck under three-point bending and the corresponding numerical results obtained from the FE analysis (FEA). No differences were detected in the numerical results irrespective of the M-φ relationships used and a limited agreement with the experimental data was observed. Initial linear behavior up to a load of approximately 6 kN, matching the experimental results well, was predicted by the FE simulations. A slight nonlinearity followed, although it progressively deviated from the recorded load-displacement data, which showed a more pronounced stiffness reduction. At an approximately 14-kN load, sudden load drops of 20% can be observed in the numerical predictions, corresponding to two local failures appearing at the bottom junctions of the inclined 8th web and of the right external (9th) web. Local failure at the top junction of the 8th web, producing failure of the DS deck specimens at a 12.8-kN average load, was subsequently predicted, although at significantly higher loads (15.0–16.6 kN) than the experimental ones. The simulations showed a further increasing load-bearing capacity, differing from the experimentally observed sustained load capacity. These differences were attributed to shortcomings of the modeling, namely: (i) the initial thickness of the laminates remained unchanged throughout the simulations, whereas cracking propagating from the WFJs’ tensioned side towards the flange may reduce the effective thickness of the latter; (ii) the adhesively-bonded joints in the flanges were not considered; however, they may affect the deck’s global response; (iii) no experimental data were available for the M-φ relationships of the WFJs from the external webs. The in-plane shear configuration, where (ii) and (iii) do not apply (the flanges were mainly under compression and the rotational behavior of all the WFJ types involved had been studied) can thus serve better to assess the validity of the proposed moment-rotation relationships.

The measured and calculated load-displacement responses of the deck for the in-plane shear configuration are shown in Figure 1(d). The trends of the curves from the experiments and the numerical simulations compared well regardless of the M-φ relationships used, exhibiting initial linear behavior and subsequently pronounced nonlinear behavior up to the ultimate load, followed by a stopped descending branch showing decreasing load with large displacement development. Good agreement existed between the experimental results and the predictions from the FE models using the experimentally-based M-φ relationships (see FEA exp in Figure 1(d)): the calculated initial stiffness, taken as the slope of the P-δ curves, from the exp FE model overestimated the average experimental values by 13–17%; the predicted ultimate load differed from the experimentally obtained load by a maximum of 6%. This supported the validity of the experimentally-based M-φ relationships. Only a fair agreement was found when the idealized RP M-φ relationships were used in the modeling: the predicted initial stiffnesses overestimated the mean experimental ones by 37–46%; the experimental and the modeling ultimate load values differed by up to 10%; the simulated P-δ responses moderately represented the pre-peak nonlinear behavior. On the other hand, as good an agreement as with the exp M-φ curves was observed for the idealized TL M-φ relationships, as indicated by the almost coincident FEA exp and FEA TL P-δ plots. This suggested that the TL model could be effectively used to represent the moment-rotation behavior of the WFJs.

CONCLUSIONS

The rotational behavior of the three web-flange junction (WFJ) types from a pultruded GFRP deck with trapezoidal cell cross section (DS) was investigated. The following conclusions were drawn:

1. An experimental procedure to characterize the WFJ rotational behavior based on three-point bending and cantilever experiments conducted on the web elements was established.
2. The rotational stiffness, strength and failure mode of the WFJs differed depending on the web type, the WFJ location within the deck, the initial imperfections and the direction of the bending moment applied.
3. Numerical models of full-scale experiments conducted on DS deck specimens were developed, incorporating the experimental rotational responses of the WFJs. The validity of the calculated moment-rotation relationships was thereby demonstrated.
4. Two simplified relationships for the rotational responses of the WFJs were proposed: a rigid-plastic model (RP) and a trilinear model (TL). It was proven that the TL model can be successfully used to represent the actual moment-rotation behavior of the DS WFJs.

ABSTRACT

A pultruded glass fiber reinforced polymer (GFRP) bridge deck with double cells has been developed and designed in laminate levels. Ultimate capacity tests to simulate vehicle loading were conducted to investigate its mechanical performance. The test results indicated that the load displacement relationship of such GFRP deck experienced from linear stage to nonlinear stage. In the first stage, specimens showed linearity until the damage of top slab. In the second stage, the load again but kept a nonlinear relationship with deflection. PM1 stayed in the second stage for quite a long period before failure with 36% load increasing. PM2 failed when the load increased to the peak value of the first stage. The failure mode of both specimens was longitudinal tearing crack on top slab caused by overlarge transverse tensile stress. PM1 had approximately 225% higher ultimate bearing capacity than PM2 due to different load positions.

INTRODUCTION

The fiber reinforced polymer (FRP) composites have gained more and more focus in the field of civil engineering, because of its high strength, light weight and non-corrodible nature (Bakis et al. 2002; He et al. 2012; Huang et al. 2015). Various applications of FRP bridge deck systems were proposed in terms of its advantage. Three major types of these applications are concrete bridge decks reinforced with FRP bars or FRP grids, all FRP composite bridge decks and hybrid FRP-concrete bridge decks (Xin et al. 2015a, 2015b).

Taking full advantage of FRP composites, all FRP composite bridge decks are lighter and easier to construct, and have huge potential use in the future bridge construction and rehabilitation. Park et al. (2005) developed an optimum design technique which can be applied to FRP bridge decks and performed wheel load tests on pultruded GFRP deck modules. The failure load was close to the computed value and three times larger than the axial design load specified in the specification. Lee et al. (2007) conducted wheel load tests on GFRP decks using two different lamination designs. In their study, it was found that the behaviour of the specimens was almost linearly elastic and showed brittle failure, and the design specification was sufficiently satisfied. Punching shear tests on GFRP tubular bridge deck specimens with multi cell cross-section or single cell cross-section was carried out by Prachasaree et al. (2009). The failure modes and punching shear capacities were obtained and compared with theory results. Researches above mainly focus on the macro properties of GFRP bridge decks. While the performance of GFRP profiles are affected by fiber volume fraction, fibre properties, resin properties, lamina thickness, lamina orientation, etc., it will be more significant to design FRP components from multiscale level. The integration of lamination design and structure design still needs further study.

A new pultruded GFRP bridge deck modular profile has been designed and manufactured from fiber/resin level to structure level in this paper. Double cells and double mortise and tenon joint structures were especially designed to accelerate the construction process and improve connection performance between deck modulus profile and deck modulus profile. The dimensions of unit module are shown in Figure 1(a). The laminate is designed based on classical laminate theory and the lay-up is shown in Figure 1(b). In order to investigate its mechanical
performance, ultimate capacity experiments were carried out, and responses including variation of displacements, stiffness, strains, cracks with the increasing of loading were investigated. All the results of experimental investigations in this study may provide reference for the design and construction of such type bridges.

EXPERIMENTAL PROGRAM

Test specimen

As shown in Table 1, the specimens were divided into two groups denoted as PM1 and PM2. The load position of PM1 was on top of the center web while PM2 was on top slab of a side cell at midspan. The load patch for PM1 was 250 mm × 250 mm based on vehicle model specified in the Standard of Loadings for the Municipal Bridge Design (CJJ 77-98), while the load patch for PM2 was reduced to 115 mm × 60 mm based on numerical calculation to consider tyre-to-deck contact pressure distribution (Sebastian et al. 2013). Before the test, the mechanical properties of top slabs, bottom slabs and webs of GFRP pultruded profiles were measured through a series of material tests. The test results were listed in Table 2.

Test setup and instrumentation layout

The specimens were simply supported at both ends using two hinges spaced at a distance of 1.8 m. The load was applied under displacement-control at a rate of 1 mm/min by a universal testing machine with loading capacity of 500 kN. Experimental setup along with LVDTs layout and strain gages layout are shown in Figure 2 and Figure 3 respectively. Load, deflection and strain signals were continuously recorded during testing using a high-speed data logger.

RESULTS AND DISCUSSION

Test results are summarized in Table 3. For each specimen, elastic capacity indicates the endpoint load value of linear segment of the load-displacement curve. Maximum deflection indicates the maximum deflection measured
at the time that the specimen reached ultimate bearing capacity. The elastic capacity, ultimate capacity and maximum deflection for PM1 (PM2) is 86.8 kN (35.6 kN), 117.7 kN (36.0 kN) and 15.27 mm (4.45 mm). Due to difference in load position, PM1 was more likely to bear the load by webs. In consequence, PM1 had approximately 225% higher ultimate bearing capacity than PM2.

Example: Failure process and mode

The failure mode of the specimens is shown in Figure 4. For PM1, a longitudinal crack appeared at the center of top slab at 86.75 kN. The specimen kept bearing and the crack propagated for the contribution of web after first crack, resulting in a new longitudinal crack at one side of top slab and several on outer webs at midspan. This new crack propagated and tore the top slab at 117.7 kN, leading to the failure of the specimen. For PM2, a longitudinal crack was observed at the load point of top slab at 18 kN, and more were observed on the outer web of loading side subsequently. Another top slab crack appeared beside the previous one at 35.6 kN leading to a sudden decrease of load. After then Cracks propagated while load increased nonlinearly. The specimen failed when one of the top slab cracks opened at 36 kN.

Load-deflection relationship

The load-deflection behaviour for the measuring points at midspan is shown in Figure 5. Both PM1 and PM2 exhibited elasticity in the beginning. The first damage of top slab reduced the load value by 50% and 25% respectively. Then the load-deflection curve behaved nonlinearly. In nonlinear stage, PM1 went through a long process before failure with load growth of 36% and noticeable increase in deflection. For PM2, there was little increase in load or deflection at the second stage.
Figure 5(a) indicates that the loading state of PM1 was almost symmetric in transverse direction. The center web bore more load and had larger deflection than outer webs. Figure 5(b) shows that there was noticeable torsion at midspan in PM2, and inverted camber in transverse direction in the bottom slab of loading side because of the rotation of web-flange joints. It is noted that cracks before 35.6 kN had almost no impact on the stiffness of PM2.

![Figure 4 Failure mode](image1)

**Figure 4 Failure mode**

**Figure 5 Load-deflection curve at midspan**

**Strain variations**

The deformation of top slab and bottom slab in the local bearing test was composed of two ways. The first was the longitudinal compressive or tensile deformation as top slab or bottom slab of the whole flexural member, and the second was the transverse and local deformation as elastic supported two-span continuous slabs which were fixedly connected to three webs. The overall longitudinal strain distribution for both specimens was similar to that of three-point bending beam, namely compressive strains on top slab and tensile strains on bottom slab. For PM1, the longitudinal strain distribution along section was almost symmetric, as shown in Figure 6(a). As for PM2, longitudinal strains gradually reduced to 0 from loading side to the opposite side because of eccentric load, and there was large local deformation at load point, as shown in Figure 7(a). The transverse strain distribution differed much more between two specimens. For PM1, the load was applied on top of center web, causing larger deflection at center web than outer webs. Consequently, as shown in Figure 6(b), transverse strains on top and bottom slabs were similar to the ones on top and bottom surfaces of an elastic beam, which is rigidly fixed at both ends and has vertical displacement at midspan. For PM2, the top slab deformed greatly and the deformation difference of each cell in transverse direction was more obvious, as shown in Figure 7(b).

Figure 8 shows the longitudinal strain distribution for outer webs at midspan. Both distributions were nonlinear. For PM1, longitudinal strains on two outer webs showed consistency. For PM2, the longitudinal strains on the web of loading side were much larger than those on the opposite web or web strains of PM1, indicating the web of loading side was in unfavourable state.
The strain results can be summarized as follows. For PM1, the maximum longitudinal strain at midspan was positioned at the center of top slab, and the maximum transverse strain at midspan was positioned on the outside of top slab. As for PM2, the maximum longitudinal strain at midspan was positioned on the outside of top slab, and the maximum transverse strain at midspan was positioned at the center of top slab. But for both specimens, the maximum strain measured was transverse strain on top slab, and the absolute values of top slab strains were generally higher than those of bottom slab strains. PM2 had a more serious state of local strain than PM1 under the same load level, and large strains of both directions were positioned on its top slab near the outer web of the loading side. So it is important to focus on the bearing condition of the outside of top slab as well as the outer web of the loading side under eccentric load during design.
CONCLUSIONS

A new pultruded GFRP bridge deck modular profile has been designed and manufactured from fiber/resin level to structure level in this paper. Local bearing test was carried out to evaluate the mechanical performance under wheel load. The following conclusions can be drawn from the present study:

(1) The failure mode of both specimens was longitudinal tearing crack on top slab caused by overlarge transverse tensile stress. PM1 had approximately 225% higher ultimate bearing capacity than PM2 due to different load positions.

(2) The loading process of local bearing test can be divided into two stages. In the first stage specimens showed linearity, until the damage of top slab. In the second stage the load rose again but kept a nonlinear relationship with deflection. PM1 stayed in this stage for quite a long time before failure, with an increase in load by 36%. PM2 failed almost as soon as the load recovered to the peak value of the first stage.

(3) Under the same load level, the average deflections of two specimens were close, but the strain states varied widely. For PM1, strain distribution was symmetrical in both longitudinal and transverse directions, and the maximum strain measured was positioned on the sides of top slab as transverse tensile strain. For PM2 which twisted under eccentric load, strains of the loading side were much larger than those of the opposite side whether on top, bottom slab or web. And the maximum strain measured was positioned at the center of top slab as transverse tensile strain. Therefore, during design, serious attention should be paid to transverse stress strain state of top slab when local loading, especially to the state on the loading side.

ABSTRACT

Pultruded glass fiber reinforced polymer (GFRP) members, are extensively used in industrial applications, particularly those subject to aggressive operating environments such as oil and gas exploitation. While many applications are ‘nonstructural’, increasingly, pultruded members are used in structural load bearing applications; typically as a ‘replacement’ for steel. The structural performance of pultruded GFRP members is strongly related to buckling behaviour. Although many designs treat GFRP buckling in a manner similar to hot- or cold-rolled steel, the behaviour is, in fact, notably different. Buckling and post-buckling behaviours of pultruded GFRP are affected by both the material’s anisotropy and the relatively low stiffness to strength ratio. The present research studied the flexure behaviour of pultruded I-shaped members having a variety of section geometries in order to identify the buckling behaviours: local flange buckling and lateral torsional buckling. The interaction between local and global buckling modes, which depends on the slenderness values related to each mode, was also identified. An extensive experimental program is reported and contrasted with proposed standards-based and computational (using the finite strip method) analyses. From these results the Finite Strip Method shows a good agreement with the experimental results, providing a reliable tool to predict the buckling behaviour of GFRP sections.

KEYWORDS

Pultruded GFRP, flexure tests, flange local buckling, lateral torsional buckling.

INTRODUCTION

The flexural performance of pultruded glass fibre-reinforced polymer (GFRP) structural members is often dependent on its buckling behaviour and structural resistance is affected by both the material strength and post buckling behaviour. Considered as an open thin-walled section, pultruded I-beams subject to flexure have three fundamental buckling modes: flange and/or web local buckling (FLB and WLB), lateral torsional buckling (LTB) and the interaction between FLB and lateral LTB. Buckling interaction depends on the slenderness associated with each buckling mode and its contribution to the reduction of the critical buckling load. Buckling interaction is rarely considered in extant studies of pultruded GFRP I-sections despite these elements often being used in applications in which such interaction is critical (Cardoso et al. 2015). Many researches including Kollár (2003), Sapkás et al. (2002) and Nguyen et al. (2014) have studied flexure stability (FLB and LTB) of pultruded GFRP beams using the classic plate theory approach, although such studies do not address interaction of FLB and LTB).

In addition, standards for pultruded GFRP are being developed. The 2010 American Society of Civil Engineers (ASCE) Pre-Standard for Load and Resistance Factor Design (LRFD) of Pultruded Fiber Reinforced Polymer (FRP) Structures (ASCE 2010) is presently being formalised into a forthcoming standard. The European Commission has proposed the Prospect for New Guidance in the Design of FRP - EUR 27666 (2016).

Moreover, computational analysis methods permit the buckling behaviour of the complete cross-section to be predicted avoiding approximate formulations based on plate theory. Besides the finite element method (FEM), the finite strip method (FSM) in which the cross-section is discretized into longitudinal strips (Shafer et al. 2006) has been shown to be very accurate for thin-walled longitudinal members. The FSM has fewer degrees of freedom than the FEM and is more easily implemented numerically since is not necessary to discretize the section in the longitudinal and transverse directions.

The objective of this paper is to study the flexure behaviour of pultruded GFRP I-shaped members having a variety of section geometries in order to identify the buckling behaviour: local flange buckling, lateral torsional buckling
and the interaction between the two. An experimental program is reported and contrasted with analytical and computational analyses promulgated ASCE (2010) and EUR 27666 (2016). The computational program CUFSM 4.05 (Li and Schafer 2010) was also used to obtain critical buckling loads and buckling modes.

**EXPERIMENTAL PROGRAM**

The experimental program was divided into two parts, with tests to identify the FLB and LTB behaviours, respectively. Both series of tests were conducted using the 900 kN capacity servo-hydraulic universal test frame shown in Figure 1.

Flange Local Buckling – Four-point Bending Tests

To evaluate FLB, five I-section geometries and four spans were defined. The geometries were selected according with the flange slenderness, b/2t, and the ratio of b/d. All profiles were fabricated from the same wide flange I-section: 6 x 6 x ⅛ (d x b x t in inch units; equivalent to 152.4 x 152.4 x 6.35 mm), having b/2t = 12. To obtain the other flange slenderness values, the flange tips (both compression and tension flanges) were simultaneously cut off using a band saw. The resulting profiles are summarised in Table 1. Simply-supported four-point flexure tests having spans of 2900 (two 1000 mm shear spans (i.e., a = 1000 mm) and a 900 mm constant moment region), 2600 (a = 900 mm), 2200 (a = 800 mm) and 1800 mm (a = 700 mm) were used.

In all tests, lateral support to prevent LTB was provided at both reactions points. For beams with low flange slenderness, additional lateral support was provided along the span, placed near the load points.

In order to obtain the onset and development of FLB, and the critical load, strain gages and digital images were used. The strain gages were placed on either side of the compression flanges in the constant moment region.

Lateral Torsional Buckling – Three-point Bending Tests

To study LTB behaviour, the same cross sections used for FLB were used (Table 1). The simple span lengths and slenderness $L_{fb}/r$, given in Table 1, were selected to capture the LTB behaviour while mitigating to the extent possible FLB. Each specimen was tested over five unbraced clear span lengths as given in Table 1: 2896, 2438, 2134, 1829, and 1524 mm. Lateral support was only provided at the beam simple supports. Displacement transducers, strain gages, and digital images were used to capture the onset of LTB behaviour so as to determine the critical load.

Material

The pultruded profiles described above were made with fire retardant polyester resin and E-glass fibre from the same batch. Table 2 shows the average values (and COV in parentheses) of the mechanical properties obtained experimentally as well as those reported by the manufacturer and the minimum requirements from the ASCE Prestandard (2010). The transverse modulus, $E_T$ was determined with a non-standard test since the geometry of the pultruded profile did not permit coupons to be extracted having ASTM standard dimensions.

The material presents a high degree of anisotropy with the ratios of longitudinal to transverse modulus on the order to 2.6 and 3.3 for the flange and web, respectively. This kind of high anisotropy was also reported by Cunningham et al (2015).

RESULTS AND DISCUSSIONS

Flange Local Buckling – Four-point Bending Tests

The experimentally observed critical FLB moments and those obtained from various analytical and computational analyses are reported in Table 3. The experimental values represent an average of four tests from two different beams except those reported for FB3 which is based on three tests for the span of 2900 mm, and a single value for the span of 2200 due to a beam failure unrelated to buckling.

The experimental values obtained are in generally good agreement with the Finite Strip Method (FSM). The two ‘standard-based’ calculations – ASCE (2010) and EUR 27666 (2016) are conservative. In particular, the EUR 27666 (2016) yields predictions rarely exceed half of the experimentally determined critical loads. Both standard documents reportedly account for the interaction of FLB and LTB, which reduces the critical local flange moment. Table 3 reports the observed range of the ratio of analytical/computational predictions and experimental results.

All tests began with lateral support only at the reactions points. The interaction of FLB and LTB was expected for the beams with low flange slenderness, $b/2t \leq 6$; for these tests, additional lateral support was added along the span near the points of load application. In the initial test of FB5 ($b/2t= 10$), unanticipated interaction of FLB and LTB was observed for the 2900 mm span. A second test at a shorter span of 1800 mm was carried out to verify this result. These two tests are denoted with an asterisk in Table 3. Following these tests, additional lateral support was provided for all tests having $b/2t \leq 10$. The FB3 specimens exhibited significant LTB in which case the smallest FB2 tests, having $b/2t = 4$ and $b/d = 0.33$ were not conducted.

Figure 2 shows examples of the observed FLB for beams without the additional lateral support, FB6 and with the additional lateral supports, FB5.

* interaction of FLB and LTB observed.

Lateral Torsional Buckling – Three-point Bending Tests

Table 4 summarises the experimental and analytical/computational results of the LTB tests for all sections. The experimental values represent the average and COV of at least two tests. For the LTB tests, the position of the applied load needs to be taken into account since it may induce the LTB behaviour. Beams which are loaded above the shear center (top flange) are more susceptible to LTB and the critical load is lower than if the load is applied at or below the shear center (Bank 2006). The equation for critical LTB moment proposed by the ASCE Prestandard (2010), assumes that the load is applied at the shear center, while the equation propose by EUR 27666 (2016) specifically accounts for the position of the load. The critical load can be reduced nearly 30% when the beam is loaded at the top flange rather than the shear center, according with the tests results from Nguyen et al. (2014). All beams in this study are loaded at the top flange (Figure 1).

The ASCE (2010) standard calculations, yield generally unconservative predictions – more so for beams with greater flange slenderness, \(b/2t\). This behaviour is believed to be due to the interaction between the FLB and LTB observed in the experimental tests. A degree of the over-prediction from the ASCE Prestandard (2010) results from the fact that experimental loads were applied above the shear center.
The EUR 27666 (2016) predictions are unconservative for cases in which $b/2t > 8$, again, likely reflecting FLB/LTB interaction in the experimental beams. Figure 3 shows examples of the observed LTB from the tests of beams LTB6 and LTB3.

(a) LTB 6 test  
(b) LTB3 test  
Figure 3 Lateral torsional buckling for the beams with the span of 2896 mm.

**CONCLUSIONS**

Existing standards (ASCE 2010 and EUR 27666 2016) are found to provide conservative predictions of the flange local buckling (FLB) critical moment. The Finite Strip Method (FSM) shows a good agreement with experimental results, providing a reliable tool to predict the local buckling behaviour of GFRP sections.

In the case of lateral torsional buckling (LTB), based on the experimental tests and analytical/computational studies, the ASCE (2010) is found to be unconservative in all flange slenderness. On the other hand, EUR 27666 (2016) provides unconservative predictions for beams with high flange slenderness which are expected to have FLB-critical behaviour, while for beams with flange slenderness less than 8, EUR 27666 (2016) yields relatively
accurate, if conservative predictions. The interaction between FLB and LTB observed in the experimental tests is the subject of an ongoing study.

ABSTRACT

GFRP pultruded profiles in GFRP–concrete hybrid structural elements present a remarkable structural capacity, not only for rehabilitation purposes but also in construction, for pedestrian bridges or lightweight bridge deck. In the literature, static, dynamic and creep experiments were performed on medium-scale structures. The connection between GFRP and concrete has been shown to be a shear connection since the friction is practically zero. Therefore, the shear connection test is used in this study to characterize both bolted and bonded connections. I-section GFRP pultruded profiles are connected to ordinary concrete by steel bolts in the first set and by epoxy in the second set. The experiments are monitored with a CCD-camera and digital image correlation (DIC) is used to evaluate the mechanical behaviour at the interface between GFRP and concrete. DIC allows a close examination of the deformation around the interface. Stiffness of the connection and distribution of the deformations around the area are compared and may be used to develop a mechanical model that will enable the simulation of GFRP–concrete elements on a larger scale.

KEYWORDS

Shear connection test, shear behaviour, GFRP-concrete connection, DIC.

INTRODUCTION

GFRP-concrete hybrid structural elements, consisting of GFRP pultruded profiles connected to concrete slabs, show a remarkable structural capacity not only for rehabilitation purposes, but also in the construction of lightweight bridge decks or footbridges. In fact, GFRP profiles have interesting mechanical and environmental properties such as high strength to self-weight ratio and good resistance to chemical agents. These properties make these elements suitable for structural applications for both building and bridges (Mendes 2011). Moreover, the association of these profiles with concrete compression elements makes a better use of both GFRP profile and concrete. Indeed, concrete elements increase the bending stiffness and the structural strength, reduce the deformations of GFRP profiles, and prevent the lateral buckling phenomenon.

GFRP-concrete hybrid structural elements have been studied in the literature. Static, dynamic (Correia 2007, 2009, El_Hacha 2012) and creep experiments (Gonilha 2014) were performed on medium-scale structures. Correia et al. 2009 investigated the connection between GFRP and concrete at the specimen scale. This connection has been shown to be a shear connection since the friction between GFRP and concrete is practically zero. Therefore, the push-out test (figure 1), similar to the standard push test in (EN 1994), is conducted in this study in order to characterize and compare bolted and bonded connections.

Data inferred from the force/displacement measurements on the test machine and by full-field digital image correlation (DIC) are used to accurately determine the stiffnesses of the both bolted and bonded connections. In future studies, results will be used to predict the mechanical behaviour of GFRP–concrete hybrid structural elements.
Figure 1 Dimensions of push-out test specimens (units are in mm)

SHEAR CONNECTION TEST

Test Setup

Push-out test specimens are fabricated according to the dimensions indicated in figure 1. In this study, two sets of 5 specimens are built. The first, POPB2, is connected by bonding while the second POPB3, is bolted. The composition of the concrete substrates was formulated in previous internal works. Compression tests done on 100 mm cubic specimens on the same day as push-out tests gave in case of bonding 48.4 MPa (± 3.7 MPa) and bolting 51.4 MPa (± 0.6 MPa).

For the bolted specimens, I-section GFRP profiles are prepared (cleaned, degreased), then the concrete blocks are cast in place successively. The two blocks of each push-out specimen are therefore not from the same mix (7 days apart). For bonded specimens, all concrete blocks are cast in one batch, and then the bonding is carried out after sandblasting and dusting down the surface to be bonded. The adhesive used is a bi-component epoxy Sikadur 31 CF. The thickness of the adhesive joint is not controlled, but estimated to be less than a millimetre. For bolting, 80 mm long M10 galvanized bolts with a class resistance of 6.8 are used. Four bolts are used for a specimen (two bolts per block).

Primary test results

Shear connection tests are performed on a Wolpert compression press under increasing monotonic loading until failure. The effort is applied on the top side of the I-section GFRP, the wood stiffener prevent local buckling. The crosshead speed is 0.6 mm/min. The effort and crosshead displacement are recorded. Force-displacement curves for all the specimens are given figure 2.

Excluding specimens with premature failure, bonded specimens show similar behaviours. After a loading phase while contacts are rearranged between the specimen and the testing machine, the force-displacement curve is almost linear up to failure. The shift between curves 1, 3 and 4 is due to the contact rearrangement at the beginning of the test. A load/unload cycle would probably overcome this issue. Among 5 specimens, two of them showed premature failure, probably due to mishandling or improper positioning of the specimen on the testing machine. For the 3 other ones, rupture occurs abruptly by shearing in the concrete near the interface and parallel to its plane (cohesive failure in the concrete). Before failure, no deformation is visible to the naked eye. Considering only the samples 1, 3 and 4, the average stress at failure is 7.95 MPa (± 0.9 MPa).
Bolted specimens also exhibit similar behaviour. At failure, the bolts are severely inclined, the slip between concrete and GFRP is visible. Failure comes after yielding then rupture of the bolts by bending. The average failure load is 26.3 kN (± 3.5 kN) per bolt.

Measurements with DIC

The DIC software Icasoft is used in this study to measure the displacement fields at the GFRP-concrete interface. Optical equipment specifications are given in Table 1. The specimens are prepared for the DIC: a black and white speckle pattern is applied to the zone of interest (ZOI). The optical sensor is placed at 45 ° with respect to the specimen at a distance of about 0.60 m as shown in figure 3. Thus, the visible faces of the profile and the concrete block are not in the same plane, this is taken into account when operating the results. By default, the following values are used for calculation (i) Pattern size, min = 25, max = 32 (ii) Grid step = 9 (iii) Precision = 1/100 pixel.
DIC RESULTS

Bonded connections

Out of the 5 specimens of POPB2 set, two tests are put aside due to premature rupture. A third test (bonded specimen 1) is also not exploitable with the DIC due to synchronization problems between the image acquisition and the crosshead displacement values. Then, only bonded specimens 3 and 4 will be discussed in the following. Vertical displacement fields for bonded specimen 3, for different loading values, are shown in figure 4. There is no clear discontinuity in the displacement field. The vertical displacements measured for the concrete block and the profile are not homogeneous. The displacement that is measured depends on the distance to the optical sensor. The further the point, the lower the measured displacement is. This observation is consistent; it indicates that the 2D field measurement is disturbed when the object is not included in a plane perpendicular to the optical axis.

![Figure 4 Bonded specimen 3, vertical displacements field for three loading values (left) 13.0 kN (center) 136.8 kN (right) 269.3 kN](image)

However, this aspect does not completely discredit the measurements. Here the measured displacements, rigid body displacements excluded, are comprised between -100 and 100 microns, while the size of a pixel is estimated to be 165 microns. The slip between concrete and GFRP, if there is any, is less than 200 microns at failure, and is not properly captured by the optical equipment available. The same observations are made for the bonded specimen 4. As a consequence, the behaviour at the interface between concrete and GFRP pultruded profile connected by bonding is regarded as infinitely stiff. Thus, we make the assumption of no slip at the interface until failure.

Bolted connections

The 5 specimens of POPB3 set are workable from the perspective of the DIC. For example, the ZOI of the bolted specimen 5 at the beginning and end of the test (last picture before failure) is given in figure 5. The deformation of the bolt is visible to the naked eye, it is strongly tilting downward. The slip measurement is done by comparing the vertical displacements between the points P1, P2 and P3 (situated on the profile) on one hand and B1, B2 and B3 (situated on the substrate) on the other hand (figure 5).

Vertical displacements fields for the bolted specimen 5, at different load levels, are shown in figure 6. We can observe the rigid body motion of the GFRP profile and the concrete block. The deformation of the specimen predominantly occurs at the junction, by deformation of the bolt.
At the beginning of the test, displacement is different from the upper section to the bottom of the concrete block. Figure 6.a, the difference is of the order of 0.3 mm, while the measured slip at the interface is 0.05 mm. This small difference is visible up to a load of 15.5 kN. Then from 15.5 to 18.6 kN, a vertical displacement jump appears between profile and concrete block. The measured slip is 0.1 mm. Subsequently, the slip is clearly observed between the two parts. Picture 3 (figure 6.c) is the last for which the image correlation can be made using a single ZOI. Over 48 kN, vertical slip strongly disturb the DIC measurement. It is then necessary to use two ZOI (Figure 6.d to 6.f).
A similar slipping behaviour is observed for all 5 specimens. The maximum slip is approximately 2.5 to 3.0 mm before failure, for a maximum load included between 23 and 30 kN per bolt. Thus, the behaviour at the interface between GFRP pultruded profile and concrete block bolted together will be modelled with a constitutive law that links slip to force. This law will be used to predict the mechanical behaviour of GFRP–concrete hybrid structural elements.

CONCLUSION

Two test series, 5 specimens per each, were tested by push out tests and the results were operated to compare both types of GFRP-concrete connection: bolting and bonding. The experimental approach using DIC to measure the relative displacement between the assembled elements shows promising results, with some limitations.

The study shows that the bonded connection demonstrates a very stiff behaviour with very small relative displacement recorded before failure. An average stress of 7.95 MPa (± 0.9 MPa) was measured at failure, without being able to accurately determine the corresponding slip. The DIC equipment used in this study indicates a relative displacement lower than ± 100 microns, but does not allow to define the slip more accurately. Further efforts are needed to investigate this point. In a first approach, the behaviour at the interface between concrete and GFRP pultruded profile connected by bonding is regarded as infinitely stiff. We can make the assumption that no slip occurs at the interface.

Bolted connections show a significant slip at the interface mainly due to bending of the bolts. The DIC technique allows measuring a homogeneous slip at the interface. The behaviour at the interface between GFRP pultruded profile and concrete bolted together will therefore be modelled by a constitutive law. This model will be used in interface modelling of GFRP-concrete hybrid structural elements.

REFERENCES

This paper presents an experimental investigation into the static performance of an all-composite modular composite beam under positive and negative bending moments. The deck was fabricated using lightweight pultruded GFRP box profiles adhesively bonded between two GFRP flat plates, adhesively bonded onto two FRP I-girders. A bidirectional pultrusion orientation was present within the deck structure, where the pultrusion (i.e. longitudinal fibre) direction of the box profiles were placed perpendicular to the pultrusion direction of the flat plates. This orientation improves structural performance by enhancing the junction between the box profiles and face plates to prevent premature cracking. In this paper, three different span lengths were investigated: a 4.5 m continuous span and 9 m and 6 m single spans. Composite action of the connections and the bidirectional deck was studied, along with shear lag under both positive and negative bending.

KEYWORDS

single span, and a 4.39 m continuous span. The spans were subjected to a uniformly distributed load (UDL). Bending stiffness, effective width and the degree of composite action provided by the adhesive connections (between the deck and girder) and by the transversely placed box profiles within the deck was investigated.

**EXPERIMENTAL INVESTIGATION**

**Material Properties**

Flat plates and FRP profiles were supplied by Exel Composites, Australia. The tensile properties were tested in accordance with ASTM D3039 (ASTM 2000). The material properties are given in Table 1 as an average of 10 specimens for the 6 mm-thick sections (flat plates, connecting plates and I-profiles) and 9 mm-thick sections. In addition, the in-plane shear modulus $G_{LT}$ for the 6 mm-thick sections was found using a 10° off-axis tensile test on coupons of size 250×25 mm. A two-part epoxy (R180 epoxy resin and H180 hardener supplied by Fiber Glass International) was used to adhesively bond the GFRP components together.

**Design of FRP composite system**

The 9 m modular FRP composite system is shown in Figure 1a. The sandwich deck was constructed using pultruded GFRP box-profiles adhesively bonded between two 6 mm-thick GFRP flat plates. Flat plates each had a width of 500 mm and a length of either 1.5 m or 3 m, placed in a staggered configuration as shown in Figure 1b. Adjacent flat plates were connected together using 6 mm-thick pultruded GFRP connecting plates, the pultrusion direction of which was placed parallel to that of the flat plates (along the $x$-axis, see Figure 1b). The box profiles had dimensions of 76×76×9.5 mm, with their pultrusion direction placed along the $y$-axis of the bridge (see Figure 1b), perpendicular to the pultrusion direction of the flat plates. The sandwich deck was adhesively bonded onto 203×203×6 mm pultruded I-beams spaced 900 mm centre-to-centre. The typical cross-section of the footbridge is shown in Figure 1c. The thickness of all bond lines was controlled by using 5 mm-long spacer wire of 0.7 mm thickness, placed at regular intervals along the adherend surfaces.

![Figure 1](image)

**Figure 1** a) Assembled composite system; b) plan view of composite system; c) typical cross-section of composite system (units in mm).

**Instrumentation and Experimental Setup**

Three span configurations were tested: 8.785 m simply supported span (Test 1, see Figure 2a), 6 m simply supported span (Test 2, see Figure 2b) and a 4.39 m continuous two-span (Test 3, see Figure 2c). All span configurations were tested under a 4.07 kPa uniformly distributed load, which corresponds to the SLS load based on design criteria for an FRP pedestrian footbridge (AASHTO 2008). Loading was applied by placing weights on the surface of the deck in 10 load steps. Loading was maintained for five minutes after each load step to collect strain and displacement data. Load levels were measured using load cells placed underneath each support. For Tests 1 and 2, two 25 kN load cells were placed at each support (LC1 to LC4, see Figures 2a-b). Test 3 had two additional 50 kN load cells at the central support (LC5 and LC6, see Figure 2c).
Figure 2 Plan view showing cross-sections and positions of displacement transducers for a) 8.785 m simply supported (Test 1), b) 6 m simply supported (Test 2) and c) 4.39 m continuous two spans (Test 3).

Four different cross-sections were instrumented for strain measurements. Strain gauges were placed along the depth of the deck and I-profiles in the longitudinal bridge direction at cross-section CS 1-1, which was 2.25 m from the end of the bridge. Strain gauges were also placed on the deck in the transverse bridge direction at this cross section. At cross sections CS 2-2 (situated 3 m from the end of the bridge) and CS 3-3 (situated 3.75 m from the end of the bridge), longitudinal strain gauges were placed along the upper flat plate. Finally, longitudinal strain gauges were placed along the depth of the structure and along the upper flat plate, and transverse strain gauges were also placed along the upper and lower flat plates of the bridge deck at cross-section CS 4-4 (situated 4.5 m from the end of the bridge).

Finally, deflections were measured using displacement transducers placed along the span of the bridge at either 1.5 m intervals (Test 1) or 1 m intervals (Test 2) on one side, with an additional transducer at the midspan position on the opposite side of the bridge as shown in Figure 2a and 2b. Deflections for Test 3 were measured along one span length as shown in Figure 2c, with maximum deflection measured by $D3$ situated 1.85 m from the support.

**RESULTS AND DISCUSSION**

**Load-deflection response**

The load-deflection responses for all test scenarios of the GFRP composite beam system are shown in Figure 3. Linear responses were observed for all specimens up to a load of 4.07 kPa. The bending stiffness $EI$ was calculated from the load-displacement curves using Euler beam theory, found to be 6.61×10$^{12}$ Nmm$^2$ for Test 1 and 6.02×10$^{12}$ Nmm$^2$ for Test 2 (with a difference less than 10%). However, the bending stiffness calculated for Test 3 was 2.58×10$^{12}$ Nmm$^2$, which was about 60% lower than those calculated for Tests 1 and 2. This might be due to the effect of shear deformations in the 4.39 m span of Test 3. The effects of shear deformations can be taken into account using Timoshenko beam theory. One span of a continuous beam can be considered as a propped cantilever. Deflection $z$ is calculated using Eq. 1 (Wang et al. 2000):

$$z = z_E + \frac{1}{GAK_s} \left[ \frac{3Lwx}{8} - \frac{wx^3}{2} \right] + \frac{3}{GAK_s(1 + 3\omega)} \frac{x}{L} \left( \omega + \frac{1}{2} - \frac{x^2}{6L^2} \right) \left( \frac{wL^2}{8} \right)$$  

(1)
where $G$ is the shear modulus (taken as 3.26 GPa from Table 1), $A$ is the area of the section (taken as the area of the I-profiles as it is assumed that the shear stresses are carried by the I-profiles only), $L$ is the span length, $w$ is the uniformly distributed load and $x$ is the position along the span measured from the support. A shear correction factor $k_s$ was calculated based on an I-section as 0.28 from Cowper (1966). $z_E$ is the deflection based on Euler beam theory given as Eq. 2 and $\Omega$ is a factor calculated using Eq. 3. For Test 3, the bending stiffness $EI$ calculated from Eq. 1 was $5.5 \times 10^{12}$ Nmm$^2$, which was 9% less than that found for Test 2. Shear deformations contributed to 51% of the overall deflection.

$$z_E = \frac{wx}{48EI} \left( \frac{L^3}{3} - 3Lx^2 + 2x^3 \right)$$ (2)

$$\Omega = \frac{EI}{GAK_s}$$ (3)

Figure 3 Midspan load-deflection curves for of 8.785 m (Test 1), 6 m (Test 2) and 4.39 m (Test 3) spanning composite systems under a uniformly distributed load of 4.07 kPa.

**Longitudinal strain distribution along specimen depth**

The longitudinal strain distribution along the depth of the composite system is shown in Figure 4 at 4.07 kPa. The strain distributions were obtained at midspan (CS 4-4, see Figures 2a and 2b) for Tests 1 and 2, and within the positive bending region (CS 1-1 in Figure 2c) for Test 3. As bending moments were low in the negative bending region for Test 3, the resulting strain values were small (less than 100 μstrain) and their accuracy was not sufficient. Therefore strain distributions were not presented for the negative bending region (CS 4-4) for Test 3. As shown in Figure 4, the axial strain distributions were linear from the lower flange of the I-profiles to the lower flat plate, indicating that full composite action was provided by the adhesive bond between the I-profiles and the deck. In addition, the strain distributions were also linear from the lower flat plate to the upper flat plate, indicating that the transverse webs of the deck provided full composite action for the positive bending regions.

Figure 4 Longitudinal strain distribution along the depth at 4.07 kPa.

Full composite action provided by the transversely placed box profiles within the deck was not observed in a previous study by Satasivam and Bai (2015) that also utilised built-up decks with bidirectional orientations. In that study, partial composite action was observed between the upper and lower flat plates as a result of the weak in-plane shear stiffness of the transversely oriented webs. The thickness of the box-profile webs in Satasivam and Bai (2015) was 6 mm, with box-profiles spaced 105 mm centre-to-centre. In comparison, the web-thickness of the
box-profiles in this study was 9.5 mm and spaced at 252 mm centre-to-centre. These strain distributions indicate that a thicker transverse web can provide sufficient shear stiffness. Hence, built-up pultruded sandwich decks with bidirectional pultrusion orientations can show full composite action between the upper and lower decks, depending on the in-plane shear stiffness offered by the web sections.

**Longitudinal strain distribution along specimen width**

Figure 5 shows the longitudinal strain distribution of the upper flat plate along the specimen width for Test 1 (8.785 m), measured from the centre of the beam width. At CS 2-2, the absolute values of compressive strains along the upper plate were lowest at positions where connecting plates were situated compared to the compressive strains at the centre of the beam (y=0 in Figure 5a). At CS 3-3, which does not have connecting plates, the compressive strains were relatively uniform along the width of the beam. At CS 4-4, the absolute values of compressive strains were lowest at the centre of the beam width where connecting plates were situated. These changes in strain distribution were therefore due to the presence of connecting plates. The connecting plates increased the stiffness of the flat plate locally (because of the increased thickness), resulting in a lowered compressive strain. The change in the strain distribution along the deck width caused by the change in thickness of the flat plates (due to additionally bonded connecting plates) may therefore affect the determination of the effective width. Such behaviour was also observed for Test 2 (6 m).

![Figure 5 Longitudinal strain distributions along the width of the upper flat plate for Test 1 at 40%, 60%, 80% and 100% of 4.07 kPa loading measured at a) CS 2-2, b) CS 3-3 and c) CS 4-4.](image)

The transfer of loads between adjacent flat plates joined together with connecting plates was measured using strain gauges L9, L10 and L18 at CS 2-2 (as shown in Figure 6a), and L31, L32 and L36 at CS 4-4 (see Figure 6b). The stresses at these positions were obtained from measured strain results and are summarised in Table 2. It can be seen that loads were directly transferred across the upper flat plates, considering the similar stress values on either side of the connecting plate (i.e. from L9 to L10 for CS 2-2 and from L31 to L32 for CS 4-4). This also indicates that the changes in effective width shown in Figure 5 are mostly due to the increase in plate thickness rather than insufficient load transfer at the connection plates.

CONCLUSIONS

A modular GFRP composite system was developed in this paper with a built-up sandwich deck with bidirectional pultrusion orientations, and then adhesively bonded to and supported by pultruded GFRP I girders. This composite system was investigated under static loading and different span configurations with positive and negative bending scenarios. The following conclusions can be drawn:

1) The load-deflection curves showed linear responses up to a load of 4.07 kPa. Shear deformations are negligible in the 8.785 m (Test 1) and 6 m (Test 2) spanning composite systems. However, shear deformations account for 51% of total deflections in the 4.39 m (Test 3) spanning continuous system.

2) Full composite action can be achieved at the adhesive connection between the I-beams and the lower flat plate. Full composite action can also be achieved within the FRP deck between the upper and lower flat plates because the transverse webs provide sufficient shear stiffness.

3) The presence of connecting plates results in a localized increase in the thickness of the upper flat plate, resulting in a reduction in compressive strains in the longitudinal direction. This may result in a change in the determination of the effective width.

4) Full load transfer occurs between adjacent flat plates joined together with connecting plates, indicating that changes in effective width do not arise as a result of insufficient load transfer at connecting plates.

Taking advantage of the light weight of such a modular GFRP composite beam, this structure is used as a footbridge to investigate human-induced vibration at Monash University. It is also expected that such a modular approach of structural assembly may be considered for potential footbridge construction.

ABSTRACT

Cables are widely used in large-span structures. A FRP cable net structure was constructed at first, then the anchorage system, joints and construction steps were also detailed. An improved rigid cable method was provided to calculate the internal forces of FRP cable net structures. After nonlinear analysis based on the improved rigid cable method, the force performances of the FRP cable net structure were discussed. The FRP cable net structures are applicable with enough structural strength and stiffness. A very light weight is worthy of being noted. A shortcoming of the FRP cable net structures is that its displacement is large relatively. The reason is the Elastic modulus of FRP is small relatively. This shortcoming can be remedied by improving structural design. The FRP cable net structures are specially suitable in long-span structures due to high strength-to-weight ratio and easy construction.

KEYWORDS

FRP, cable net structures, nonlinear analysis, improved rigid cable method.

INTRODUCTION

Cables are widely used in large-span structures(Richard,2002; Gould, 1998). Except of the graceful geometrical configuration, cables have excellent load carrying performances. Cables can make full use of the bearing capacity of tensile materials for there is only the tensile axial force in a cable. In tropical regions of India, Africa and South America, vines cables were used to build suspension bridges long time ago. Vines are weak material but those suspension bridges were strong and stable enough to support Spanish armies and their horses.

Steel, the main material nowadays, contributes to the application of cables greatly(Billington,1990; Farshad,1992; Tedesco,1991; Dong,2012). Steel cables have high strength-to-weight ratio, so they are fitful to go across large distance. Transmission tower lines all over the world are good examples. Steel cables were used to build bridges in ancient times. It has been over 400 years since ancient Chinese build the Luding bridge in Sichuan province in 1696. Steel cables were only used in some important or special structures in ancient time for the quantity of steel was rare. Till twenty century steel cables were widely used in all kinds of large-span structures, such as suspension bridges, roofs of stadium, arena, airport terminal and exhibition halls(Robert,1999; Karbhari,2000; Teng,2002; Feng,2007).

Cable net structures, only made of cables, are the best examples to embody the characters of grace and lightness(Reis,2008; Sharaf,2010; Stone,2001; Zhu,2009). World famous constructions, including the Raleigh Arena(USA 1953), the Exhibition Hall at Portmunn(German,1956) and Pengrowth Saddle Dome(Canada, 1983) are all landmarks. However the weight of steel cables are still large when they stride over larger distance. And corrosion and fire-resistant are also steel cables’ shortcomings.

The Fibre Reinforced Polymer(FRP) composites bring new opportunity to the use of cables. FRP composites are being promoted as 21st century materials because of their high strength-to-weight ratio, superior corrosion resistance and excellent thermo-mechanical properties. FRP composites are also greener material than conventional material such as steel. The use of FRP composites in civil engineering can improve innovation, reduce life-cycle costs and provide longer service lives(Dawood,2010; Vaidya,2010; Mousa,2012).
In this paper, a FRP cable net structure was constructed and the anchorage system, joints and construction steps were also detailed. After nonlinear analysis based on the improved rigid cable method using ANSYS, the force performances of FRP cable net structure were discussed comparing with steel cable net structure.

**CONFIGURATION OF FRP CABLE NET STRUCTURES**

**FRP laminates**

FRP laminates are used as cables instead of steel wire ropes in cable net structures. Aslan 400 CFRP laminates, made by Hughes Brothers Inc USA, are recommended. The width of a laminate is 100mm and the thickness is 1.4mm. Tensile and modulus properties are measured per ASTM D3039, the standard test method for tensile properties of polymer matrix composite materials. Aslan 400 mechanical properties are provided in Table 1.

<table>

In comparison, stainless steel cable mechanical properties are in the list too. The stainless steel wire rope type 304, provided by E-rigging.com is the most common type of cables. From the information in table 1, the weight CFRP laminates is about one fifth of steel wire rope when they resist the same load.

**Structural model**

A FRP cable net structure was built using the software ANSYS, as shown in Figure 1. The double curved roof was designed for it was good to drain off water and reduce the horizontal reactions at supports. It is also graceful with curved configuration. The plane projection is a rectangular whose size is 150m(length) $\times$ 90m(width). The cables along the width are the main load bearing members under downward loads, so it bends downward. And the cables along the length bend upwards and become the main load bearing members under upward loads of wind (Figure 2).

![Figure 1 A model of FRP cable net structure](image1)

![Figure 2 Main bearing cables under downward and upward loads](image2)

The sag at the middle point of each cable is 15m, which is determined after many trial calculations by considering architectural factors and inner forces. The grid size of cable net structure on planar projection is 3m$^2$. This size is fitful to pave roof surface members. The initial shape of cables were set to be art, while final shape under pre-stress and loads can be obtained by form finding analysis. A ring beam made of concrete was set on concrete columns to provide supports for cables.

**Anchorage system**

FRP’s high ratio of axial tensile strength to lateral compressive strength, approximately 20 to 1, is the main challenge to enlist an anchorage system that will ensure full development of FRP strength. The ends of each FRP laminate need to be anchored on the ring beam by hinge supports. Some anchorage systems for FRP sheets have been proposed, and in these systems FRP sheets are adhesive on concrete surface and they do not lead to the hinge joints at the ends of laminates. A tentative hinge joint scheme, where the FRP laminate is clamped between two stiff plates, was provided, however, it is difficult to apply pre-stress to cables.
A new hinge joint scheme between a strip and a ring beam is shown in Figure.3. Two steel plates are fixed on the ring beam. A bolt is set between two steel plates. The FRP laminate binds around the bolt and bonds using adhesives Pilgrim EM5-2 GEL. The pre-stress can be applied by rotating the bolt to shorten the laminate. Then a piece of film made of carbon fibre bundles the joints area to strengthen the connection. The film wraps the bolt and laminate in-side.

Figure 3 The hinge joint anchorage system

NONLINEAR ANALYSIS

FEM model and load cases

A structural model is provided in Figure 1. The FEM software ANSYS is adopted to perform the analysis of the FRP cable net structure and the steel cable structure. Geometrical nonlinear and large displacement analysis are required. The cables are simulated using three-dimensional (3D) Link10 element. The ring beam and columns are simulated using 3D Beam4 element. Two load cases are considered. In load case 1, the pre-stress, self-weight and downward 1kN/m² uniform load are included. In load case 2, the pre-stress, self-weight and upward 1kN/m² uniform load are included.

Optimization of pre-stress

The cable net structure requires a pre-stress to complete configuration. At present, there are three cable pre-stressed optimization methods for cable net structures. They are geometric method, the tangential balance method and the rigid cable method. Now the rigid cable method is the most convenient for it has clear concept and easy to operate by applying initial strain. However, the pre-stress losses caused by the structural deformation is not included. An improved rigid cable method is provided here. At first, according to the rigid cable method, the elastic modulus of each cable is amplified 100 times. And static calculations are carried out using ANSYS to obtain the axial force of each cable element, which is recorded as \( N_i \). The initial strain is:

\[
\varepsilon_i = \frac{N_i}{E_i A_i} \quad (1)
\]

where, \( \varepsilon_i \) is the initial strain of cable element \( i \), \( E_i \) is the elastic modulus of cable element \( i \), and \( A_i \) is the section area of cable element \( i \).

Then the elastic modulus of each cable is changed to go back original values and initial strains are applied to cable elements. Compute initial strain based on \( N_i \), then static calculations are carried out again using ANSYS to obtain the axial force of each cable element, which is recorded as \( \bar{N}_i \). The pre-stress loss of each cable element can be obtain, which is recorded as \( \Delta N_i \):

\[
\Delta N_i = N_i - \bar{N}_i \quad (2)
\]

Then the temperature stress is adopted to offset the pre-stress loss. Since

\[
\Delta N_i = \frac{\Delta L_i}{E_i A_i L_i} \quad (3)
\]

\[
\Delta L_i = T_i \alpha L_i \quad (4)
\]

Where \( L_i \) is the length of cable element \( i \), \( \Delta L_i \) is the change of length of cable element \( i \), \( T_i \) is the temperature of cable element \( i \), and \( \alpha \) is the material line expansion coefficient of temperature.

So, we obtain

\[
T_i = \frac{\Delta N_i}{E_i A_i \alpha} \quad (5)
\]

Therefore, if the temperature \( T_i \) is applied to the corresponding cable element, pre-stress loss \( \Delta N_i \) can be offset by the temperature stress to offset. The concept of above improved rigid cable method is to compensate pre-stress loss using temperature stress.
The optimized pre-stress force of each FRP cable along the direction of length and width were 591kN and 324kN respectively. While the value for each steel cable along the direction of length and width were the same when we analyzed the steel cable net structure.

**Results of displacement and stress analysis**

Based on the previously described finite-element model, numerical calculations with ANSYS were conducted. The results of nonlinear static analysis are summarized in Figure 4 and Figure 5.

![Figure 4 Stress of the FRP cable net structure](image1)

![Figure 5 Displacement of the FRP cable net structure](image2)

It can be observed that the maximum stress of FRP cable net is 2248 MPa, which shows the axial stretch force is the main internal force. The maximum vertical displacement of the FRP cable net is 1.625 m (Figure 5). In comparison, the maximum vertical displacement of the steel cable net is only 0.884 m. This indicates that the structural stiffness of FRP cable net is weak because the Elastic modulus of FRP is small relatively.

Geometrical nonlinear and imperfections often lead to conservative results of Eigen-value buckling analysis. And nonlinear buckling analysis can satisfy the real-world situation such as large deflection and initial imperfection better. In respect to the geometric imperfection, the first-order buckling mode shape was used for the configuration of the most dangerous geometrical imperfection structure which is similar to the first-order buckling mode shape. The maximum deformation value of geometric imperfection was 1/1000 of the span. The value is according to the Chinese Code for Acceptance of Construction Quantity of Steel Structures [GB50205-2001], and it is consistent with the Code for Standard Practice for Steel Buildings and Bridges [AISC 2005]. The imperfection was considered in ANSYS by updating geometry after Eigen-value buckling analysis.

Analytically predicted results for the FRP cable net structures are presented. The results are obtained from finite element models of geometrically perfect structures and structures that include initial geometric imperfections. It can be observed that the influence of geometrical nonlinear is dramatic. The analysis considering large deformation is necessary. It is also can be observed that the buckled mode shape of geometrical nonlinear analysis does not agree with the first-order mode shape from the Eigen value analysis. Since the Eigen value analysis predicts the theoretical buckling strength of a structure which is idealized as elastic and linear. However, the applied loading incrementally causes a large change in displacement during the modification and interaction of structural stiffness matrix. Therefore, the first-order mode shape from the Eigen value analysis may be different from the nonlinear buckled mode shape. It is necessary to run nonlinear buckling analysis to obtain the actual displacements, forces, and reactions.

**CONCLUSIONS**

Cable net structures made of FRP were presented in this paper. Based on the ANSYS program, the geometrical nonlinear analysis is carried out. The connection is also investigated. The main conclusions from this study can be summarized as follows:

1. Proposed FRP cable net structures have the advantages in terms of light weight, mass production, ease of assembly, lower skill required for field construction, good quality control and worker safety, and corrosion resistance.
2. The FRP cable net structures are applicable with enough structural strength and stiffness. A very light weight is worthy of being noted.
A shortcoming of the FRP cable net structures is that its displacement is large relatively. The reason is the Elastic modulus of FRP is small relatively. This shortcoming can be remedied by improving structural design. A structural system combined of FRP and steel members is worth to study further.

ABSTRACT

Glass fibre reinforced polymer (GFRP) pultruded profiles are being increasingly used in the construction industry due to their numerous advantageous over the conventional materials. However, most pultruded GFRP sections fail prematurely without utilising their high tensile strength due to their thin-walled sections. As a result, several hybrid systems made out of GFRP profiles and concrete as a filler material have been proposed in order to enhance their structural performance. Most of these studies utilised high strength concrete wherein the additional cost does not justify the enhancement in the stiffness and strength of the infilled GFRP profiles. This paper presents an experimental investigation on the effect of the compressive strength of concrete infill on the flexural behaviour of beams with a view to determine a lower cost infill for GFRP profiles. Pultruded GFRP square beams (125 mm x125 mm x 6.5mm) were filled with concrete having 10, 37 and 43.5 MPa compressive strength and tested under static four-point bending. The results showed that the capacity of the filled beam sections increased by 100 to 141% than the hollow sections. However, the compressive strength of the concrete infill has no significant effect on the flexural behaviour of the beams. The increase in concrete compressive strength from 10 to 43.5 MPa increased the ultimate moment by only 19% but exhibited an almost same flexural stiffness indicating that a low strength concrete is a practical solution to fill the GFRP profiles.

FRP, hybrid beams, concrete infill, low-strength concrete.

INTRODUCTION

Fibre reinforced polymer (FRP) composite materials have recently been used in the construction industry especially in corrosive environment. One of the innovative applications is the concrete filled FRP tubes (CFFTs) due to the relatively low elastic modulus as well as thin-walled sections of the FRP tubes. Extensive research was carried out on CFFTs as columns, but relatively limited research was conducted on CFFTs as beams (Fam & Rizkalla 2001; Mirmiran & Shahawy 1996; Mohamed & Masmoudi 2010; Ozbakkaloglu 2012). Most of these research concentrated on the ability of this system to take advantage of the confinement provided by the composite tube to the concrete core. The growing incorporation of CFFTs in compression application let to expand the investigation of the feasibility of this system for beam applications. In the last decade, several research efforts were made to investigate the flexural behaviour of concrete filled FRP tubes. Roeder, Lehman and Bishop (2010) concluded that the local buckling resistance of the FRP tubes increases due to the contribution of the concrete infill. Similarly, Fam and Rizkalla (2002) carried out experimental investigation on the flexural behaviour of hollow and filled GFRP circular tubes with a range of concrete infill strength between 30 and 60 MPa. They concluded that the flexural behaviour is affected to some extent by the concrete compressive strength. In addition, Mirmiran and Shahawy (1996) carried out experimental investigation to compare the flexural behaviour of concrete filled FRP tubes and the conventional reinforced concrete beams. The results showed the performance of the concrete filled beams is comparable or better than the conventional reinforced concrete beams. Chen and El-Hacha (2010) studied the flexural behaviour of FRP sections filled with ultra-high performance concrete (138 MPa). They concluded that the concrete core provides lateral support for the section and it prevents compressive flange buckling at higher loads.
Most of the previous research utilised high strength concrete as a suitable filling material of FRP where the additional cost does not justify the enhancement in the stiffness and strength of the infilled GFRP profiles. This paper presents an experimental investigation concerning the flexural behaviour of GFRP tubes filled with concrete having different compressive strength. The main objective of this study is determining a lower cost infill for GFRP profiles.

**EXPERIMENTAL PROGRAM**

**Material Properties**

Glass fibre reinforced polymer (GFRP) pultruded tubes and concrete are the main materials used in this study. Details of these materials are provided in the following sections.

**GFRP tubes**

A square Pultruded GFRP sections (125 mm x 125 mm x 6.5 mm thickness) produced by Wagner’s Composite Fibre Technologies (WCFT), Australia were used in this study. The tubes were produced using pultrusion process using vinyl ester resin with E-glass fibre reinforcement. Burnout test was conducted according to ISO 1172 (ISO 1172 1996) where the density and the fibre volume fraction are found to be as 2050 kg/m³ and 78% by weight, respectively. The stacking sequence of the plies is [0°/+45°/0°/-45°/0°/+45°/0°/-45°/0°/+45°/0°], where the 0° direction accords with the longitudinal axis of the tube. The mechanical properties (elastic modulus and shear modulus) of GFRP sections were determined previously by Muttashar et al. (2015). In addition, coupon tests were conducted to find the compressive and tensile strength of the sections. Table 1 shows the mechanical properties of the tested samples.

**Concrete**

Three different concrete strengths were used as concrete infill of the tubes. Five plain concrete cylinders have been sampled from each batch and cured under the same conditions as the beam sections. The 28 days average compressive strength was of 10, 37.5 and 43.5 MPa, respectively.

**Test specimens**

Three GFRP hollow sections and six GFRP filled sections were used in this study to investigate the flexural behaviour. The total length of the tested beams was 2000 mm. The details of the tested specimens are shown in Table 2. Considering the strength of the filled concrete, the specimens were identified using the code listed in the Table. The term BH indicates the hollow geometry, while, BC-10, BC-37 and BC-43 represent the beams filled with concrete having 10, 37 and 43 MPa compressive strength, respectively.

Test setup and instrumentation

Four-point bending test was performed over a simply supported clear span of 1800 mm following the procedure in ASTM D7250 (ASTM D7250 2006). The specimens were tested on a 400 kN capacity universal testing machine at a load rate of 3 mm/min. The load was applied at two points with a load span of 300 mm. Figure 1 shows the test set up for the flexural behaviour. To minimise the indentation failure, steel plates were added at the support and loading points. The strain on the top and bottom faces of the beams were measured by using four uniaxial strain gauges (types PFL-20-11-1L-120). The load was increased until failure. The load and mid-span displacement were measured with the electronic load cell and a laser displacement transducer connected to a Data Acquisition System, respectively.

TEST RESULTS AND DISCUSSION

Moment-deflection behaviour

Figure 2 shows the moment-deflection response of the tested beams. The hollow beams (BH) showed a liner elastic behaviour until failure at 31 kN.m. The average ultimate flexural stress at the top and bottom of the tested beams was 291 MPa. This stress value is approximately 45% of the compression failure stress based on coupon test results for GFRP profile. The main reason behind this behaviour is compression local buckling of the top flange at the constant moment region. The buckling is then followed by separation of the web-flange junction, delamination and crushing of the web. On the other hand, figure 2 shows the significant gain in strength and stiffness of the filled beams compared with the hollow beams. The overall behaviour of the filled beams is linear elastic until failure. The average failure moment of the filled beams BC-10, BC-37 and BC-43 is greater than the hollow beams by 100%, 140% and 145%, respectively. It is due to the contribution of the concrete core which restricting and delaying the local buckling of the GFRP tubes, the filled beams capacity is higher. However, with 335% increase in concrete strength from 10 to 43 MPa, only 19% is the improvement of the strength of the section. Two possible reasons might be causing this behaviour. Firstly, the brittleness of the concrete is increased with the increasing concrete strength. Secondly, the overall behaviour of the filled beams is controlled by the behaviour of the outside tube.

![Figure 1 Experimental set up details](image1.png)

![Figure 2 Moment-deflection behaviour of the tested beams.](image2.png)
Figure 3 shows the flexural stiffness of the tested beams. The average flexural stiffness, $EI$ of the hollow beam is $2.38 \times 10^{11}$ N:mm$^2$. This value was calculated using the following equation:

$$EI = \frac{P a}{48 \Delta} (3L^2 - 4a^2)$$

(1)

Where $EI$ is the effective flexural stiffness in N:mm$^2$; $P$ is the applied load in N; $a$ is the shear span in mm; $\Delta$ is the mid-span deflection mm; and $L$ is the span in mm. The calculated un-cracked flexural stiffness of the 10 MPa and 43 MPa concrete are $3.19 \times 10^{11}$ N:mm$^2$ and $4.19 \times 10^{11}$ N:mm$^2$, respectively. These values are 34% and 75% higher than the stiffness of the hollow beams. These results reflect the contribution of the concrete core in the overall stiffness of the filled beams. On the other hand, the flexural stiffness of the beams after the initiation of the tensile cracks in the concrete is approximately 26% higher than the hollow beams for all types of concrete. These results might be attributed to the difference in the cracking stress between the 10 MPa and 43 MPa concrete that results in lower contribution of concrete area for higher concrete strength than lower concrete strength to achieve the equilibrium of the internal forces.

Figure 3 Flexural stiffness of un-cracked and cracked sections.

**Moment-strain relationship**

The moment-strain relationships of the hollow and concrete filled beams are shown in Figure 4. The figure shows that the hollow section failed at compressive strain of 3140 microstrains and tensile strain of 6100 microstrains. The compressive strain tends to become positive which reflecting the local buckling effect on the top flange as shown in Figure 4a. In contrast, the filled beams failed at tensile strain of 12400, 14800 and 14820 microstrains for BC-10, BC-37 and BC-43, respectively as shown in Figure 4b. These strain levels are much higher than that of hollow beams in addition it approximately represents 77, 92 and 93% of the failure strain of the pultruded GFRP section based on coupon tests (Table 1). These results indicate that no tension failure had occurred at the tension site. Similarly, the tested beams showed a higher level of compressive strains of 11100, 11200 and 11250 microstrains for BC-10, BC-37 and BC-43, respectively. Again, these values are much higher than the strain levels of hollow beams and it approximately represents 97, 98 and 98.5% of the ultimate compressive strains of GFRP section. The results indicate that the filled beams failed at onset of the compression failure.

Figure 4 Moment-strain relationship of hollow and filled beams.
Modes of failure

The failure of the hollow beams started with the local buckling of the top flange followed by separation of the web-flange junctions and by delamination and crushing in the web as shown in Figure 5a. Similar behaviour has been reported in the literature (Guades, Aravinthan & Islam 2014; Vincent & Ozbakkaloglu 2013). On the other hand, the failure of the filled beams began with an inflated flange at the compression side due to the high compressive strains followed by cracks in the fibres in the transverse direction. As the concrete core cracked, the failure progressed into the side as shown in Figure 5b, c and d. The complete failure occurred after the fibre cracking in the top flange and the webs of the section at a strain level of approximately 11200 microstrains. The strain level is far greater than the failure strain of the hollow beams which illustrates that the concrete infill prevented the occurrence of the local buckling. The results also indicate that no failure has been occurred in the tension side due to the fact that the tensile strain levels are still lower than the ultimate level.

CONCLUSIONS

This paper presented the experimental results of four point bending tests on concrete filled GFRP tubes (CFFTs). Concrete compressive strength was the main parameter examined in this research. Based on the results, the following main conclusions can be addressed

- The concrete filled GFRP sections show a considerable strength and stiffness increase with 100-145% and 26%, respectively compared with the hollow sections.
- Increasing the compressive strength of the concrete core from 10 MPa to 43 MPa result in increasing the ultimate moment by 19%. However, the flexural stiffness of the filled beams is almost the same.
- In view of using concrete filled GFRP tubes as a viable structural solution to prevent local buckling of the tube, low strength concrete can be considered as a practical infill for the GFRP tubes.

ACKNOWLEDGEMENTS

ABSTRACT

Nowadays free formed buildings with organic shapes and biomorphic structures in combination with resource and energy efficiency as well as functional integration are getting more and more in the focus of modern civil engineering. The Basis of such innovative buildings are conventional construction materials like steel, glass and reinforced concrete, whereby these classic materials are limited regarding requirements as degree of lightweight, freedom of design and efficiency as wells as functional integration. For this reason, innovative buildings often cannot be realised or only with high costs and expenditure of resources. Within the scope of the research project “New lightweight structural components and processing technologies for the application in support structures”, supported by the Sächsische Aufbaubank SAB, the theoretical and experimental basis for a new function integrated, modular support structure in lightweight design was established. The focus here was on the designs development of a support structure with integrated sensor technology for bridge monitoring and lighting control and its realization by the use of new production technologies. Especially the use of glass-fibre reinforced plastics (GFRP), because of their low weight, excellent mechanical properties and corrosion resistance as well as the possibility of a load-adjusted dimensioning, resulted in new solution approaches. In connection with the realization of the production, different technological concepts were analysed with reference to their suitability, integration of required force transmission and further functions during and after production. The analysis of the lightweight elements with regard to their production and their mechanical properties resulted in a holistic production and tool concept, which represents the whole process chain from the textile to the structural component. The transfer of the results into practice was done within the construction of a new smart GFRP honeycomb arch bridge with interactive lighting in Chemnitz (Saxony).

KEYWORDS

lightweight construction, GFRP, honeycomb sandwich structures, interactive, functional integration, arch bridge

INTRODUCTION

The focus of modern architecture is increasingly on free-formed buildings with organic shapes. Design and form-finding process are therefore increasingly conducted via complex, computer-assisted methods. The implementation of these form-finding process is largely dependent on the performance of the material. This is also challenging. For the construction and operation of buildings, creative aspects are as important as demands for load capacity, function implementation, resource and energy efficiency. These demands cannot be realized with conventional building materials alone. New approaches are required, which include the development of innovative bond materials by combining hardening, functional and shaping material structures (Ehrlich and Gelbrich 2014). Inspired by properties of natural lightweight structures, like marine algae and plant leaves, bionic approaches and natural structures are increasingly adapted for technical applications (Gelbrich and Pfalz 2010). In modern architecture as well as in nature, efficient lightweight design is essential for bridging maximum spans (Ehrlich and Gelbrich 2014). The focus is on a material-saving, weight-reducing way of construction, with light designs based on nature. This is to be achieved by replacing heavy material with light bond material.

The implementation of lightweight design thus involves lightweight material in combination with support structures that are dimensioned in a load-adjusted way. Efficient, functionally integrated material combinations are needed. Further research is necessary, particularly in the field of fiber-reinforced composite material for the application in civil engineering (Ehrlich et al. 2011).
FROM THE FORM-FINDING-PROCESS TO MANUFACTURING

Form-finding-process and selection of material

The main challenge in the development of support structures in lightweight design for resource-efficient bridges was to realize maximum spans with a minimum of weight in structure and with materials of low density and with integrated functions like monitoring and lighting. Based on these key points, the design was conducted, the material selected and finally a reference object built.

The starting point of the form-finding-process was the workshop “Form-Finding: form follows material”, that accompanied the research project. In this workshop, architects worked out a lot of creative ideas and designs for innovative lightweight bridges. Particularly, the bridge design of the architectural firm Beier.Steiner Architekten und Ingenieure was selected to execute a closer examination of honeycomb support structures in bridge designs (Figure 1).

GFRP was selected as material for the bridge modules. In combination with the structure, chosen for the bridge design, this led to a support structure with low use of materials and low dead load. Translucent GFRP covers were used as filling material for the honeycombs. By the application of translucent GFRP covers in combination with integrated LED technology, different lighting scenarios can be realized.

GFRP has many advantages for building complete support structures, given that design and production are appropriate for the material. GFRP is not only translucent, it is also resistant to environmental influences and many aggressive substances, such as de-icing salt. GFRP combines very good mechanical properties and low weight. When designed and produced in a load-specific way, it ages only to a small degree. Examinations of dynamically loaded laminates over a period of 30 years showed no negative changes in the supporting laminates [Hönninger et al. 1999]. Thus, extremely durable buildings can be produced that need only low maintenance.

Construction, design and optimization

Based on the idea to use a honeycomb as basic form for the innovative support structure in bridge elements, a honeycomb-sandwich (Figure 2) was implemented into a feasible solution, appropriate to material and production. Inspired by lightweight constructions in nature, the honeycomb-sandwich structure was developed following the natural honeycomb, which consists of evenly shaped hexagonal cells and has an ideal ratio between wall material and volume. Due to its stiffening function, it is often used in engineering to stabilize constructions. With an optimal material input, honeycombs ensure a uniform distribution of force within the component and thus meet the requirements imposed on lightweight design.

The sandwich design was chosen for the implementation of the innovative support structure. Components of this design are characterized by a high second area moment and low material input. This is particularly favorable for components exposed to great bending strain. The honeycomb core acts as basic material for transmitting shear forces and increasing the space between the covering layers, which are exposed to tension and pressure. Both basic material and covering layers consist of GFRP (Figure 2).

The finite elements method (FEM) is used to design and optimize the GFRP honeycomb module. The geometry model of the GFRP honeycomb module was conducted fully parametrically, to permit a fast adaptation of the geometrical situation. In this way, different variant types could be calculated. The geometry (length, width, height) of the single honeycombs can be modified via the corresponding parameters, their number can be modified via length and width of the GFRP honeycomb module. The module is furthermore divided into the four elements upper...
and lower covering layer, honeycomb core and module border. The thickness can be determined for each element separately.

![GFRP honeycomb module in sandwich design](image)

Figure 2 GFRP honeycomb module in sandwich design

The discretization was realized with shell elements, to keep the computing time for the simulation within reasonable limits. The computing time for a single run is of considerable importance, especially with regard to the subsequent optimization, since many runs are necessary for the optimization to get reliable results.

Apart from the dead load of the GFRP honeycomb module, a distributed load and a single load in the middle of the honeycomb are forces that act on the GFRP module in the preliminary design. The bearing is realized by the two edges upon which the GFRP module rests during the mounting process. The maximum principal and shear stress and the maximum deflection are analyzed for the evaluation of the GFRP module, in accordance with the ultimate limit state and the serviceability limit state (Figure 3).

![Framework conditions and results of the simulation](image)

Figure 3 Framework conditions and results of the simulation

The optimization of the GFRP module is conducted by means of an implemented calculation algorithm which is integrated into the software. The parameters that are going to be optimized have to be activated, the framework conditions (external influences, storage), voltage and deformations limits have to be defined. From a certain number of calculation runs results a GFRP honeycomb module with a set-up that is perfectly adapted to the defined conditions.

![Testing and simulation of a single honeycomb](image)

Figure 4 Testing and simulation of a single honeycomb

To verify the simulation, the results were compared to the values measured in pressure tests of single honeycombs (Figure 4). In those tests, the single honeycombs were loaded with a compression force of 10 kN on an area of 10...
cm x 10 cm in the middle of the honeycomb. Tests and simulation showed a very good agreement of the shift values. With a deviation of 6 %, the simulation is very suitable for the preliminary design of the GFRP honeycomb modules.

Based on the simulation results of the preliminary design, the final structural dimensioning was conducted with the software Sofistik. Sofistik provides simple tools to display and calculate a variety of load combinations. However, the parameterization is extremely time-consuming, which justifies the splitting of the design process into preliminary design with ANSYS Workbench and final structural dimensioning with Sofistik.

**Implementation of production**

Two different technology concepts were developed and tested to implement the production of the structural elements. The first concept includes the production of the single honeycombs using the winding method, followed by agglutinating the single honeycombs to honeycomb modules (Figure 5). The winding method was chosen with regard to the dimensions of the components, the necessary reinforcing brackets and the notified medium-sized batches. The mounting of the single honeycombs requires small tolerances within the single honeycombs to keep addition errors and significant deviations within the module at a low level.

![Figure 5 Process chain from toolmaking to complete single honeycombs](image)

Producing the modules in the winding method is not feasible for curved bridges, because it is too much effort to design and produce the different winding cores.

The second concept includes the production of geometrically adjusted half-honeycombs in the wet-in-wet technology. The honeycomb core is made out of joint laminate strips in a meander-like shape with a thickness of 8 mm, which are stuck together and pressed into the wet-laminated cover layer afterwards (Figure 6). Due to their design, the laminate strips that are used for the production of the cores facilitate the production of different module types. The costs for tools are low, compared to the production of the modules from single honeycombs, because fewer molds are needed to depict the curved modules.

For the pre-assembly of the honeycomb-core a mounting aid was developed to facilitate the agglutinating of the laminate strips (Figure 6). The mounting aid consists of a 60 mm thick multiplex board, into which the honeycomb pattern was cut with a CNC cutter to guarantee the required tolerances.

![Figure 6 Production of the modules from meander-formed laminate strips with slip-resistant wearing layer](image)

A further step in the production of the modules was the application of a slip-resistant wearing layer onto the cover layer, which is the walking layer of the lightweight honeycomb bridge. Different types of quartz sand with differently sized grains were tested during the production of the single honeycombs to guarantee the required slip-resistance.

**Functional integration**

In extensive research work over recent years, various structurally integrated sensor systems have been developed to monitor fibre-reinforced plastic components. The Department of Lightweight Structures and Polymer
Technology at Chemnitz University of Technology in cooperation with the Kompetenzzentrum Strukturleichtbau e.V., Chemnitz, designed textile-based stitched sensors and tested these in various applications (Ulbricht et al. 2011). To control the desired bridge lighting, the integrated stitched sensor system has been specially adapted to meet the particular requirement of interactive walking. The task of the integrated sensor system is to detect the position of pedestrians on the GFRP bridge elements and then control the switch function for the automatic bridge lighting.

The sensor antennas consist of insulated copper strands and are connected segmentally via a cascaded signal-processing unit (Figure 7). Combined with the sensor system a consistent lighting of the translucent GFRP honeycomb modules can be reached by the use of LED lights.

The electronics creates a localized electromagnetically field on the antennas, which allows a feedback after a change of the electrical resistance and/or the dielectricity. When a pedestrian steps on a sensor integrated bridge segment, the electrical resistance and dielectricity changes due to the isolating shoe and food. The resulting field characteristic of the sensor causes a switching function in the electronics unit. The electronics unit sends a signal to the control of the bridge and switches on the lighting.

![Figure 7 Integrated sensor system for bridge monitoring and lighting control](image)

An innovative lightweight honeycomb bridge was developed and implemented in Chemnitz in the scope of a research project. It was built in the course of revitalizing and converting the former dyeing factory Haase into a company building and connects it with the opposite bank of the river Chemnitz. In accordance with the local

![Figure 8 Lightweight honeycomb-bridge in Chemnitz](image)
situation, especially flood protection, the bridge was realized as a footbridge with a span of 30 m and a pavement width of 2.50 m (Figure 8).

The shape and design of the reference object comprises a bridge with an unequal round arch. A steel support served as support structure, together with a spanning pipe turn. The pavement is mounted into the third points of the pavement construction, by means of two hanger pairs.

The pavement construction has a curved floor plan. It consists of torsion-free main girders lengthwise and functionally integrated lightweight honeycomb modules made of GFRP in transverse direction. The lightweight honeycomb modules have a width of 2.60 m and a height of 276 mm (upper covering layer: 17 mm, core: 250 mm, lower covering layer: 9 mm). The modular fibre composite construction between the main girders is a flat honeycomb structure that acts as secondary support structure, which spans the steel girders. The pavement is embedded on both sides of the river. Massive abutments are used for this purpose, consisting of textile concrete in modular composite design. A functionally integrated exposed-concrete formwork was developed and applied.

CONCLUSIONS AND OUTLOOK

As saving of resources, freedom in design and functional integration are becoming more and more important, the focus in architecture and civil engineering shifts to lightweight design. Without a significant increase of resource efficiency, future-oriented designs are hardly realizable. Materials for lightweight design have to be highly effective and multi-functional hybrids. Fiber composites are ideally suited to meet these requirements.

Innovative, functionally integrated support structures have been developed within the scope of a research project. They are produced in GFRP sandwich design with stiffening honeycomb cores. Thus, they are the basis for combining innovative lightweight technologies and progressive functional design in support structures. Due to the strict restrictions in civil engineering the GFRP honeycomb modules are to be used as secondary support structures in larger bridges with spans of more than 15 m. For smaller bridges with spans up to 15 m no steel supports are needed and support structures in GFRP sandwich design are feasible. These support structures can be prefabricated in the factory. Small cranes are sufficient for the on-site mounting, due to the low weight of the structure. This significantly increases the effectiveness of the mounting process.

Although fiber composites have been further developed in recent years, they were rarely used in civil engineering. Architects, planners and building authorities are lacking experience, there are no reliable parameters for durability, standards, guidelines, approvals and accepted test methods. Thus, there is no basis for the application of fiber composites in support structures.

The main objective of research and development now is to create a base for the application of fiber composites in support structures by developing innovative lightweight material composites, technologies for their production and integrating suitable sensors for monitoring. A close connection of research and practice (building companies, architects, and planners) and cooperation with approving authorities are decisive factors. A couple of reference objects were implemented successfully in the recent years. This is a decisive step towards the approval of new lightweight materials and composites.

ACKNOWLEDGEMENTS

The research project “New lightweight structural components and processing technologies for the application in support structures” was successfully realized thanks to the close and always fruitful cooperation between Fiber-Tech, Steelconcept, Hentschke-Bau, Stfi and TU Chemnitz. Great thanks also goes to the development fund provider Sächsische Aufbaubank SAB, DFG Deutsche Forschungsgemeinschaft, the engineering office Schulze&Rank, the architects Beier, Steiner Architekten and engineers Dankhard Remmler, ARC Architekturconcept and Architekturkanal for supporting the project.

EXPERIMENTAL STUDY ON THE PERFORMANCE OF GFRP CONNECTORS FOR USE IN PRECAST CONCRETE SANDWICH PANELS

J.Q. Huang¹ and J.G. Dai⁷
¹Department of Civil and Environmental Engineering, The Hong Kong Polytechnic University, Hong Kong, China. Email:cejgdai@polyu.edu.hk

ABSTRACT

In this paper, three kinds of glass fiber reinforced polymer (GFRP) connectors were proposed for use in precast concrete sandwich panels, including “I” beam, corrugated plate and hexagonal tube. Direct shear tests based on a typical push-out configuration (i.e., three concrete wythes linked with connectors and two rigid foam layers in between) were conducted to compare their performance with that of one commercially available product, which is being widely used in PCSPs in prefabricated construction. The test results indicated that, the shear resistance of all proposed connectors was governed by the material failure in GFRP and no pull out failure of the connectors from the concrete wythes occurred. All proposed GFRP connectors showed a higher shear stiffness and shear resistance (more than 13kN per connector) than corresponding existing systems. The corrugated GFRP plate performed the best while the GFRP tube performed the second in terms of shear stiffness and shear resistance, demonstrating their good potential for applications in partially or fully composite concrete sandwich panels. Finite element analyses were also conducted to investigate the stress condition in the proposed connectors during the loading stage. The analytical results indicated that “I” beam and corrugated plate connectors mainly generate shear deformation whereas the hexagonal tube generate both significant flexural and significant shear deformation.

Precast concrete sandwich panel, GFRP tube, connector, direct shear test, shear stiffness, shear resistance.

INTRODUCTION

Precast concrete sandwich panels (PCSPs) consist of inner and outer reinforced concrete (RC) or prestressed concrete (PC) wythes, a core foam insulation layer, and connectors penetrating through the insulation. They have been widely used in office and residential buildings particularly in Europe and North America to achieve both structural and thermal efficiency. According to the degree of the composite action, PCSPs can be divided into fully composite, partially composite and non-composite types (Edward 2005). The degree of composite action mainly depends on the stiffness and resistance of connectors that transfer in-plane shear force between two concrete wythes. Traditionally, solid concrete blocks and steel bent up bars (i.e., steel trusses) were used as the connectors in PCSPs (PCI 2011). Although PCSPs with these traditional connectors exhibit a higher degree of composite action, they lead to the thermal bridge effect due to the higher thermal conductivity of steel and concrete, and consequently the panel thermal efficiency is largely compromised. In order to solve this problem, fiber reinforced polymer (FRP) composites have been introduced to manufacture the connectors in various forms owning to their lower thermal conductivity and high strength (Salmon et al. 1997). Currently, the widely used FRP connectors include pin-type glass fiber-reinforced polymer (GFRP) (Woltman et al. 2013), grid-type carbon FRP (CFRP) and GFRP (Gleich 2007; Frankl et al. 2011; Kazem et al. 2015), truss-type GFRP (Choi et al. 2015) and plate-type GFRP (Pantelides et al. 2008; Chen et al. 2015; Lameiras et al. 2013). Among them, the plate type and grid type connectors are often used to manufacture the composite type PCSPs because of their relatively high shear stiffness and shear resistance. However, both the plate and the grid types of connectors have significantly different stiffness in two orthogonal directions and usually can only designed to transfer one-way shear force. In addition, the issue of how the section of FRP connectors influences the shear transfer efficiency remains unknown.

This paper aims to propose optimal one-way and two-way FRP connectors and to evaluate their performance. Three types of new GFRP connectors were proposed, including “I” beam shape, corrugated plate shape and hexagonal tube shape. In order to evaluate their shear performance, direct shear tests were conducted through the widely used push-out configuration. Besides, shear performance of a typical commercial GFRP connector, which has been widely used in PCSPs in prefabricated building industry was also examined for comparison. The failure
modes, shear stiffness and shear resistance of the above-mentioned four kinds of connectors were observed and discussed, providing valuable information for further optimization of these FRP connectors.

PROPOSED FRP CONNECTORS

The three kinds of GFRP connectors and their connection details in PCSPs are shown in Figs.1(a)–1(c). The “I” beam and corrugated plate connectors were mainly proposed for one-way PCSPs in which the connectors only need to transfer the in-plane shear force along the longitudinal direction. The “I” beam FRP connectors belong to the plate type but provide more reliable anchorage to the two concrete wythes. It should be noted that the out-of-plane buckling often occurs in plate type connectors. To delay or avoid the buckling, corrugated plate type GFRP connectors was proposed (Figure 1(b)). The hexagonal GFRP tubular connector was mainly proposed for PCSPs, in which the connectors need to transfer two-way in-plane shear (e.g., Benayoune et al. 2008). Compared to solid sections, the tubular section is thought to be optimal because it provides more transverse stiffness when the connectors are subjected to flexure/shear in PCSPs. It should be mentioned that the GFRP connectors bear both shear and flexure in PCSPs although they are called “shear connector” in literature (e.g. PCI 2011). Considering the manufacturing convenience and structural efficiency, GFRP tubes with a hexagonal section was first explored in this paper.

All proposed GFRP connectors were made of resin impregnated dry glass fiber sheets through vacuum-assisted wet lay-up method. The glass fiber sheets used were biaxial type provided by Colan Australia Inc. and the areal weight is 855g/m². The epoxy resin used was provided by West System Inc. At first, the mechanical properties of GFRP formed based on the above fabric and resin were tested. The tensile modulus and strength of resin impregnated glass fiber sheets were evaluated through uniaxial tensile test of GFRP coupons with a fiber orientation of 0° & 90° (ASTM D3039) while the shear modulus and strength were evaluated through uniaxial tension test of GFRP coupons with a fiber orientation of ±45° (ASTM D3518). The coupon test set up can be found in Figure 2. The test results are presented in Table 1.

The GFRP laminates in all proposed connectors were composed of four plies of fiber sheets with fiber orientation of ±45°. The thickness of the formed laminates varied between 2.4mm and 2.7mm. The overall heights of the connectors were 160mm for the “I” beam shape, 166mm for the corrugated plate and hexagonal tube shape, respectively. For the “I” beam connector, both the length and the width of the flanged part were 110mm (Figure 2).
3(a)). For corrugated plate connector, the overall length and each wavelength were 160mm and 40mm, respectively (Figure 3(b)). For hexagonal tube connector, the side length of the cross sectional hexagon was 40mm (Figure 3(c)). Figure 3(d) is a commercial FRP connector that is being popularly used for the construction of partially composite PCSPs.

IN-PLANE DIRECT SHEAR TESTS

A total of 8 specimens were tested for the above-mentioned four types of connectors under direct in-plane shear. Two identical specimens were fabricated for each type. The specimen IDs are indicated in Table 2. The “I” beam, the corrugated plate, the hexagonal tube and the commercial connector are symbolized as “I”, “T”, “H” and “C”, respectively. The direct shear tests were conducted using the popularly used push-out configuration (e.g., Tomlinson et al. 2016). The overall dimensions of the test specimens were 400mm×300mm×300mm (length×width×height), representing two sandwich panels back to back. Details of the specimen geometry can be found in Figure 4(a). In the specimens, extruded polystyrene (XPS) foam with smooth surface condition was used as the insulation layer. The effect of insulation on the test result can be ignored due to its weak bond with concrete (Hassan and Rizkalla 2010). In order to measure the relative slip between the core concrete wythes and the two outer concrete wythes, linear variable differential transformers (LVDTs) were placed at the front and back of core concrete wythes as shown in Figure 4(b). The load was applied in a displacement-controlled manner at a loading rate of 1 mm/min. A load cell was placed at the top center of core concrete wythes to measure the load on force.
TEST RESULTS AND DISCUSSION

The direct shear test results are summarized in Table 2 and the shear force vs. relative slip relationships for each type of connector are shown in Figs. 5(a) ~5(d). The average response of two identical specimens of four types of connectors are compared in Figure 6.

where \( f_c \) is the cylinder compressive strength of concrete, \( P \) is the shear resistance of connector; \( P_a \) is the average shear resistance of two tested connectors.

From Figs.5(a)~(c), it seems that the shear force vs. relative slip relationships of proposed FRP connectors can be divided into three stages. Initially, the transferred shear force increased linearly with the relative slip between two
concrete wythes. When the shear force reached the peak value (around 24kN, 69kN and 49kN for I series, T series and H series specimens, respectively), the transverse shear failure occurred in the GFRP laminate (Figs.7(a)–7(c)). After that, the I and H series specimens exhibited a yielding plateau with the increase of relative slip. However, the T series specimens exhibited a sudden drop of shear force and followed by a stable plastic stage. Finally, fibers at the tensile region ruptured gradually and the transverse shear force decreased until the connector was completely broken. The slip between the insulation and the concrete wythes could be clearly observed in this stage (Figure 8(a)). For specimens with the commercial connector, the failure mode was similar as shown in Figure 7(d). All proposed FRP connectors could provide a shear resistance of more than 13kN and their transverse stiffness are much higher than that of the commercial one, indicating that they have good potential for applications in partially or fully composite PCSPs.

There was no shear failure observed in XPS insulation. The surface of XPS insulation remained intact after tests as shown in Figure 8(b). Due to the smooth surface of XPS insulation board, it can be assumed to contribute no shear stiffness and shear resistance. The obtained shear force vs. relative slip curves reflected fully the performance of FRP connectors.

FINITE ELEMENT ANALYSIS

A preliminary finite element (FE) analysis has been conducted to investigate the stress condition in the proposed connectors during loading (for the linear stage only). Herein, general FE program ANSYS was used. Eight nodes solid element (SOLID45) was used for concrete wythes. The elastic modulus and Possion’s ratio were gave the values of 30GPa and 0.2, respectively. Multi-layer shell element (SHELL181) with 8 layers was used to model the GFRP laminate, as shown in Figure 9(c). In each layer, the GFRP material was treated as a linear elastic orthotropic
material. The elastic modulus along the fiber direction \(E_{11}\) and the shear modulus (assumed \(G_{12}=G_{13}=G_{23}\) according to Arman et al. 2006) used were the tested values as indicated in Table 1. The elastic modulus perpendicular to the fiber direction \((E_{22} \text{ and } E_{33})\) was equal to the resin’s tensile modulus provided by the manufacturer (West System Inc. 2016). For Poisson’s ratio \((\nu_{12}, \nu_{13} \text{ and } \nu_{23})\), a value of 0.3 was adopted for \(\nu_{12} \text{ and } \nu_{13}\). A value of 0.5 is adopted for \(\nu_{23}\) (Kishore et al. 2009).

Due to the symmetry, only half model was analyzed. The finite element models are shown in Figure 9, in which the connector and concrete elements shared the same nodes at contacted points. Nodes at the bottom of outer concrete wythes were restrained in all translational degrees of freedom. Vertical degrees of freedom of nodes at the top surface of core concrete wythes were coupled to ensure all nodes to move together. Load was applied in a displacement control manner. In the FE model, geometrical imperfection related to the first buckling mode of the connector was introduced. The amplitude of initial imperfection was set as 0.1 times of the GFRP laminate thickness (Debski et al. 2013).

After the analysis was completed, the vector plot of the 1st and 3rd principle strains was obtained and shown in Figs.10(a)~10(c). It can be seen that for both “I” beam and corrugated plate (Figs.10(a) and 10(b)), the principle strains are mainly along the orientation of approximate ±45°. However, for the hexagonal tube (Figure 10(c)), only the strain in “A region” is along the ±45° orientation. The tensile and compressive zones induced by tube bending can be observed in Figure 10(c). Therefore, the relative slip in cases of “I” beam and corrugated plate connectors was mainly composed of shear deformation, whereas in case of hexagonal tube it was composed of both significant flexural and significant shear deformation.
CONCLUSIONS

In this paper, three kinds of GFRP connectors have been proposed for use in PCSPs. Direct shear tests were conducted to evaluate their shear performance in comparison with that of a commercial FRP connector, in terms of the shear stiffness, shear resistance, failure mode and the full-range shear load-slip curve. The following conclusions have been arrived:

(1) All proposed connectors showed a linear behavior till the initiation of transverse shear failure in GFRP laminate, which was found to be progressive afterwards.

(2) All proposed connectors presented a considerable shear resistance of more than 13kN. Their shear stiffness was much higher than that of the used commercial one, indicating their good potential for use in partially or even fully composite sandwich panels.

(3) The preliminary FE analysis revealed that the deformation of “I” beam and corrugated plate connectors was mainly induced by shear whereas for the deformation of hexagonal tube connector both flexural and shear components were significant.

ABSTRACT

Pre-cast multi-layered concrete sandwich panels gain popularity in construction of commercial as well as residential buildings. Such panels consists usually of two concrete layers and an insulation layer in between. Both concrete layers, reinforced commonly with steel reinforcement, are joint together by use of connectors. Replacement of steel reinforcement by glass fibre reinforced polymers (GFRP) rebars enable the design of much thinner panels (40 mm for concrete layer) due to the reduction of the required concrete cover. A four-point flexural test was adopted to fully understand the load-carrying behaviour of sandwich panel components. The experimental study included instruments to measure the vertical deflection along the beam, strains inside of the connectors and shear deformation of insulation layer. Investigated parameters are the thickness of insulation layer, connectors’ arrangement as well as reinforcement ratio of the concrete wythes. This paper describes the results of experimental and theoretical investigation on flexurally stressed thin sandwich panels with internal GFRP reinforcement and connectors. Flexural load-bearing behaviour and transfer of shear stresses between the concrete layers are analysed.

KEYWORDS

Flexural tests, sandwich panels, connectors, FRP internal reinforcement.

MOTIVATION AND OBJECTIVES

Pre-cast multi-layered concrete sandwich panels usually consist of load-carrying concrete layer, insulation layer and facing concrete layer (see Figure 1). Currently they gain more and more popularity in industrial as well as residential construction industry. Therefore optimisation of their production and design process constitutes an attractive task as a direct response to the market needs. Application of glass fibre reinforced polymer (GFRP) rebars instead of traditionally used steel rebars enhances their thermal performance and due to much higher corrosion resistance of such rebars, in comparison to steel reinforcement, the investigated sandwich panels feature much thinner concrete wythes.

Figure 1 Components of sandwich wall panel

In case of commonly used sandwich panels, only one concrete wythe (the thick load-carrying concrete wythe) is considered to carry the whole bending load. The thinner facing concrete wythe acts solely as a protection against environmental exposure. For analysis of the investigated sandwich panels with double-sided thin concrete wythes, the contribution of both layers including the sandwich effect has to be considered. As it was proved in tests, even for panels with much lower stiffness of facing concrete wythe, the sandwich effect acting can provide significant load capacity reserves (Schmitt et al. 2014).
The objective of the experimental study is the investigation of the flexural load-carrying behaviour of complete sandwich panel system and its components.

**EXPERIMENTAL INVESTIGATIONS**

**Test series and test set-up**

The experimental programme including eight test specimens is presented in Figure 2. All specimens can be divided into four groups. In each group there are two specimens, with insulation thickness of 60 mm and 140 mm respectively, made of expanded polystyrene (EPS, compressive elastic modulus of 6 MPa). Thickness of both, upper and bottom concrete wythes of all specimens is 40 mm. Dimensions of test specimens are for all 1700x400 mm (LxW).

Varying parameters are:
1. thickness of the insulation layer
2. reinforcement ratio of concrete wythes
3. type of reinforcement (steel or GFRP)
4. arrangement of connectors

The GFRP rebars Schoeck ComBAR® (diameter of 12 mm) with elastic modulus of 60 GPa cut at both ends at the angle of 30° with length equal the thickness of the panel are applied as connectors between the concrete layers. The concrete mixture with maximal aggregate size of 8 mm was used. The compressive tests of 12 samples provided average cubic strength of 52.2 MPa with the standard deviation of 3.3 MPa. The test specimens of Group A are reinforced with usual steel rebars B500B with diameter of 8 mm and the same reinforcement ratio as Groups B and C. All the other sandwich panels are reinforced with GFRP rebars Schoeck ComBAR with a longitudinal elastic modulus of 60 GPa and diameter of 8 mm. Test specimens of Group D feature reinforcement ratio for each concrete wythe of \( \rho_D = 0.044 \), while in case of all other specimens reinforcement ratio is \( \rho_{A,B,C} = 0.031 \). In each panel the reinforcement of the upper layer is the same as of the bottom layer. Connectors’ grid for Group C is 20 x 30 cm while for Groups A, B and D is 20 x 50 cm. Test specimens of Group A reinforced with steel serve as a reference for GFRP reinforcement. Transversal reinforcement is applied in form of straight rebars of 8 mm with spacing of 240 mm.

All test sandwich panels were tested in four-point bending test. Load was recorded using 50 kN load cell. Vertical deflection along the test beam was recorded during the loading by use of five linear-differential digital transducers (see Figure 3). Flexural response of connectors was measured by strain gauges appliqued double-sided on the connectors close to the restraint in the bottom concrete layer. Relative displacement of concrete layers was measured at both ends of the test panels at the position of the most outer row of connectors using LVDTs.
Figure 3 Test set-up and measurement

Test procedure

Test specimens have been loaded displacement controlled with hydraulic cylinder with the loading rate of 0.5 mm/min until the cracking moment was captured. Then loading was applied in load increments with the loading rate 2 mm/min so that the crack pattern could be recorded and crack widths were measured (see Figure 4). The test panels were loaded up to the global failure or failure of a panel component considered as the end of service life of a structure.

Figure 4 Sandwich test panel S5 after shear failure of the insulation layer

RESULTS AND ANALYSIS

Flexural behaviour

In the analysis of the test results special attention is put to the behaviour in the range of load until reaching the service load. Generally, service load is defined as the ultimate load of the system divided by partial safety factor for material $\gamma_c$ and mean partial safety factor for action (dead and live load) $\gamma_F$ (Schmitt et al. 2014):

$$F_{\text{service load}} = \frac{F_u}{\gamma_c \cdot \gamma_F} = \frac{F_u}{1.5 \cdot (0.5 \cdot (1.35 + 1.5))} = \frac{F_u}{1.5 \cdot 1.425} = \frac{F_u}{2.14}$$

(1)

Resulting from the variety of materials and interfaces between them, number of failure modes can occur. Failure modes, which could be considered as eliminating the structure from further use (Ultimate Limit State), were: (1) shear cracking and bond failure of an insulation, (2) concrete crushing in a concrete wythe as well as (3) shear rupture of connectors. In all tests some or all of mentioned failure modes occurred up to the load around 20 kN. Using Eq. 1 the service load of 10 kN can be obtained. It need to be noted that in all tests global behaviour of the panels was very ductile and reaching ultimate load was indicated by large deformations. No abrupt failure occurred. Another failure modes can be recognized, describing the Serviceability Limit State: (1) excessive crack widths as well as (2) excessive deflections. Except those global failure modes, a number of failure modes of particular components of the system should be considered in order to create clear design recommendations.
Linear behaviour of panels was changing at the load ~5 kN (see Figure 5) when the first cracks occurred in the bottom concrete layer. From this point on, the flexural stiffness was decreasing along with development of the crack pattern. At the higher load levels (~15÷20 kN) insulation layer failed in shear or in bond to concrete or in combination thereof, causing significant drops of stiffness. For each test panel concrete crushing was the ultimate failure mode of the concrete layers, occurring at ~20÷25kN.

Mainly due to the lower modulus of elasticity of GFRP rebars, the developed crack widths were bigger than in case of panels S1 and S2 reinforced with steel. Nevertheless, at the service load of 10 kN maximal crack widths in the bottom wythe in any case did not exceeded 0.1 mm. Maximal observed crack widths bigger than 0.4 mm were reached at the very high load level while many other failure modes had already been developed. A uniform redistribution of crack pattern in both concrete layers was observed.

Influence of the parameters

Figure 6 and 7 show particular groups of specimens highlighted for comparison. Panels reinforced with steel (S1, S2) do not show higher stiffness in lower load range. It can be explained by the complicated distribution of internal forces along with development of damage in the insulation layer. Steel-reinforced panels, however, were stiffer in higher load range when the contribution of wythes’ stiffness itself had bigger influence on load-bearing behaviour. In a similar way, panels reinforced with higher reinforcement ratio (S7, S8) do not show any noticeable increase of stiffness. The highest stiffness and bearing capacity, also after development of cracks, was observed for test beams of Group C (S5, S6), which indicates great influence of amount of connectors and their arrangement on shear transfer capability. In each case, the panel with thicker insulation layer within each group showed lower stiffness, which can be contributed to relatively lower shear stiffness of insulation layer along with increase of its length.
**Load-carrying behaviour of the connectors**

Shear stiffness of a core layer (insulation + connectors) is essential for activation of sandwich carrying action. Although contribution of stiffness of polystyrene is significant in the lower load range, it decreases greatly after shear or bond failure of insulation. It was observed that insulation material fails at low load levels ~10÷20 kN and quality of its bond to concrete is highly variable, since the good adhesion of polystyrene to concrete is very dependent on the manufacturing process of sandwich panels.

In Figure 8 strains measured at both sides of the connector above the support (SG1,2) in test S5 are compared with the strains calculated from the measured relative displacement between the wythes (SRD1,2). Additionally in the figure the strain of connector in the second row (SG3,4) is depicted. In the calculation, the model of a bar restrained at both ends was adopted.

\[
\varepsilon = S_{RD1} = -1 \cdot S_{RD2} = \frac{6\mu l_c}{W_c d^3_A}
\]

where \(\varepsilon\) – strain of the connector derived from relative displacement of concrete panels, \(\mu\) - relative displacement of concrete panels, \(l_c, W_c\) - geometrical properties of connector’s cross section, moment of inertia and section modulus respectively, \(d_A\) – effective length of the connector (thickness of insulation layer + 2 * connector’s diameter) (ETAG-001).

Good agreement of calculation shows that stress in connectors can be derived directly from relative displacement of concrete layers with high accuracy.

**CONCLUSIONS**

In case of construction of thin concrete sandwich panels, the consideration of joint load-carrying action of both concrete wythes (sandwich effect) is essential to predict load capacity of the system. However, beside the global flexural failure a number of various failure modes can occur. Load-carrying behaviour needs to be in-depth considered, which is particularly important having the aim of preparation of clear guidance for the design of
sandwich panels. Relevance and impact on the global response of the structure of particular failure modes need to be analysed.

Test results showed that if the sandwich action is taken into account, the weakest point of the system is reliability and effectiveness of shear transfer between the concrete layers. Due to highly production-dependent bond properties of insulation, its contribution to the overall shear action, although substantial, need to be approached with conservativeness. The connectors remain the main shear transfer component in this system (after failure of the insulation), and therefore the deflection can be reduced by increase of the number of them.

Since the thin concrete layer cross-section is generally in over-reinforced condition (according to ACI 440.1R 15), the concrete crushing failure governs the design. Except smaller crack spacing and crack widths panels reinforced with steel rebars do not show remarkable difference in stiffness from panels with GFRP rebars within the service load range. Their ultimate load-bearing capacity, however, is higher by 20%.

Manufacturing of thin sandwich panels, except from complicated description of their load-bearing behaviour, is a challenging task, having in view practical implementation of the system into the construction market. Preparation process of test specimens proved that the providing of low concrete covers in case of thin concrete layers is possible under pre-cast plant conditions with satisfactory accuracy.

ABSTRACT

Hybrid FRP-concrete-steel double-tube concrete columns (DTCCs) are a new type of hybrid columns proposed at The Hong Kong Polytechnic University. A hybrid DTCC consists of an outer tube made of FRP and an inner tube made of steel, with all the space inside the two tubes filled with concrete. This combination of materials is expected to lead to a very ductile, high-strength and corrosion-resistant column, even when both the steel and the concrete have very high strengths. In this paper, the results from a series of axial compression tests on hybrid DTCCs with a high-strength steel (HSS) inner tube are presented to demonstrate the excellent structural response of the new column form with a HSS steel tube. The test results confirm that in a DTCC with a HSS steel tube, the local buckling of the HSS tube is effectively prevented and the concrete is very well confined, leading to a very ductile column response. DTCCs thus provide an effective column form for the efficient use of HSS.

KEYWORDS

FRP, high-strength steel, concrete, tubular columns, hybrid columns, axial compression, confinement

INTRODUCTION

A significant number of studies (e.g. Rasmussen and Hancock 1995; Zhao et al. 2004; Ban et al. 2013) have been conducted on the use of high-strength steel (HSS) (defined herein as steel with a yield stress in the range of about 450 MPa to about 1000 MPa) products in civil engineering structures, but its use has so far been rather limited. One of the limiting factors for the structural use of HSS is the greater susceptibility of HSS members to buckling failures compared to normal-strength steel members. Such buckling failure means that the yield strength of HSS cannot be fully utilized and the ductility of the structural member can be greatly compromised.

Against the above background, a new form of columns incorporating a HSS tube has been recently proposed at The Hong Kong Polytechnic University (Teng and Yu 2015). The new column comprises two concentric circular tubes with all the space inside the tubes filled with normal-strength or high-strength concrete (Figure 1a). The outer tube, made of fibre-reinforced polymer (FRP), is primarily used to provide confinement and shear resistance to the column in addition to serving a protection skin for the column and as formwork during construction, so the fibres in the FRP tube are oriented close to the hoop direction. The inner tube, made of HSS,
provides the ductile longitudinal steel reinforcement needed by the column and additional confinement to the core concrete. These columns, referred to herein as double-tube concrete columns (DTCCs), have the following advantages over conventional concrete-encased HSS columns: (a) the FRP tube confines the column so that the strain capacity of concrete is greatly enhanced to ensure the full development of the yield strength and the ductile response of the HSS section under both tension and compression; (b) a steel tube is used instead of a typical open section, so that both tubes function as confining devices so the concrete is well confined; (c) the FRP tube provides additional protection to the steel section against corrosion; and (d) the two tubes eliminate completely the need for formwork and steel reinforcing bars. Indeed, the non-ductile responses of all three materials (for HSS this is due to buckling) in a DTCC are suppressed by their interaction, leading to a high-performance column that is highly resistant to both seismic loading and corrosion.

Hybrid FRP-concrete-steel DTCCs as a column form were first proposed as a variation that results from the filling of the inner void of hybrid double-skin tubular columns (DSTCs) (Teng et al. 2004, 2007) which consist of an outer FRP tube, an inner steel tube and a layer of concrete in between (Figure 1b). The concrete infill in the inner steel tube prevents inward buckling of the steel tube, which may occur in DSTCs when a strong outer FRP tube and/or a thin/HSS inner tube is used (Wong et al. 2008); it also significantly enhances the axial load capacity of the column. DTCCs are also an attractive alternative to DSTCs whenever the column size needs to be minimized; they are particularly attractive for use in high-rise buildings where the columns are normally subjected to a high axial load ratio and a reduced column size is attractive to achieve larger usable floor areas. The behaviour of DTCCs with a normal-strength steel tube has received some research attention (Ozbakkaloglu and Fanggi 2013, 2015; Zhang et al. 2015).

To demonstrate some of the expected advantages of DTCCs with a HSS steel tube, a series of stub column tests have recently been conducted. The results of these tests are presented and discussed in the present paper.

EXPERIMENTAL PROGRAMME

Test Specimens

Four hybrid DTCC specimens were prepared and tested, comprising two pairs of nominally identical specimens; the only difference between the two pairs was the thickness of the FRP tube. The specimens all had a nominal diameter (i.e. the outer diameter of concrete) of 300 mm and a height of 600 mm. The steel tubes inside the DTCC specimens all had an outer diameter of 260 mm and a thickness of 6 mm. The specimens were cast in two batches with the same concrete mix design for the two pairs of specimens, respectively. For ease of reference, each specimen is given a name, which starts with a letter “D” to represent DTCC specimens; this is then followed by a number (4 or 6) to represent the number of layers of fibres in the FRP tube. The Roman numeral at the end of specimen names is used to differentiate two nominally identical specimens.

When preparing the specimens, the FRP tube and the steel tube were used as the formwork for casting concrete. The two tubes for each specimen were levelled in a workshop and then fixed onto a wooden bottom plate. Strain gauges on the steel tube were attached before casting. Before testing, a 50 mm wide carbon FRP strip was applied at each end of the specimens to avoid premature failure in the end regions.

Material Properties

Two types of filament-wound glass FRP (GFRP) tubes were used in the tests. They had the same fibre winding angles of ±80 degrees to the longitudinal axis of the tube, and were formed from four and six layer of fibres, respectively; each layer had a nominal thickness of 0.42 mm based on the weight of fibres. The so-called curved coupon tensile tests, which were recently proposed by the authors’ group (Teng et al. 2016), were conducted to obtain the elastic moduli of the GFRP tubes in the hoop direction. In the curved coupon test, a curved coupon cut from a circular GFRP tube is directly pulled at the two ends; the instrumentation of the tests follows ASTM D3039/D3039M (2000). For each type of GFRP tubes, six curved coupons, each with a width of 35 mm and a gauge length of 150 mm, were tested. For the four-ply tubes, four additional curved coupons with a gauge length of 100 mm were tested to examine the effect of gauge length. The test results showed that the scatter of elastic moduli obtained from different coupons was small, and that within the tested range the gauge length had little effect on the results. The elastic modulus values obtained range from 35.6 GPa to 37.3 GPa except one tensile specimen which had a significantly larger value of 39.8 GPa and was excluded in calculating the average elastic modulus, which was found to be 36.3 GPa for all four FRP tubes.

Cold-formed HSS tubes were used in the DTCC specimens. Tensile tests on six steel coupons were conducted in accordance with BS18 (1987) for the HSS tubes used in the DTCC specimens. The coupons were cut from a
HSS tube along the longitudinal direction. The average values of elastic modulus and yield stress were found to be 191.9 GPa and 669.8 MPa respectively. In addition, two hollow steel tubes, which had the same height as those in the DTCC specimens (i.e. 600 mm), were tested under axial compression. Both steel tubes showed large plastic deformation until failure occurred by local buckling in the elephant’s foot mode. The average axial load capacity of the two steel tubes was found to be 3509.6 kN.

Three plain concrete cylinders (150 mm x 300 mm) were tested for each batch of concrete to determine the mechanical properties of concrete. The elastic modulus, compressive strength and compressive strain at peak stress of the concrete averaged from the cylinder tests were 28.9 GPa, 36.3 MPa and 0.00298 respectively for the D4 batch, and were 29.6 GPa, 37.2 MPa and 0.00298 respectively for the D6 batch.

Test Set-up and Instrumentation

For each specimen, four axial strain gauges and eight hoop strain gauges, all with a gauge length of 20 mm were installed on the outer surface of the GFRP tube; the same number of strain gauges with a gauge length of 5 mm were installed on the outer surface of the steel tube. The circumferential layout of the strain gauges is shown in Figure 2. In addition, for each specimen, four linear variable displacement transducers (LVDTs) were used to measure the overall axial shortening, while four other LVDTs were used to measure the axial deformation of the 250 mm mid-height region. All the compression tests were conducted using a 1000 tonne Universal Testing Machine with a displacement control rate of 0.5 mm per minute.
TEST RESULTS AND DISCUSSIONS

General Behaviour

All four specimens except Specimen D6-I were tested to failure, which was due to the hoop tensile rupture of the GFRP tube and was accompanied with loud noises. The test of Specimen D6-I was unexpectedly terminated when the load was close to the capacity of the testing machine. All four specimens displayed a continuous, monotonically ascending load-shortening curve. The four specimens after test are shown in Figure 3. The steel tubes of all the DTCC specimens were taken out for examination, and no significant buckling deformation was found, suggesting that the GFRP tube together with the concrete provided effective restraints to the inner steel tube against buckling deformation.

Axial Load-Strain Behaviour

The key results of the column specimens are summarized in Table 1. In this table, $P_u$ is the ultimate load of a DTCC specimen from the compression test, $\varepsilon_{cu}$ is the ultimate axial strain of the DTCC specimen, which is the strain at the rupture of the GFRP tube (for Specimens D4-I, D4-II and D6-II) or at the point when the test was terminated (for Specimen D6-I), $\varepsilon_{hu}$ is the ultimate hoop strain corresponding to the ultimate axial strain and was obtained by averaging the readings of the eight hoop strain gauges. In Table 1, the axial strain of unconfined concrete at peak stress, $\varepsilon_{co}$, found from tests on standard plain concrete cylinders is used to normalize the measured ultimate axial strain $\varepsilon_{cu}$. In this paper, compressive stresses and strains are defined to be positive, while tensile stresses and strains are defined to be negative, unless otherwise specified. It is evident from Table 1 that the ultimate axial strains of all DTCC specimens are very large, and up to around 10 times the peak axial strain of unconfined concrete.

* Test unexpectedly terminated before failure

The axial load-strain curves of all four DTCC specimens are shown in Figure 4, where the axial strains were averaged from the readings of the four LVDTs covering the 250 mm mid-height region. Figure 4 shows that the DTCC specimens all had a bilinear axial load-strain curve with excellent ductility. The curves of Specimens D6-I and D6-II had a slightly steeper and longer second branch than those of Specimens D4-I and D4-II because of the use of a thicker GFRP tube in the former.

![Figure 4. Axial load-strain curves](image)

![Figure 5. Axial strain-hoop strain curves for the outer GFRP tube and the inner steel tube](image)
Lateral Dilation Behaviour

The axial strain-hoop strain curves of the outer GFRP tube for all the specimens are shown in Figure 5, where the hoop strains were averaged from the readings of the eight strain gauges installed on the GFRP tube while the axial strains were obtained from the average readings of the four LVDTs covering the 250 mm mid-height region. It is evident that the curves of the D6 pair are slightly higher than those of the D4 pair because of the use of a thicker GFRP tube in the former, but the differences between the two pairs of curves are very small. These differences are smaller than may be expected based on existing knowledge of GFRP-confined solid concrete columns, and are believed to be due to the existence of an inner steel tube, as further discussed later using a well-established analysis-oriented stress-strain model for FRP-confined concrete proposed by Jiang and Teng (2007).

Figure 6. Axial load-strain curves of DTCC specimens

Behaviour of Confined Concrete

In a DTCC specimen, the concrete is subjected to confinement from the inner steel tube in addition to that from the outer FRP tube, so its behaviour is expected to be different from that of concrete in an FRP-confined solid section column. Figure 6 is used to examine this issue. In Figure 6, the axial load-strain curves of the four DTCC specimens are each shown against three curves: the axial load-strain curve of the steel tube alone based on the hollow steel tube tests, the axial load-strain curve of the FRP-confined concrete (FCC) alone obtained using Jiang and Teng’s (2007) analysis-oriented model for FRP-confined concrete with the axial resistance of the FRP tube ignored, and that of the sum of the steel tube and Jiang and Teng’s (2007) predictions for the FRP-confined
concrete. As one of the two hollow steel tube tests was terminated at an axial strain of 0.021, the axial load-strain curve of the steel tube alone (averaged from the two hollow steel tube tests) beyond this strain value was extrapolated from the average experimental curve via an exponential extension for all the four DTCC specimens for comparison purposes. The extended portion of the axial load-strain curve of the steel tube alone for each DTCC specimen in Figure 6 is clearly indicated. In making the predictions for the FRP-confined concrete for each DTCC, the ultimate hoop strain obtained from the compression test of the DTCC specimen was used (see Table 1). It is evident from Figure 6 that the curves of DTCC specimens are much higher than the corresponding curves of the sum in the post-buckling stage of the hollow steel tubes, suggesting that the performance of DTCC specimens is far superior to what could be expected if there were no interaction between the steel tube and the concrete. The main benefit of interaction is the prevention of local buckling of the HSS tube by the FRP-confined concrete, demonstrating that DTCCs provide an effective column form for the efficient use of HSS. At failure as a result of the hoop tensile rupture of the GFRP tube, the load resisted by the DTCC exceeds the sum of steel tube and FRP-confined concrete by an average of 38.6% for the two D4 specimens and an average of 42.8% for the two D6 specimens. As the compression test of Specimen D6-I was unexpectedly terminated before failure, the load resisted by the DTCC specimen is compared in Figure 6 with the sum for the steel tube and the FRP confined concrete corresponding to the hoop strain in the GFRP tube at test termination.

It should be noted that in Figure 6, the curve of the steel tube alone was calculated using results from the hollow steel tube tests where the steel tube was subjected to uniaxial compression. In DTCCs, the steel tube is subjected to internal pressure due to the expansion of concrete inside the steel tube, as well as external pressure due to the existence of a GFRP confining tube. In general, the steel tube is expected to be in hoop tension and to confine the core concrete, which means that the internal pressure on the steel tube from the core concrete is larger than the external pressure on the steel tube from the FRP-confined concrete outside. In the four specimens tested in the present study, the inner steel tubes were all under hoop tension except during the very early stage of loading. As the steel tube in these DTCCs was under hoop tension, at the same axial strain, the axial load resisted by the steel tube is expected to be lower than that resisted by the same steel tube subjected to uniaxial compression only. This explains why the curve of the sum before the HSS tube buckles is generally higher than the corresponding test curve of DTCC (Figure 6).

The axial-hoop strain curves predicted by Jiang and Teng’s (2007) model for FRP-confined concrete in a solid circular section are also shown in Figure 5 for comparison. For these DTCCs, the existence of an inner steel tube did not affect significantly the axial-hoop strain relationship. The curve predicted by Jiang and Teng’s (2007) model is slightly lower than the experimental curves of Specimens D4-I and D4-II, suggesting that the steel tube may contribute more to constraining the lateral expansion of the column when the GFRP tube is relatively weak.

CONCLUSIONS

This paper has presented the details of a newly proposed form of FRP-concrete-steel hybrid columns, which is referred to as FRP-concrete-steel hybrid double-tube concrete columns (DTCCs). The new column consists of an FRP outer tube and a steel inner tube, with all the space inside the two tubes filled with concrete. The paper has also presented the results of the first set of axial compression tests on stub columns to demonstrate the favourable structural response of DTCCs. The results showed that the buckling of the HSS tube was effectively prevented and the concrete very well confined, leading to a very ductile column response. DTCCs thus provide an effective column form for the efficient use of HSS. In addition to resisting axial stresses, the HSS tube is also expected to provide confinement to the core concrete unless a very stiff FRP tube is used; the detailed mechanism of interaction between the FRP tube and the steel tube in DTCCs is a subject worthy of detailed analysis.

ABSTRACT

Hybrid FRP-concrete-steel double-skin tubular members (DSTMs) are a recent development that exploits the advantages of FRP composites (e.g., corrosion resistance, high strength-to-weight ratios and tailorability of material properties) to achieve high-performance and durable structures. Hybrid DSTMs consist of an annular layer of concrete sandwiched between an outer FRP tube and an inner steel tube. This paper presents a preliminary experimental study designed to investigate the feasibility of using the DSTM cross-section in arches for use in bridge construction (i.e., double-skin tubular arches or DSTAs). The fibres of the outer FRP tube are oriented close to the hoop direction to provide confinement to the concrete annulus. The inner steel tube, while also providing confinement to the concrete annulus, is mainly used to provide the steel tensile reinforcement for the section to resist bending. The inner steel tube also acts as propping during the construction process while the outer FRP tube serves as the formwork during concrete casting, thus considerably simplifying the construction process and reducing the labour cost. The experimental programme presented in this paper consisted of three tests on hybrid DSTAs subjected to two closely-spaced point loads near the mid-span covering two different FRP tube thicknesses and two steel tube locations (i.e., concentric and eccentric steel tube positions). The experimental results are presented and interpreted to understand the behaviour of hybrid DSTAs, particularly how the FRP tube thickness and inner steel tube eccentricity affect the behaviour of hybrid DSTAs.

INTRODUCTION

The use of fibre-reinforced polymer (FRP) composites in new construction, including the hybrid and optimal use of FRP with other materials (e.g., concrete, steel, timber) to create economical, corrosion-resistant structures, has become a topic of high interest in recent years (Holloway 2010). One of the most notable forms of FRP-based hybrid structural elements developed in recent years is the FRP-concrete-steel hybrid double-skin tubular member (DSTM) (Teng et al. 2007). These hybrid DSTMs consist of an outer tube made of FRP and an inner tube made of steel, with the space in between filled with concrete. The two tubes may be concentrically located (Figure 1a) to produce a section form more suitable for columns, or eccentrically located (Figure 1b) to produce a section form more suitable for beams (Teng et al. 2007; Wong et al. 2008). Hybrid DSTMs may be constructed in-situ or precast, with the two tubes serving as the stay-in-place form. The main advantages of hybrid DSTMs include: (a) excellent corrosion resistance, as the FRP tube is highly resistant to corrosion while the steel tube is protected by the FRP tube and concrete; (b) excellent ductility and energy absorption capacity, as the concrete is well confined by the two tubes and outward local buckling of the steel tube is constrained by the concrete; (c) a high strength/stiffness ratio as the inner void largely eliminates the redundant concrete; (d) ease of construction, as the two tubes function as a permanent form for casting concrete and the presence of the inner steel tube allows easy connection to other members (Teng et al. 2007).

Many studies have been carried out to understand the behaviour of hybrid double-skin tubular columns (DSTCs) (e.g., Teng et al. 2007; Yu 2007; Yu et al. 2010a,b; Fanggi and Ozbakkaloglu 2013; Idris and Ozbakkaloglu 2014; Ozbakkaloglu and Fanggi 2014; Zhang et al. 2015), leading to a sound understanding of the behaviour of DSTCs. In hybrid DSTCs, the FRP tube, with fibres oriented close to the hoop direction, offers mechanical resistance primarily in the hoop direction to confine the concrete and to enhance the shear resistance of the
member. Investigations into hybrid double-skin tubular beams (DSTBs) (e.g., Yu et al. 2006; Zhao et al. 2016) have revealed that DSTBs have a very ductile response under flexural loads; furthermore, an eccentric steel tube can significantly improve the flexural stiffness, ultimate load and cracking resistance of hybrid DSTBs (Yu et al. 2006).

Figure 1 Typical cross-sections of hybrid DSTMs

This paper presents the results of a preliminary experimental study designed to investigate the feasibility of using DSTMs as arches in bridge construction. The fibres of the outer FRP tube are oriented close to the hoop direction to provide confinement to the concrete annulus. The inner steel tube, while also providing confinement to the concrete annulus, is mainly used to provide the steel tension reinforcement for the section to resist bending. Hybrid double-skin tubular arches (DSTAs) not only possess a high strength-to-weight ratio, but also significantly reduce the construction cost of arch bridges due to the elimination of formwork.

**EXPERIMENTAL PROGRAMME**

**Specimen Design**

The curvature of the arch was selected to match an existing arch bridge, namely the Galena Creek Bridge in the United States (Durski 2010). Considering the physical laboratory and construction constraints associated with the size of specimens, only a segment of the arch was studied in the laboratory. The span of the test arches was selected to be 3600 mm and the height at crown was selected to be 480 mm (Figure 2a). In order to achieve a reasonable cross-sectional void ratio (defined as the ratio between the inner diameter and the outer diameter of the annular concrete section) with a reasonable concrete wall thickness, an inner diameter of 154 mm was selected for the FRP tube and a 88.8 x 4 circular hollow section (CHS) standard steel tube (which had an actual outer diameter of 90 mm) was adopted as the inner steel tube (Figure 2b). With these dimensions, a sectional void ratio of 0.58 was achieved. The diameter-to-thickness ratio of the steel tube was 22.2, which is within the limits (20-42) recommended by Yu (2007).

Figure 2 Arch geometry

In total, 3 arch specimens were designed and prepared in the laboratory. Instead of using prefabricated FRP tubes by filament winding, the FRP tubes for the arch specimens were formed in the laboratory via the wet-layup process by wrapping FRP layers on the concrete annular section. This alternative method of forming FRP tubes was expected to have little effect on the behaviour of the test arches. One of the three specimens was wrapped with 6 layers of glass FRP (GFRP) having a 1025 g/m² fibre density per layer, while the other two specimens had 4 layers of the same GFRP each. In all the arch specimens, the fibre direction was controlled to be between 0°-10° to the hoop direction of the tube. In one of the two specimens with 4 layers of GFRP, the steel tube was placed with an 18 mm eccentricity, while in the other specimens, the steel tube was concentrically located. The steel tube eccentricity is defined as the distance between the centre of the steel tube and the centre of the concrete annulus (Figure 2c). Further details of the specimens are summarized in Table 1.

Each specimen has a unique six-character name as shown in Table 1. The first two characters indicate the number of FRP plies (i.e., “6P” means 6 plies while “4P” means 4 plies). The third and fourth characters represent the steel tube outer diameter. The fifth character indicates the thickness of the steel tube. The last character indicates the position of the steel tube within the concrete annulus, with “C” indicating a concentrically-placed steel tube and “E” indicating an eccentrically-placed steel tube. For example, specimen 6P904C was confined by a 6-ply FRP tube formed via the wet-layup process and had a concentrically-placed circular steel tube of 90 mm in diameter.

**Specimen Preparation**

In practical applications, the FRP tube should be prefabricated by filament winding and the steel tube should be placed inside the FRP tube before the casting of concrete, so that no temporary formwork is required for casting the concrete. However, prefabricating the FRP arch tube was found to be too expensive at this preliminary stage. Therefore, it was decided to first cast a concrete arch with a curved steel tube inside and then wrap the desired number of GFRP layers around the steel-concrete arch. The method involved the use of a mould, where the steel tube was properly positioned and restrained in the mould, for the casting of concrete to form a steel-concrete arch, which was then removed from the mould upon appropriate curing. These steel-concrete arches were next wrapped with the desired number of GFRP layers to form the external FRP tube.

A negative mould (i.e., the void for casting the concrete of a DSTA) was first produced in two halves, which were then joined to form a continuous negative mould. Each mould was designed to cast two arches simultaneously. The moulds were manufactured using high density foam and were then fixed to a backing plate (Figure 3a) to provide enough strength for carrying the weight of wet concrete. In order to water-seal the high density foam, a coating of PVA glue was applied to the exposed (i.e. internal) surface of the foam mould which was then followed by a layer of enamel paint. The two halves of the mould were fixed to a stiff steel frame to ensure that no relative movement between the two halves would occur. A photograph of the half moulds and the closed mould are shown in Figures 3a and 3b respectively.

The steel tubes were bent to the required curvature using cold mandrel bending at a cold bending facility. In order to ensure composite action between the concrete and the steel tube in a DSTA, shear studs were welded at a 100 mm spacing in the longitudinal direction at both the topmost and the bottommost points of the steel tube cross-section. The steel tube was then placed in the mould and the mould was set upright (Figure 3c). The steel tube was next fixed in place using an external mount welded to the mould frame (Figure 3c). This was necessary as the buoyancy acting on the steel tube during the casting of concrete applied lifting forces to the steel tube. Once all steps of the above procedure were completed, the concrete was poured (Figure 3c). Due to the limitations imposed by the existing mixer, three batches of concrete had to be mixed for the three DSTA specimens respectively. The same mix design was adopted for all three batches with a 28-day target cylinder compressive strength of 70 MPa. After 7 days of curing, the steel-concrete arch was removed from the mould.

After 28 days of curing, the steel-concrete arches were suspended vertically on a steel frame (Figure 3d). To avoid stress concentrations in the GFRP tube, jagged regions of the cast concrete tube were ground to a smooth surface. For specimen 6P904C, the glass fibre sheets were cut in to 100mm strips, impregnated with epoxy and then wrapped around the steel-concrete arch in a spiral with a 50mm overlap between passes until the end of the arch to form a GFRP tube. Once wrapped, a roller was used to squeeze out any excess epoxy. Next, a perforated release film was wrapped around the GFRP tube, and a peel ply and filter cloth were applied on top to absorb any excess adhesive. Finally, a shrink tape was wrapped around and heated to apply pressure on the arch surface and squeeze out any excess adhesive. During the specimen construction process, due to the gravitational flow of epoxy and the geometry of the specimen, achieving a section of uniform thickness through the wet lay-up...
process was found to be difficult. Therefore, GFRP prepreg sheets were used instead in the next two DSTA specimens to form the GFRP tube. The formation of a GFRP tube from the prepreg sheets followed the same process as used for forming the GFRP tube from fibre sheets for specimen 6P904C (Figure 3e). Once the GFRP tube was formed, a release film was applied, which was then followed by the wrapping of a shrink tape around the steel-concrete arch. Once all these steps were completed, heat blankets were wrapped around the arch to cure the adhesive. Specimens were cured for two hours at 120 degrees Celsius. A fully cured specimen is shown in Figure 3f. Once cured, the end regions of the arches were reinforced by 3 additional GFRP layers of 50 mm in width at each end.

**Figure 3 Construction of hybrid DSTAs**

**Material Properties**

Five tensile coupons each were made from a GFRP sheet and a GFRP prepreg sheet and tested for fibre direction tensile properties. All coupon tests were carried out according to the ASTM-D3039/3039M (2010) specifications. The average properties from the coupon tests are given in Table 2. The obvious differences in the elastic modulus between the two types of GFRP materials are believed to be due to a higher amount of adhesive in the GFRP sheets made using the wet lay-up process than the GFRP prepreg sheets. Three 100 mm x 200 mm concrete cylinders were made from each batch of concrete and tested for the 28-day compressive strength. The average properties from the concrete cylinder tests are also given in Table 2. The elastic modulus of steel was 195GPa while its yield stress was 270 MPa according to the manufacturer’s data sheet.

**Experimental Setup**

All three tests were conducted under two-point loading (with a 200 mm distance between the two loading points) using a 500 kN capacity actuator. An overall view of the experimental setup is given in Figure 4a. Specially designed bearing plates were used to support a DSTA specimen at the ends. These bearing plates were designed with the objective of versatility to accommodate different specimen sizes with diameters within the range of 100 mm to 200 mm at an angle of 29°±5° with respect to the horizontal direction. A threaded bar was used for minute angle changes of the adjustable bearing plate, which allowed for the nearly perfect seating of the arch at the supports. A bearing plate with a DSTA in place is shown in Figure 4b. Floor brackets (Figures 4a and 4c)
were used to stop any out-of-plane movements while allowing in-plane movements. Loading was applied to the arch using a clamp system attached to the actuator head (Figure 4d).

**Figure 4 Experimental loading setup**

**Instrumentation and Loading**

Strain gauges were attached to both the steel tube and the FRP tube to measure axial and hoop strains. In total, five sections were selected for measurement (Figure 5a), including the mid-span section (L1), sections of 200 mm (L2), 300 mm (L3) and 800 mm (L4) offset from the mid-span section, and the section at 100 mm offset from the support (L5). The strain gauge arrangement on each section is shown in Figure 5b. Considering the symmetry conditions, the strain gauges were placed only on one half of the section. Ten strain gauges, including five in the axial direction (denoted by “A” in Figure 5b) and 5 in hoop direction (denoted by “H” in Figure 5b), were installed on the FRP tube at each section to capture the axial strain and hoop strain distributions at each section and also along the arch axis. In addition, the strains of the steel tube were measured by four strain gauges at each section, including two in the hoop direction and two in the axial direction.

To obtain the deformation curve of each arch during the loading process, seven symmetrically-arranged linear position transducers (Figure 5c) were employed to measure the displacements of the arch at different locations. Actuator readings were taken for both the load and the crown displacement. Loading was applied at a rate of around 2 mm/min.

**TEST RESULTS AND DISCUSSIONS**

**Load-Deflection Responses**

The curves of load vs mid-span deflection of all three specimens are shown in Figure 6. The initial stiffnesses of all the specimens are similar, but as the load increases, the stiffnesses of specimens 4P904E and 6P904C tend to decrease faster than that of specimen 4P904C. The faster decreases in stiffness of specimen 4P904E are believed to be due to the eccentric placement of the steel tube, resulting in a reduced section rigidity in the hogging moment regions. The faster decreases in stiffness of specimen 6P904C are believed to be due to manufacturing defects during the wet-layup process.

Of the three specimens, specimen 4P904C achieved the highest load-carrying capacity, with an ultimate load of 259 kN (referring to the sum of the two point loads in the present paper). Specimens 6P904C and 4P904E
attained ultimate loads of 230 kN and 170 kN respectively. All three specimens were able to undergo large deformations without substantial reductions in the load. The unloading stiffnesses of all three specimens were found to be similar to the respective initial stiffnesses. During the testing of specimen 6P904C, a sudden load drop accompanied by a loud noise occurred, after which the specimen could be reloaded to its ultimate load. Specimen 4P904E also experienced a small load drop close to its ultimate load.

**Failure Modes**

In all three specimens, tensile cracks of the FRP tube in the fibre direction were observed (Figure 7). These tensile cracks initiated during an early stage of loading (at a load of approximately 40 kN) near the mid-span (Figure 7a); more cracks of the same nature appeared in other regions of the arch (within the region of approximately 1100mm to 1400mm from the mid-span on each side) as the load continued to increase (Figures 7b and 7c). Naturally, these tensile cracks on the GFRP tube were always in the tensile region of the cross-section and their horizontal locations are related to the distribution of bending moment along the arch.

After the test, the GFRP tube was cut open to inspect the concrete annulus. Near the tensile cracks, concrete cracking was observed. However, these concrete cracks were localized in the cracked regions of the GFRP tube, and no cracks were observed in the compression region of the cross-section. Upon unloading, significant plastic deformation of the arch was observed for all three specimens (Figure 7c).

**Axial Strains**

Due to space limitations, only the axial strains of selected locations are discussed in this paper. The axial strains of the FRP tube at sections L3 and L4 of specimen 4P904C are selected to represent the sagging moment and the hogging moment regions respectively and are given in Figures 8a and 8b. The strain readings at section L4 of the steel tube are given in Figure 8c.

Axial strains of the FRP tube were found to vary over the cross-section of the arch at both sections L3 and L4, obviously as a result of bending effects. At section L3, the top part of the section (i.e. points C1 & C2 in Figure 5b) are seen to have high compressive strains while points C3-C5 had relatively low strain values. At section L4,
the top part of the section (points C1 & C2) showed low tensile strains, while the bottom part (points C4-C5) showed relatively high compressive strains. Similar trends were observed in specimens 6P904C and 4P904E.

Similar to the FRP tube, the steel tube had axial strains that vary significantly over the cross-section due to bending effects. A clear change in the strain increase rate is seen when the load is close to 220kN (Figure 8), indicating the yielding of the steel tube. However, the strain readings on the steel tube at this load were higher than the yield strain based on the manufacturer’s data. Steel coupon tests are yet to be carried out in order to obtain the actual material properties for the steel tubes.

### Hoop Strains

Hoop strains at sections L3, L4 and L5, shown in Figure 9, are seen to vary over the cross-section as well. The hoop tensile strain values were generally higher where the axial compressive strains were higher; the hoop tensile strains reduce in value or even change to be compressive strains down the section height (i.e., point C5 at section L3 and point C1 at section L3). At section L5, while the hoop strains were non-uniform over the cross-section, all hoop strain values were positive (i.e., GFRP tube was in tension around the entire circumference) at higher loads.

### Discussions

The test results showed that the hybrid double-skin tubular section can function effectively in arches. The test DSTAs showed a highly ductile response, which cannot be expected of similar steel-concrete arches without the external GFRP tube. Increasing the FRP volume from 4100 g/m² (4P904C) to 6150 g/m² (6P904C) did not increase the load-carrying capacity of the arch. In fact, specimen 6P904C had a load-carrying capacity that is 11.2% lower than that of specimen 4P904C. This may have been caused by the difference in the manufacturing technique, with a better quality control for the GFRP tube in specimen 4P904C. The eccentricity of the steel tube resulted in a reduction in the load-carrying capacity. Eccentric placement of the steel tube increases the sagging moment capacity but reduces the hogging moment capacity of the cross-section, leading to an overall effect of reduction in the load-carrying capacity of the DSTA.

### CONCLUSIONS

This paper has presented the results of three tests on hybrid double-skin tubular arches (DSTAs) under two concentrated loads near the mid-span (four-point bending tests). A DSTA is composed of a steel inner tube, an FRP outer tube, and a concrete infill between the two tubes. The main parameters examined in this study include...
the number of layers forming the FRP tube and the section configuration. Based on the test results and discussions, the following conclusions may be drawn:
(1) DSTAs have much higher load-carrying capacities than similar steel-concrete arches without an FRP tube;
(2) DSTAs possess a very ductile response;
(3) The DSTA specimen with an eccentrically-placed steel tube had a lower load-carrying capacity than its counterpart with a concentrically-placed steel tube;
(4) Increasing the GFRP tube thickness from 4 layers to 6 layers did not increase the load-carrying capacity; instead a reduction was observed. This could be attributed to defects during the manufacturing of the DSTA with a 6-layer GFRP tube.
(5) Further research is necessary to better understand and model the behaviour of DSTAs.

ACKNOWLEDGMENTS

The authors wish to thank Messrs Steven Ettema, Samuel Rech, Samuel-Hislop Lynch and Samuel Caldwell for their efforts in manufacturing the test specimens.

ABSTRACT

Recent research at the University of Queensland (UQ) has led to the development of a new type of structures called “hybrid fibre reinforced polymer (FRP)-timber (HFT) structures”. In HFT structures, FRP is combined with timber veneers to create high-performance, lightweight, easy-to-construct structural members. These HFT members utilize the orthotropic properties of both timber and FRP in a complementary combination to produce much improved composite properties and to maximise the load-carrying capacity of members for a given amount of material. While preliminary experimental work has demonstrated the potential of HFT sections as high-performance sustainable structural components, much more work is needed to better understand the behaviour of HFT structures. This paper presents the results of an experimental study into the local buckling behaviour of HFT thin-walled Cee section short columns. The experimental programme consisted of fifteen HFT column specimens, including all-timber columns and three different types of HFT columns. The test results are presented and discussed. HFT Cee section short columns carried significantly higher axial loads than the corresponding all-timber columns. The ultimate load-to-weight ratio of the HFT sections is shown to be comparable to or significantly higher than that of cold-formed thin-walled steel Cee sections.

KEYWORDS

Timber, FRP, Hybrid FRP-timber columns, local buckling, thin-walled structures, lightweight structures.

INTRODUCTION

Lightweight steel and aluminium thin-walled structures have become popular in the construction industry due to their advantages such as ease for assembly, transportation and installation. Steel or aluminium thin-walled lightweight structural sections, manufactured using the cold-forming technique, often exist as open profiles such as Cee or Zee sections. The load-carrying capacity of these members is typically governed by buckling failure in a local, distortional or global buckling mode. While these structural members possess many advantages, steel and aluminium are greenhouse gas-intensive materials. Therefore, steel and aluminium thin-walled structural members have been considered as non-sustainable (Yan et al. 2010).

At the University of Queensland (UQ), much recent research has been devoted to the development of high value end uses of low-quality timber products, which has resulted in the development of a new form of composite structures. These new structures, termed hybrid fibre reinforced polymer (FRP)-timber (HFT) thin-walled structures, are formed by combining FRP with thin veneers to create high-performance, lightweight, easy to construct structural members. These new products have many potential applications such as roof purlins, floor panels, stud walls, facades, load-bearing walls, bridge decks, etc. These new products utilize the orthotropic properties of timber and FRP in a complementary combination: the fibre directions are appropriately oriented to produce near-optimal composite properties and to achieve cross-sectional shapes that maximize the load-bearing capacity for a given amount of material. The grain orientations of the veneer in the section shown in Figure 1 are approximately parallel to the longitudinal axis while the fibres of the FRP layers are oriented perpendicular to the longitudinal axis. These HFT sections take advantage of the veneer’s natural tendency to curl towards one side, making the formation of open sections easily achievable around a mandrel, with the veneer grains oriented in the direction of the member longitudinal axis. However, due to this orientation of the veneer grains (parallel to the longitudinal axis), HFT sections would have weak properties in the transverse direction if no FRP layers were provided. Therefore, in these HFT sections, FRP layers with the fibres oriented predominantly in the
transverse direction are provided to enhance the transverse properties. The presence of FRP layers can significantly enhance the buckling strength of HFT thin-walled members.

Figure 1 HFT Cee-section (arrow heads indicate the FRP fibre and timber grain directions)

HFT sections take advantage of two existing novel technologies, namely the use of FRP composites to reinforce low-quality timber products (Buell and Saadatmanesh 2005; Fernando et al. 2016) and veneer-based innovative timber sections made from hardwood thinnings (Gilbert et al. 2014). A preliminary experimental investigation showed that HFT wall panels can significantly outperform all-timber wall panels in terms of axial load-carrying capacity (Fernando et al. 2015). The recent study of Gilbert et al. (2014) showed that all-timber thin-walled structures have a compressive capacity-to-weight ratio of up to 30% greater than cold-formed steel structures, while having a much higher bending stiffness (up to 3.3 times higher). These observations clearly suggest that HFT sections can be expected to perform significantly better than cold-formed steel columns in terms of load-carrying capacity-to-weight ratio. Therefore, HFT sections are believed to have great potential in structural applications.

This paper presents an experimental study into the local buckling failure of HFT Cee sections under axial compression. The test program consisted of fifteen short column specimens, including three all-timber columns and twelve HFT columns. The column specimens were constructed of softwood (hoop pine) veneers and FRP layers; different FRP materials were explored in the study, including glass FRP (GFRP), natural fibre FRP (NFRP), and natural fibre mat FRP (NMFRP).

EXPERIMENTAL PROGRAMME

General

In the present study, fifteen HFT Cee section column specimens were manufactured and tested under axial compression. These specimens included three all-timber columns, four each of hybrid GFRP-timber (HGFT), hybrid NFRP-timber (HNFT), and hybrid NMFRP-timber (HNMFT) columns. The NFRP used linen fabrics produced from fibres extracted from the flax plant while the NMFRP used fibres extracted from the Kenaf plant. For ease of reference, the name of each column specimen starts with a letter of “A” - “D” representing the all-timber, HGFT, HNFT, and HNMFT specimens respectively, followed by a Roman number to differentiate the four nominally identical specimens of each type. For an example, specimen A-I means the first specimen of all-timber Cee section columns.

Figure 2 HFT Cee-section column

The nominal dimensions of the cross-section for the test columns are shown in Figure 2a. The internal depth, internal width and internal radius of the cross-section were 150 mm, 73 mm and 15 mm respectively. Each
specimen consisted of three 0.7 mm nominal thickness hoop pine timber veneer layers as the core and a number of FRP layers applied on the inner and outer surfaces of the timber core: (a) two GFRP layers, with one each on the inner and outer surfaces of the timber core in the HGFT specimens, (b) six NFRP layers, with three each on the inner and outer surfaces of the timber core in the HNFT specimens, and (c) two NMFRP layers, with one each on the inner and outer surfaces of the timber core in the HNMFT specimens. The numbers of NFRP and NMFRP layers were selected to match the weight of GFRP layers used in the HGFT specimens. Preliminary finite element (FE) analysis was carried out to determine the elastic buckling modes of the columns. Based on the FE results, a height of 280 mm was selected for the column specimens to ensure that local buckling would govern the failure. The measured thicknesses of the column specimens are given in Table 1. As the different fibres had significantly different absorption rates for the adhesive, some variations in the thickness were observed. These thickness variations were enlarged by the different volumes of adhesive absorbed by the filter cloth used during the manufacturing process. In particular, HNMFT specimens showed significant variations in the thickness.

**Specimen Preparation**

In all the column specimens, the grain orientation of the veneers was aligned with the column longitudinal axis. In the HGFT and HNFT specimens, the fibre orientation of FRP was perpendicular to the longitudinal axis, while the NMFRP had fibres oriented at random directions. In all the HFT specimens, the FRP layers were expected to enhance the transverse properties of the timber. The specimen preparation process started with the bonding of veneers and FRP layers together around a mandrel, followed by the application of pressure using a vacuum bag to maintain the shape until the adhesive had cured properly (Figure 3). During the preparation process, filter clothes were used between the vacuum bag and the Cee section external surface to absorb any excess adhesive. Based on the recommendations of Miao et al. (2015), a commercially available polyurethane adhesive, PURBOND, was used to bond the layers together in all specimens. The curing time recommended by the manufacturer for the PURBOND adhesive was 4 hours. After 4 hours, the vacuum bag was removed and the specimen was removed from the mandrel. Each specimen was initially 400 mm in height, but was cut to a height of 280 mm upon full curing. The offcuts were used to obtain coupons for material testing.
Material Properties

The mechanical properties of the HFT sections were determined by tensile coupon tests. Ten 100 mm *10 mm coupon specimens, five for each direction (parallel and perpendicular to the column longitudinal axis respectively) were cut from the web of the offcuts. Two aluminium tabs of 25 mm in length were attached to each end of a coupon specimen to avoid failure within the gripping regions. The dimensions of the coupons were selected as per the recommendations given in ASTM-D3039/D3039M (2014). The coupons were then loaded in axial tension using a 100 kN capacity INSTRON testing machine. A video extensometer was used to obtain the longitudinal and transverse strains during the loading while the load was obtained from the testing machine. The average mechanical properties from coupon tests for the column specimens, in terms of tensile stiffness (Et) and tensile strength per unit width (σu), are given in Table 2.

Test Set-up and Instrumentation

All the column tests were carried out using a 250 kN capacity INSTRON testing machine. The test set-up is shown in Figure 4. The specimen was seated on a fixed steel base plate, and the load was applied at the top through a steel plate with a hemispherical block to allow rotational movements between the machine loading head and the top steel plate. When placing a specimen in the testing machine, the centre of the hemispherical
block was aligned with the centroid of the specimen cross-section to ensure concentric axial loading. The axial load was applied with displacement control at a rate of 0.2 mm/min.

Three linear variable displacement transducers (LVDTs) were used to measure the horizontal column displacements at a specific height (i.e., mid-height or quarter height) where the buckling mode was expected to have its maximum displacement according to finite element analysis. A non-contact 3D optical method (DIC system) was employed to capture the deformed shape of the inter surface of one of the flanges.

RESULTS AND DISCUSSIONS

All column specimens failed due to local buckling. The typical buckling mode observed for each specimen type is shown in Figure 5. Compared to type A specimens, a significant reduction in the half-wave length was observed in specimen types B and C (Figure 5). In the HFT specimens, the lateral movements of the flanges were often concentrated in either the lower or the upper portion of the column (Figures 5b and 5c) instead of closely following a sinusoidal pattern. This is attributed to the inherent non-uniformity of material and/or geometric properties down the column height. Upon removal of the load, all specimens bounced back to being close to their respective original shapes, showing little to no damage.

![Figure 5 Typical buckling modes of different specimen types before removal of axial load](image)

The load-axial displacement curves obtained from the testing machine for specimens “A” - “D” are given in Figure 6. In terms of the initial stiffness, the HFT specimens showed better consistency than the all-timber specimens. The HFT specimens also had a much higher initial stiffness than that of the all-timber specimens. The differences in the average initial stiffness amongst the different types of HFT specimens are small.

![Figure 6 Load-displacement curves of all column specimens](image)

The ultimate loads of the column specimens are given in Table 3. The addition of FRP layers significantly increased the local buckling capacity of the column. The highest load increase was achieved by type D specimens, with the average ultimate load increase being 276% over type A specimens. The average ultimate loads of types B and C specimens are 158% and 267% higher than that of type A specimens. Types A and B specimens had average measured weights of 0.131 kg and 0.287 kg, respectively. The average ultimate load per
unit weight for type B specimens is 17% higher than that of type A specimens. Although the weights, thus the volumes of adhesive of the four type B specimens were different, the ultimate loads showed limited differences. Similar observations can be made about types C and D specimens.

While the HFT Cee section columns achieved significantly higher ultimate loads than the all-timber Cee section columns, the average ultimate load per unit weight of the HFT Cee section columns is only marginally higher than that of the all-timber Cee section columns. Since only three 0.7mm thick timber veneers were used in the present HFT Cee section columns, the weight of the FRP layers was higher than that of the timber veneers in these HFT sections. However, in HFT sections with a significantly higher timber mass ratio, the ultimate load per unit weight can be expected to be increase accordingly. HFT wall panels tested by Fernando et al. (2015) showed a 91% increase in the average ultimate load due to the addition of FRP while the average weight increase was less than 28%.

**COMPARISON WITH COLD-FORMED STEEL**

Mulligan (1983) tested cold-formed steel Cee section columns under axial compression. Specimens SC120x60 (156mm in depth, 76mm in width, 1.2mm in thickness and 474 mm in height) and SC180x60 (225 mm in depth, 76 mm in width, 1.21 mm in thickness and 457 mm in height) were found to have axial load capacities of 36.49 kN and 37.91kN respectively (Table 1). These columns failed by local buckling, so it is reasonable to assume that the ultimate load depends little on colour height. Specimen SC120x60 weighed 0.806 kg per 280 mm in length while specimen SC180x60 weighed 0.994 kg per 280 mm in length, both being much heavier than the present HFT sections. The axial load capacities per unit weight of the HFT section columns (with a height of 280 mm) exceed...
those of the SC120x60 and SC180x60 section columns, confirming that the HFT sections can perform significantly better than similar standard cold-formed steel sections in terms of ultimate load-weight ratio.

CONCLUSIONS

This paper has presented an experimental investigation into the buckling behaviour of hybrid FRP-timber (HFT) thin-walled Cee section short columns. The 280 mm long HFT columns were formed by adhesive bonding of timber veneers and FRP layers. The performance of HFT columns made with three different types of FRPs [namely, glass FRP (GFRP), natural fibre FRP (NFRP), and natural fibre mat FRP (NMF FRP)] were investigated. Tensile coupon tests were carried out to determine the material properties for each column specimen. The column compression test results showed that: (i) HFT specimens performed much better than all-timber specimens in terms of both load-carrying capacity and axial stiffness; (ii) NMHFT specimens achieved the highest axial load capacity; (iii) GHFT specimens had the highest axial load capacity per unit weight; and (iv) the load-carrying capacity per unit weight of HFT sections can be significantly higher than that of lightweight thin-walled cold-formed steel sections. The last conclusion means that HFT sections can be used as an attractive sustainable alternative to cold-form steel sections in practice. While the load-carrying capacity per unit weight of the present HFT sections are only marginally higher than that of the present all-timber sections, it can be expected to become significantly higher in sections with a higher timber mass ratio. Further investigations are required to study the different buckling failure modes of HFT columns and to develop numerical/analytical models to predict the behaviour of HFT columns.

ABSTRACT

A novel GFRP-concrete-steel composite beam was proposed to improve durability, which is consisted of GFRP-concrete composite deck and steel girder and then tested under the static loads. In our study, two GFRP-concrete-steel composite beams with different GFRP-concrete interface were fabricated and a traditional steel-concrete composite beam was used as a control sample. The deformation, bending performance and failure modes of the model beams were discussed and compared. The experimental results show that all specimens are failed with concrete crush. Both GFRP-concrete-steel composite beams had lower stiffness than that of traditional steel-concrete composite beam. However, the slip effects of GFRP-concrete-steel composite beams were similar to the effect of traditional steel-concrete composite beam. Moreover, different GFRP-concrete interface have no effect on the experimental results of GFRP-concrete-steel composites. Also the consistence of our theoretical results with experimental results demonstrated that the ultimate capacity of GFRP-concrete-steel composite beams could be predicted by the bending bearing capacity calculation method based on considering elastic-plastic performance.

KEYWORDS

FRP, composite beams, GFRP-concrete deck, slip, ultimate capacity, deformation.

INTRODUCTION

Highway bridges, especially bridge decks, are exposed to environment erosion and overweight vehicles, which increase the costs at the later stage of maintenance. In order to improve the durability of bridge structure, increase fatigue and corrosion resistance, prolong the service life, fiber reinforced polymer (FRP) has been applied in different components of bridges, such as: CFRP Cable, GFRP beam, GFRP bridge deck. Recently, GFRP-concrete composite bridge deck has been concerned by many researchers as a method for improving the durability of concrete bridge deck, which has the characteristics of corrosion resistance, easy construction, low maintenance cost (Nelson et al. 2014). At present, the research efforts on the interface between GFRP and concrete, the cross section types of GFRP and the static performance of composite deck are reported. The types of interface include wet bond interface, coarse sand coated, combined shear connector system, etc. (Honickman et al. 2009, Cho et al. 2010). According to different forms of composite slabs, the cross section types of GFRP may include T-up stiffeners on plate, dual cavity system, tubular sections on plate, etc. (Dieter et al. 2002, Nelson et al. 2014). The static tests cover one-way simply supported slabs, two-way slabs, continuous slabs (Alagusundaramoorthy et al. 2006, Huang et al. 2015).

The composite girder bridge with GFRP-concrete deck has better resistance to the overweight vehicles and environment erosion. Although experimental and analytical work on the mechanical characteristics in the transverse bridge direction have been widely reported, the research on the composite action of GFRP-concrete deck and steel girder is rare. This paper presents the experimental results of GFRP-concrete-steel composite beams which consist of GFRP-concrete deck with GFRP groove plate and steel beam. The samples include two GFRP-concrete-steel composite beams with different surface treatment (with or without wet bonding technique) and a steel-concrete composite beam as a contrast specimen. The bending mechanical characteristic of composite beams was tested. The tests emphasize on strain distribution across section, load and displacement relationship, slip value from support to mid-span. In the end, the bending failure load was calculated by elastic-plastic calculation method. The prediction agreed well with test data.
EXPERIMENTAL PROGRAM

Test Specimens

Three composite beams, referred to as S-1 to S-3, were fabricated and tested. Table 1 provides a summary of the test beams, including dimensions, calculated spans, reinforcement content, pitch of shear stud, GFRP-concrete interface. The GFRP panel is consisted of T-up stiffeners and bottom plate (Figure 1(c)). The three composite beams were tested to evaluate the influence of GFRP. S-1 (with wet bonding technique) and S-3 (without wet bonding technique) are both GFRP-concrete-steel composite beams. S-2 is a steel-concrete composite beam with same size and material. Figure 1 shows the cross sections of composite beams and GFRP.

NOTE: The concrete casting thickness was thicker than the designed thickness a little. The slab sizes in table 1 are measured values.

Materials

The concrete was fabricated, designed to have a compressive strength of 23.4 MPa at 28 days. The measured strengths based on test cubes from S-1 to S-3 were 24.2 MPa, 26.1 MPa and 27.1 MPa. The steel coupons cut from the bottom flange and web with a thickness of 12mm and 8mm were measured. The yield strengths of 428~502 MPa, the ultimate strengths of 554~568 MPa were obtained. 6 mm diameter bars were used as longitudinal reinforcement with yield strength 440 MPa. The compressive strength and modulus of GFRP in the transverse direction were 103.5 MPa and 10.8×10^3 MPa. The tensile strength and modulus of GFRP were 80.9 MPa and 11.48×10^3 MPa.

Fabrication of Test Specimens, Loading and Instrumentation

The fabrication process were as follows: 1) GFRP formwork panels were fabricated in the factory. 2) GFRP panels were placed directly on the steel girders. During setting, the panels were bonded together at the panel-to-panel splice location using epoxy. 3) According to the design, the steel bars were installed (Figure 3). 4) For S-1, the GFRP bottom plate was coated with a thin layer of epoxy resin no more than 50 minutes before casting concrete while the epoxy was still wet. For S-3, concrete was poured directly onto the GFRP formwork.

Four-point bending tests were performed using hydraulic jack with capacities of 1000 kN (Figure 4). The clear span was 3 m and the loading points were 0.4 m. The deflection at the mid-span and support were measured by displacement gauges. Moreover, five displacement gauges were used to measure the slip between the GFRP-concrete deck and steel beam. The stress of concrete, steel bars, steel beams, GFRP were measured by the strain gauges as shown in Figure 5. The deflection and strains were recorded with Donghua 3816N data acquisition system.
EXPERIMENTAL RESULTS AND DISCUSSION

Failure Modes

The decks of the composite beams were all compressive in the process of static test. The failure modes were all concrete crushed (Figure 6). When the load reached 415 kN, the concrete on the top of T-up stiffeners began to spall for S-1. As the load reached 440 kN, the concrete was crushed. For S-3, the failure mode was similar. When the load reached 440 kN, the concrete on the top of T-up stiffeners began to spall. When the load reached 465 kN, the concrete was crushed. There was a little difference for S-2 without GFRP. The concrete began to spall at 430 kN, the concrete was crushed at 435 kN. Because of the confining reactions provided by GFRP the buckling deformation of the steel bars were not large, the GFRP-concrete-steel composite beam achieved higher load after the top concrete began to spall. However, the reinforcing bars of the steel-concrete beam losing the efficiency of the confinement had a large buckling deformation after the top concrete spalled.

Load-Deflection Relationship

The load-deflection relationship is shown in Figure 7. When the load was small, the girder response was linear. Beyond 60% to 70% of the ultimate load, the curve became progressively nonlinear. The large deformation of the composite beams at ultimate load showed that the three specimens had good ductility. The deformation of specimen S-2 is smaller than S-1 and S-3 in Figure 7, because the modulus of GFRP is lower than the modulus of concrete.

Effect of Slip

Figure 8 shows the interface slip distributions between GFRP and steel. The curves of the three specimens were similar. The value of slip at mid-span was minimum. After a rapid increase the slip curve became smooth. The maximum value of the slip occurred near the support, not the bearing point. Because the loads were not absolutely symmetric and the measuring error couldn’t be eliminated, the value of the slip at mid-span was not zero.
Strain Distribution

Figure 9 shows the strain distribution of the three specimens at mid-span. The strain gauges position is shown in Figure 5. At the beginning of the test, the value of slip at the interface of GFRP and steel can be ignored. When the load was closed to the failure load, the value of slip increased rapidly. As the top concrete began to spall near the ultimate load, the concrete stain gauges of specimens S-1 and S-3 were failure. The top strain was obtained by extending the connecting line of GFRP and reinforcing bar strains. When the load reached 97% of ultimate load, the strains of GFRP and reinforcing bars were proportional to the distance from the neutral axis and the curvature of GFRP-concrete deck and steel girder were close. The top strain of specimens S-1 and S-3 were roughly 4950 με and -5435 με, respectively. These were higher than the ultimate strain of unconfined concrete. It is because the GFRP has a confining effect on concrete. This effect may be similar to concrete confined by rectangular hoops. The longitudinal reinforcing bars confined by transverse steel and the larger bar diameter of transverse bars which provides greater flexural stiffness increase the confining effect (R.Park and T.Paulay 1975). The T-up stiffeners have confined the longitudinal reinforcing bars and provide greater flexural stiffness. Therefore, the ultimate strain on the top of concrete is greater.

Analysis of Ultimate Bending Capacity

Based on the results of the test, it is assumed that:
1) Plane sections before bending remain plane after bending, the slip effect is ignored (Nie and Shen 1997); 2) The ultimate strain on the top of concrete is assumed as 0.0035; 3) The neutral axis is in the steel beam; 4) Concrete and steel are elastic-plastic material perfectly; 5) The stress of concrete on the section at mid-span all can reach ultimate stress.

Following the plane cross-section assumption and internal force equilibrium, the elastic-plastic bending load is calculated (Huang 2004). Table 6 shows the results with elastic-plastic calculation method. The theoretical results of specimen S-2 agree well with the measured values. The results of specimens S-1 and S-3 are higher than the measured values, because the top strain is higher than 0.0035. In addition, table 6 shows the theoretical neutral axis position and measuring neutral axis position. It is in the steel web for specimens S-1 and S-3. For specimen S-2, it is in the top flange. The measuring neutral axis position is higher than the theoretical neutral axis position in table 6 because of slip. In summary, the elastic-plastic calculation method can be used to evaluate the ultimate bending capacity of GFRP-concrete-steel composite beam.

CONCLUSIONS

Based on the experimental results of GFRP-concrete-steel composite beam and the theoretical analysis, the following conclusions are drawn:
1) The failure mode of the GFRP-concrete-steel composite beams (with or without wet bonding technique) were concrete crushed. After the top concrete began to spall, the composite beams could bear higher load because of the confining effect which was provided by GFRP.
2) The flexural stiffness of GFRP-concrete-steel composite beam was lower than that of steel-concrete composite.
beam. Both the GFRP-concrete-steel composite beams with wet bonding interface and unbonded interface at the ultimate load showed great deformation ability and had good ductility.

(3) The slip distribution of GFRP-concrete-steel composite beam was similar to steel-concrete composite beam. The minimum slip position was at mid-span. The values of slip increased from the mid-span and decreased slightly near support.

(4) The elastic-plastic calculation method was suitable for predicting the ultimate bending capacity of GFRP-concrete-steel composite beam.

ABSTRACT

In this paper, a novel composite bridge deck with prestressed basalt FRP (BFRP) shell and concrete was proposed to solve the excessively low utilization efficiency of FRP shell, as well as the deficient bonding behavior between shell and concrete, in composite bridge deck. The cross-section of FRP shell was firstly optimized by finite element (FE) method. The surface of FRP shell was enhanced by corrugated teeth and adhering sand processing. The experiment on the FRP shells and the composite bridge decks with FRP shell and concrete were conducted under the construction load and ultimate load, in order to validate their effectiveness. The results show that corrugated cross-section with two arches achieves the highest geometric stiffness by unit geometry. The deflection of FRP shell under external loads can be significantly reduced by about 50%, through the camber generated by the prestressing FRP laminates. The composite bridge decks with proposed FRP shell and concrete perform higher stiffness and larger capacity compared to the control specimens.

KEYWORDS

Basalt fiber reinforced polymer (BFRP) shell, composite bridge deck, optimization, prestress, utilization efficiency, static behavior.

INTRODUCTION

Composite bridge deck, making the most of the compressive property of concrete and tensile strength of FRP, is considered as a type of highly efficient structures (Deskovic et al. 1995). The FRP-concrete composite bridge deck was firstly developed for replacing RC bridge deck of Salem Avenue Bridge in America, using pultruded GFRP slab bonded with GFRP tubes as the shell (Lopez-Anido et al. 1999). Although the composite bridge deck performed satisfactory mechanical properties, its capacity was limited due to the poor bond between GFRP slab and tube. Some improvement measures were made, for example, stiffening ribs installed on FRP slab (Cheng et al. 2005). However, those measures mostly caused the difficulty in manufacture and decreased the construction efficiency. Another problem lies in the traditional FRP shell for bridge deck is the low utilization efficiency caused by the stiffness requirement. Some measures such as FRP wrapped steel tubes or pultruded rectangular FRP tubes bonded on FRP slab (Kubo et al. 2001, Hayes et al. 2006) can increase stiffness, but they even lowered the utilization efficiency. To solve that problem, a GFRP shell, with open cross-section and corrugated profile was proposed (Zuo et al. 2014). However, this type of FRP shell still needs a further enhancement from both geometric and structural aspects. In this study, BFRP, with higher modulus, was adopted to replace conventional GFRP. The geometry of the cross-section of FRP shell was optimized to improve stiffness. A prestressed BFRP shell is proposed to offset the deflection under construction load. Furthermore, the static loading tests on the FRP shells and the composite bridge decks were conducted to validate their effectiveness.

OPTIMIZATION OF BFRP SHELL

Modelling

To optimize the cross-section of BFRP shell, a finite element (FE) model was established using ANSYS. Element type of SHELL 63 was adopted. Three alternative types of cross-section are shown in Figure 1. According to JTG D60 (2004), the total longitudinal length of shell was 3000 mm, and the span (L) was 2500 mm. The height and section width of cross-section of BFRP shell were determined to be 150 mm and 250 mm. The dead load, equal to 3.75 kN/m² multiplied by the corresponding partial factor 1.2 (JTG/T F50, 2011), was adopted in FE method.
Results of FE Analysis

According to the results of FE analysis, the deflection of Type 1 equals to 8 mm, exceeding the maximum deflection limitation of shell (L/400) according to GB 50010 (2010), which is unacceptable. Type 2 and Type 3 perform significantly smaller deflections than Type 1. Furthermore, Type 3 shows 18% less deflection than Type 2, although its cross-sectional area is 6% larger than Type 2. Based on the cross-sectional shape of Type 3, the arch radius was also optimized through FE analysis. The deflections of FRP shells, with arch radiiues of 20, 30, 40 and 50 mm, were analyzed by ANSYS. Although the deflection decreases as arch radius increases, the unit geometric stiffness, calculated by Eq. 1, reaches the maximum when the radius equals to 40 mm. Thus, the cross section of Type 3 with arch radius of 40 mm was adopted in the following experiment.

\[ s = \frac{1}{f \times A} \]  

(1)

in which, \( s \) = unit geometric stiffness; \( f \) = deflection; \( A \) = cross-sectional area.

The optimized cross-section shape of BFRP shell is shown in Figure 2. To enhance the connection between FRP shells, corrugated teeth were designed to distribute along the height direction of the web.

EXPERIMENTAL PROGRAM

Preparation of BFRP Shell Component

BFRP shell components adopted in this study were manufactured by using basalt fiber roving and unsaturated polyester resin through pultrusion, with a specially designed steel mold. Bi-directional basalt fiber sheets were also adopted during pultrusion to enhance the transversal mechanical properties. The tensile strength and elastic modulus of the BFRP shell are 622 MPa and 31 GPa according to previous tests. Three BFRP shell components were assembled into a whole BFRP shell structure in the following loading experiments, to simulate the practical engineering application of composite bridge deck. The reliable connection between FRP shell components was realized through local bolts, corrugated teeth and Sikadur-30 sticky adhesive.

Prestressed BFRP Shell

Prestressing technique was adopted to offset the deflection under construction load and further enhance the stiffness of FRP shell. Prestressing BFRP laminates (tensile strength: 775 MPa, elastic modulus: 35 GPa), bonded on the inner surface of lower flange, was used (Figure 3). The BFRP laminates, with similar mechanical properties to the BFRP shell, were adopted to avoid excessively large shear stress on their interfaces. Sikadur-30 sticky adhesive was gelatinized between the laminates and shell.
Tensioning of Prestressing BFRP Laminate

The specific tensioning setup is shown in Figure 4. At the tensioning end, the tensioning force was applied by a hydraulic jack through a tension rod. A hollow steel plate was used to transfer load during tensioning. Three adjustable bolts were used to ensure the synchronicity of BFRP laminates. BFRP laminates were all anchored by steel clamps (200 mm long) with bolts through friction. Two stiff steel plates at both ends were adopted to balance tensioning force on the BFRP shell through.

![Figure 4 Tensioning apparatus](image)

Before tensioning, the bonding surfaces on the BFRP laminates and shell were polished to be rough. The adhesive was then gelatinized uniformly along the bonding area. After the assembly of the tensioning apparatus, the prestress was firstly applied to 2 kN, and the bolts were adjusted to make the loads in three laminates be equal. Then, the laminates were tensioned, with 10 kN per step, to the predetermined tensioning force (40 kN). After tensioning, the stresses in BFRP laminates were equal to about 0.42 fu, less than the creep rupture stress of BFRP (0.52 fu) (Wang et al. 2014). The load was sustained for 48 h at a constant temperature of 30 degrees centigrade, to ensure sufficient strength of the adhesive achieves. Figure 5 shows the FRP shell during and after prestress tensioning.

![Figure 5 Prestressed BFRP shell (a) during prestress tensioning (b) after prestress tensioning](image)

**Simulation of Construction Load**

A sand casting experiment was conducted to simulate the construction process of concrete casting, due to the convenience in handling (Figure 6). The action of sand on FRP shell is similar with that of concrete during construction. According to JTG/T F50 (2011), the load of sand for the checking calculation of stiffness and strength were respectively calculated to be 10.8 kN and 25 kN, respectively. Timber frameworks were erected around the FRP shells. Data were recorded every 0.5 kN of sand loading. The span of BFRP shells was 2500 mm.

**Static Behavior Test on Composite Bridge Decks**

*Preparation of specimens*

Four composite bridge deck specimens were manufactured for the static behavior test, which simulates the state of bridge deck under vehicle load. BFRP rebars were adopted as the stirrups and longitudinal reinforcements in the concrete (Figure 7). Concrete with strength grade of C50 was cast into the FRP shells, which were also used as formwork during casting. The experimental parameters included prestress, surface treatment (adhering sand processing in Figure 8) surface profile (corrugated teeth), as shown in Table 1.

Loading procedure

The span of each specimen was determined to be 2500 mm. Three-point loading was adopted through two synchronous actuators (Figure 9), with the total loading capacity equal to 1000 kN. A steel plate, with length of 600 mm, width of 250 mm and thickness of 50 mm, was positioned at the mid-span to simulate wheel-pressure. The load was applied with the speed of 10 kN per step until 100 kN was reached. Then the load was applied with 5 kN per step. The data of mid-span deflection and load were collected by computer during the test.

RESULTS AND DISCUSSIONS

Deflections of Non-Prestressed and Prestressed BFRP Shells under Construction Load

The load-deflection curves of non-prestressed and prestressed BFRP shells under construction load are shown in Figure 10. At stiffness checking calculation load (10.8 kN), the mean deflection of non-prestressed shells in the mid-span is 4.0 mm, consistent with that calculated by FE method (4.16 mm). The deflections of prestressed BFRP shells are almost zero. Under strength checking calculation load (25 kN), the maximum deflection of prestressed FRP shell is only 3.8 mm, 50% lower than that in non-prestressed BFRP shell, showing the advantage of camber caused by prestress.
Figure 10 Construction load-deflection curves of non-prestressed and prestressed FRP shell

**Static Behavior of the Composite Bridge Deck**

The values of ultimate load and deflection under ultimate load, and failure modes are listed in Table 2. The load-deflection curves of each specimen are shown in Figure 11. The effect of adhering sand processing on enhancing the bond behavior between concrete and FRP shell can be apparently observed from the failure mods of BD-1 and BD-2. Furthermore, compared with BD-2, BD-3 performs lower stiffness and earlier slippage between concrete and FRP shell due to its lack of corrugated teeth. Finally, from the comparison between BD-1 and BD-4, prestress has no obvious effect on the ultimate load, since the failure modes of the two specimens were both dominated by concrete crushing. In conclusion, the proposed composite bridge deck possesses advantageous static behavior.

**CONCLUSIONS**

A novel composite bridge deck with FRP shell and concrete was proposed in this paper. FE method was used to optimize the cross-section. Prestress was applied onto FRP shell through FRP laminates to enhance the utilization efficiency of FRP shell. Construction loading and static behavior tests were conducted on the proposed FRP shell and composite bridge deck. The main conclusions are as follows.

1. Through FE method, the cross section with two arches (radius equal to 40 mm) was optimized for FRP shell, which achieves the highest unit geometric stiffness among the three candidates.
(2) Prestress can generate camber and reduce the deflection of FRP shell under construction load by 50%. The utilization efficiency of FRP shell is prospective to be further enhanced.

(3) Corrugated teeth and adhering sand processing of FRP shell surface can significantly enhance the connection between FRP shells and bond behavior between FRP shell and concrete, respectively, and thereby increase the load capacity and stiffness of composite bridge deck.
